Experiments tending to throw light on the nature of pittacal have also been made by Hofmann (*Ber.* xi. 1455; xii. 1371). The secondary ethers of pyrogallol yield, with chloroform and carbon tetrachloride, compounds analogous to those which are produced by the action of these same reagents upon phenol, and if the reaction takes place in presence of alkalis, blue colouring matters are formed. The best results are obtained when dimethylic pyrogallate, mixed with a quantity of alcoholic potash or soda sufficient to form a salt, is heated for some hours at 120°–130° with perchlorethane, C²Cl⁶. A blue compound is then formed, and on evaporating off the alcohol, treating the residue with water, and the filtrate with hydrochloric acid, a light red liquid (or crimson with excess of acid) is obtained, which on standing deposits brownish-yellow needles. On dissolving these crystals in boiling alcohol, and treating the solution when cold with twice its volume of ether, a substance is obtained which crystallises in long orange-yellow needles; dissolves easily in glacial acetic acid, and is reprecipitated therefrom by alcohol; bears a heat of 100° without change; melts at 200°, and decomposes partially yielding a blue sublimate. This substance is a weak acid, forming with the alkali-metals blue salts which are soluble in water, and are precipitated from aqueous solution by an excess of alkali or alkali-salt. It dissolves in sulphuric acid, forming a red solution which becomes blue when heated, and red again on addition of water. This substance has the composition C²⁵H²⁶O⁹, and is identical in composition with Liebermann's eupittone, as the following comparison will show:

		Calculation	Analyses:	
			Liebermann	Hofmann
C ²⁵	300	63.6	63.4
H ²⁶	26	5.6	5.7
O ⁹	144		
		470		
		100.00		

It likewise resembles eupittone in its properties. Hofmann names it eupittonic acid. Its formation from dimethylic pyrogallate is analogous to that of rosolic acid from phenol.

It is known indeed that perchlorethane, when heated with alkalis, is converted into oxalic acid, and this acid splits up under certain circumstances, yielding CO and CO².

Eupittonic acid (pittacal) may be regarded as hexmethoxyl-rosolic acid, C¹⁹H⁸(OCH³)⁶O³. Attempts to replace the six methoxyl-groups by hydrogen resulted, however, only in the production of pyrogallol. Its relation to rosolic acid is, however, better shown by its behaviour when heated with alcoholic ammonia in sealed tubes at 160°–170°, whereby it is converted into hexmethoxyl-rosaniline, C¹⁹H¹¹(OCH³)⁶N³, a blue solution being formed, which on cooling deposits the hexmethoxylated base in broad colourless needles containing, like those of rosaniline, 1 mol. of water (see ROSANILINE).

The sodium-derivatives of dimethylic pyrogallate and dimethylic methylpyrogallate, C⁸H³(OCH³)²(ONa) and C⁸H²(CH³)(OCH³)²ONa, which are best obtained by adding soda to the alcoholic solutions of these ethers, may be heated separately in an open vessel without forming a trace of pittacal; but when a mixture of the two with excess of soda is heated, pittacal is formed, sometimes to the extent of 10 per cent. by weight of the mixed ethers. On treating it with water, the mass dissolves, forming a deep indigo-blue solution. On adding hydrochloric acid, the solution becomes carmine-red, and deposits a resinous mass which when purified furnishes eupittonic acid (pittacal) in beautiful crystals. The pittacal may also be extracted from the acidified solution with boiling benzene, unaltered pyrogallate having been first removed by agitation with ether. The quantity of colouring matter formed is not increased by the addition of oxidising agents, chiefly on account of the extreme ease with which these

agents convert dimethylic pyrogallate into cedrret. The reaction may be thus represented:

and may be compared with that by which rosaniline is produced from aniline and toluidine:

In the former case the oxygen necessary to remove hydrogen is derived from the atmosphere, as may be proved by attempting to conduct the reaction out of contact with air.

Eupittonic acid appears to be bibasic. Its alkali-salts are blue with green reflex. The ammonium salt is decomposed when its solution is boiled, and after a time crystals of pittacal are deposited. In virtue of the intensely blue colour of the alkaline compounds of pittacal, paper steeped in a solution of it and dried, furnishes an exceedingly sensitive test for free alkalis, but its utility for this purpose is considerably lessened by the fact that hydrochloric acid also colours it blue.

When boiled with acetic anhydride, eupittonic acid yields a yellow diacetyl derivative, which strangely enough is insoluble in alkalis, although its molecule ought still to contain four hydroxyl groups.

A homologue of eupittonic acid, $\text{C}^{10}\text{H}^3\text{O}^9$ (which has not been analysed), was prepared by heating *diethylic pyrogallate* and *dimethylic methylpyrogallate* with soda. It differs from its prototype in being soluble in ether and less easily crystallisable, and in the inferior stability of its ammonium compound. It also forms a triamine when heated with ammonia, probably a *dimethoxyl-tetretroxyl pararosaniline*:

PYROGALLOQUINONE, $\text{C}^{12}\text{H}^{14}\text{O}^8 = \text{C}^6\text{H}^4 \begin{smallmatrix} \text{O.O.C}^6\text{H}^3(\text{OH})^2 \\ \text{O.O.C}^6\text{H}^3(\text{OH})^2 \end{smallmatrix}$. This compound, which Wichelhaus obtained, together with quinol, by dissolving quinone in pyrogallol (vii, 1030), according to the equation $2\text{C}^6\text{H}^4\text{O}^2 + 2\text{C}^6\text{H}^6\text{O}^2 = \text{C}^{12}\text{H}^{14}\text{O}^8 + \text{C}^{12}\text{H}^{14}\text{O}^8$, is also produced by oxidation of pyrogallol in the air in presence of sodium phosphate (p. 1709), and may be separated by agitation with ether from two other bodies formed at the same time, one of which (an acid) dissolves in ether only after acidulation of the mixture, while the other is nearly insoluble in ether. To prepare the quinone in considerable quantity, 10 grams of pyrogallol are mixed with 25 g. sodium phosphate and 250 c.c. water, and the whole is heated to 50° , and agitated for half an hour in an apparatus constructed for the purpose.

Pyrogalloquinone is sparingly soluble in water, somewhat more soluble in alcohol, still more in ether, chloroform, and sodium phosphate. It reduces Fehling's solution and silver nitrate. Its aqueous solution gives a blue-violet precipitate with ferrous salts, red-brown precipitates with copper and lead salts, and produces a dark colour with ferric chloride. The blue colour which Wichelhaus observed on treating pyrogalloquinone with alkalis is produced only in presence of free oxygen (O. Loew, *J. pr. Chem.* [2], xv, 322).

PYROGENTISIC ACID, $\text{C}^6\text{H}^6\text{O}^2$. This substance, obtained by the action of heat on gentisic acid, the colouring matter of gentian root (p. 860), and at first supposed to be isomeric with quinol (hydroquinone), has since been shown to be identical therewith, the error having arisen from incorrect determination of the melting point of quinol, which is now known to melt at 169° . In like manner, gentisic acid has been shown to be identical with hydroxysalicylic acid (m. p. 196° – 197°) (Hlasiwetz a. Habermann, *Liebig's Annalen*, clxxx, 343).

PYROLUSITE, MnO^2 . Analyses of this mineral have recently been published by Phipson (*Chem. News*, xxxiii, 243), Muir (*ibid.* xxxv, 6), and by Wright a. Luff (*Chem. Soc. J.* xxxv, 518).

PYROMARIC ACID. See PRIMARIC ACID (p. 1626).

PYROMECAZONIC ACID. See the next article.

PYROMECONIC ACID, $\text{C}^6\text{H}^4\text{O}^3$ (Ost, *J. pr. Chem.* [2], xix, 34 and 177. Ihlé, *Liebig's Annalen*, clxxxviii, 31). This acid, isomeric with pyromucic acid, is formed from meconic acid, $\text{C}^6\text{H}^4\text{O}^2$, by elimination of 2 mols. CO^2 . It crystallises in large brilliant prisms, easily soluble in water and in alcohol, less soluble in ether and in chloroform; volatilises completely at 100° ; boils at 225° (Ost); melts at 121.5° , and boils at 227° – 228° (Ihlée). In contact with excess of alkali it readily oxidises, even without warming, producing formic acid (Ost). On boiling it with baryta-water, the liquid turns red and brown, and deposits a precipitate of barium carbonate, and

the aqueous distillate yields drops of an oil which reduces silver salts (perhaps an aldehyde). The residue of the distillation contains barium formate (Ihlée).

Pyromeconic acid unites with hydrochloric and sulphuric acid. When gaseous *hydrochloric acid* is passed over it, only a very small quantity is taken up, but on mixing the ethereal solutions of pyromucic acid and pyrophorous chloride, white needle-shaped crystals quickly separate, having the composition $C^8H^3O^2.OH.HCl$. This compound is resolved into its constituents by alcohol or water, and slowly by moist air. The corresponding *sulphate*, $(C^8H^3O^2.OH)^2.H^2SO^4$, separates in prismatic crystals from a mixture of 1 mol. pyromeconic acid in ethereal solution and less than 1 mol. sulphuric acid; if the two acids are mixed in equal numbers of molecules, needle-shaped crystals separate, having the compound $C^8H^3O^2.OH.H^2SO^4$.

Pyromeconates. Besides the normal salts of the general formula $C^8H^3MO^3$, pyromeconic acid forms acid salts, $C^8H^3MO^3.C^8H^4O^3$, which easily part with a molecule of pyromeconic acid; both series of salts crystallise well and have an acid reaction. The *normal potassium salt*, $C^8H^3KO^3$, is prepared by mixing excess of potash with a concentrated solution of the acid; if a somewhat dilute solution be used, the acid is oxidised, with production of formic acid (Ost). Ihlée prepares the salt by mixing a hot alcoholic solution of the acid with alcoholic potash, the salt then separating on cooling as a crystalline pulp. The normal sodium salt has not been obtained; the *acid sodium salt*, $C^8H^3NaO^3.C^8H^4O^3$, is formed on mixing the alcoholic solution of the acid and base. An *ammonium salt* of uncertain composition, and easily undergoing decomposition, with reproduction of the acid, is formed on mixing alcoholic solutions of the acid and ammonia; if aqueous solutions are used and much ammonia is added, pyromeconic acid alone crystallises out (Ost). The *acid barium and calcium salts*, $(C^8H^3O^2)^2M = (C^8H^3O^2)^2M^2.2C^8H^4O^3$, are obtained by boiling the respective carbonates with a solution of the acid till the liquid becomes neutral; on longer boiling, decomposition takes place. The *copper salt*, $(C^8H^3O^2)^2Cu$, crystallises in green silky needles (Ihlée).

No ethereal salts of pyromeconic acid have been obtained. *Acetylpyromeconic acid*, $C^8H^4(C^2H^3O)O^3$, is easily prepared by heating the acid with acetyl chloride, and crystallising the product from absolute alcohol; it forms colourless prisms melting at 91° , easily soluble in alcohol, water, and chloroform.

Nitropyromeconic Acid, $C^8H^3(NO^2)O^3$, is formed, with violent reaction; on adding 1 to $1\frac{1}{2}$ pts. strong nitric acid to 2 pts. pyromeconic acid dissolved in 6 pts. acetic acid, and crystallises from alcohol in small well-defined yellow prisms, very slightly soluble in cold water, and decomposed with explosion by boiling water; insoluble in ether, benzene, chloroform, and carbon sulphide; dissolves most readily in absolute alcohol, acetone, or hot acetic acid.

The acid is monobasic. Its *sodium salt*, $C^8H^3(NO^2)NaO^3$, obtained by heating the nitro-acid with aqueous sodium carbonate, crystallises on cooling in golden-yellow laminae slightly soluble in cold water. It is quickly decomposed by excess of sodium carbonate or hydrate, even at ordinary temperature. It explodes with great violence when heated, also when moistened with a drop of strong sulphuric acid. The *barium* and *calcium salts* are obtained by double decomposition as crystalline precipitates. The *silver salt*, obtained by gently warming the aqueous acid with silver nitrite, forms orange-yellow crystalline nodules, insoluble in cold water; its formation serves for the detection of very small quantities of the nitro-acid. It is decomposed by water slowly in the cold, more quickly when heated, with separation of metallic silver; it explodes when heated alone.

Amidopyromeconic Acid, $C^8H^3(NH^2)O^3$. The hydrochloride of this acid, obtained by reducing the nitro-acid with tin and hydrochloric acid, removing the tin from the resulting double salt with hydrogen sulphide and evaporating, forms large rhombic crystals having the composition $C^8H^3(NH^2)O^3.HCl + H^2O$; and these, when decomposed by ammonia in aqueous solution, yield the acid, which crystallises from hot water in long needles, easily decomposed by alkalis, but not by water.

Nitrosodipyromeconic Acid, $C^{16}H^7(NO)O^6$, is obtained by passing nitrous gas (from arsenious oxide and nitric acid) into an ethereal solution of pyromeconic acid. It is very unstable, giving off hydrocyanic acid on exposure to moist air. It separates from the liquid as a light yellow precipitate, but cannot be crystallised, as the liquids which dissolve it also decompose it. Excess of nitrous acid readily converts it into nitropyromeconic acid. On warming it with water, nitrous and hydrocyanic acids are evolved, together with carbonic anhydride and other gases, and a moderately stable crystalline compound separates, having the composition $C^8H^3NO^4.C^8H^4O^3$. This compound, heated with chloroform, is decomposed, pyromeconic acid going into solution, and oxypyromecazonic acid, $C^8H^3NO^4$, remaining.

This last acid in its general character resembles pyromeconic acid; it is easily soluble in hot water, soluble in cold water and in alcohol, insoluble in ether and chloroform; crystallises in needles with 1 mol. of crystalline water, occasionally also with 2 mols., and in short anhydrous prisms.

It is readily decomposed by excess of alkali, and by oxidising agents generally: not attacked by hydrochloric acid.

Acid Sodium Oxypyromecazonate, $C^5H^4NaNO^4, C^5H^3NO^4$, separates as a crystalline pulp on mixing the free acid and sodium carbonate in the proportions to form the normal salt, which appears to be uncrystallisable. The white salt precipitated on adding a small quantity of soda to the alcoholic solution becomes deep blue on addition of more soda, but dissolves without colour in water. The *acid potassium salt*, produced like the sodium salt, crystallises in large anhydrous prisms. The *normal calcium salt*, $(C^5H^4NO^4)_2Ca$, is formed on mixing either the normal or the acid sodium salt with calcium chloride, as an amorphous precipitate which becomes crystalline on cooling; it is very slightly soluble in water, and when treated with ammonia, in contact with the air, gradually turns blue. The *barium salt*, formed like the calcium salt, is less stable in contact with the air. The *acid thallium salt*, obtained by precipitating the acid sodium salt with thallous sulphate, crystallises in very thin colourless anhydrous needles sparingly soluble in water.

Oxypyromecazonic acid combines with acids as well as with bases. The *hydrochloride*, $C^5H^3NO^4.HCl$, obtained by dissolving the acid in gently warmed strong hydrochloric acid, crystallises on cooling in hard crusts (pyromeconic acid crystallises from fuming hydrochloric acid without alteration). The crystals, when left over quicklime, do not give off a trace of hydrochloric acid, but water immediately resolves them into their components. The *hydriodide* is obtained in like manner, and exhibits similar properties.

Pyromecazonic acid, $C^5H^4NO^3$, isomeric with amidopyromeconic acid, is produced by long-continued action, at a moderate temperature, of tin and hydrochloric acid upon the foregoing acid. After removing excess of tin, the liquid is evaporated, when a double compound of pyromecazonic acid and hydrochloric acid, $C^5H^3NO^3.HCl$, crystallises out. This compound is decomposed by water, the solution is evaporated to dryness to drive off hydrochloric acid, and pure pyromecazonic acid is obtained by recrystallising the residue from hot water. Pyromecazonic acid is but very slightly soluble in cold water, almost insoluble in alcohol, and insoluble in ether: it may be partially sublimed unchanged. Its salts are unstable, being easily decomposed by the oxygen of the air, with production of blue and violet-coloured bodies. It forms double compounds with acids, and in its general behaviour resembles oxypyromecazonic acid (Ost).

PYROMELLITIC ACID, $C^{10}H^6O^8 = C^5H^2(CO^2H)^4$. The methylic ether of this acid crystallises in large plates; melts at 133° ; distils without decomposition; and is but sparingly soluble in alcohol, even at the boiling heat (Baeyer, *Liebig's Annalen*, clxvi. 325).

On the compounds produced by the action of Pyromellitic acid on α -Naphthol, see vii. 840.

PYROMUCIC ACID, $C^5H^4O^3$. This acid is best obtained by the action of alcoholic potash on furfural. This aldehyde, in quantity not exceeding 25 grams, is mixed with an equal volume of concentrated alcoholic potash, whereupon the mixture becomes very hot, and solidifies in a few minutes to laminae of potassium pyromucate. The furfuralcohol formed at the same time is removed, after cooling, by washing with ether, and the pyromucic acid is precipitated from the residue by hydrochloric acid. The quantity of pyromucic acid thus obtained amounts to 33 per cent. of the furfural, whereas the method of decomposition by silver oxide yields only 14 per cent. Dry distillation of mucic acid yields but a very small quantity (Limpricht, *Liebig's Annalen*, clxv. 278).

On the Reactions and Isomerides of Pyromucic acid, see vii. 1032. On its Constitution, see p. 836 of this volume.

Bromine-compounds. *Dibromide of Pyromucic acid*, $C^5H^4O^3Br^2$, is formed on adding bromine to a solution of ethyl pyromucate in glacial acetic acid (R. Schiff a. G. Tassinari, *Ber.* xi. 842); and the *tetrabromide*,

by exposing pyromucic acid to the action of dry bromine-vapour. This compound is a white crystalline substance easily soluble in alcohol and ether, sparingly in chloroform

and light petroleum, insoluble in cold water, decomposed by hot water with evolution of CO_2 and HBr . It melts with decomposition at 159° – 160° , giving off bromine and hydrogen bromide, and yielding an acid body in the form of a sublimate of needle-shaped crystals melting at 180° . By reducing agents it is converted into pyromucic acid; by oxidation with chromic acid, into dibromosuccinic acid (Tönnies, *Ber. xi.* 1085).

Tetrabromide of Ethyl Pyromucate, $\text{C}_4\text{H}_2\text{Br}_4\text{O}^3.\text{COOC}^2\text{H}_3$, is prepared by the action of dry bromine vapour on ethyl pyromucate for twelve hours at ordinary temperature, treating the product with a small quantity of bromine, and removing the excess of bromine with sulphurous acid. It dissolves in chloroform, and separates from the solution in colourless crystals which melt at 46° – 48° , and decompose at a higher temperature. Sodium-amalgam converts it into ethyl pyromucate (Tönnies).

Monobromopyromucic acid, $\text{C}^5\text{H}^2\text{BrO}^3$.—Two modifications of this acid are produced by the action of alcoholic potash on the dibromide of pyromucic acid, and are easily separated by taking advantage of the difference of their solubility in boiling water. The more soluble of the two crystallises in colourless needles which melt at 155° , sublime readily, and are converted into the less soluble modification by repeated boiling with water, and precipitation by hydrochloric acid. The less soluble acid, which may be purified by crystallisation from a large quantity of water or from dilute alcohol, forms beautiful micaceous scales melting at 180° (Schiff a. Tassinari, *Ber. xi.* 842; *Gazz. chim. ital.* 1878, 297).

Dibromopyromucic acid, $\text{C}^5\text{H}^2\text{Br}_2\text{O}^3$, formed in like manner from the tetrabromide, crystallises in colourless scales, which melt at 184° – 186° , and sublime without decomposition at a higher temperature (Tönnies, *loc. cit.*) When heated with bromine-water at ordinary temperatures it yields carbon dioxide and mucobromic aldehyde, $\text{C}^4\text{H}^2\text{BrO}^3$, which crystallises from ether in stellate groups of needles melting at 88° , easily soluble in water, ether, and chloroform. This aldehyde, gently heated with chromic acid solution, is converted into mucobromic acid, $\text{C}^4\text{H}^2\text{Br}^2\text{O}^3$, identical with that which is obtained by the direct action of bromine on pyromucic acid (vii. 828). The same oxidation may be effected by adding bromine-water to a boiling aqueous solution of dibromopyromucic acid till the colour of the bromine no longer disappears. It appears, therefore, that at ordinary temperatures only 1 mol. of bromine enters into the reaction with the result of forming an aldehyde, but that at higher temperatures 2 mols. of bromine enter into the reaction and produce the corresponding acid:

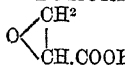

This last reaction is exactly analogous to that which takes place when pyromucic acid is treated with bromine-water at ordinary temperatures, whereby fumaric aldehyde is produced, and renders it probable that the difference in the behaviour of pyromucic and dibromopyromucic acid to bromine-water is due to the fact that, with the latter, the action stops at an intermediate stage, which, in the case of the non-brominated acid, is at once passed over. If this view be correct, mucobromic acid must be regarded as dibromofumaric aldehyde (Tönnies, *Ber. xii.* 1202).

PYROPHOSPHATES. See PHOSPHATES (pp. 1601).

PYROPHYSALITE. See TOPAZ.

PYROPISSITE. This waxy substance, which occurs in lignite, was first described by Kennigott (iv. 769), and has lately been examined by H. Schwarz (*Dingl. pol. J.* cccxxi. 465; *Chem. Soc. J.* xxxvi. 1022).

PYRORACEMIC or PYRUVIC ACID, $\text{C}^3\text{H}^4\text{O}^3 = \text{CH}^3.\text{CO}.\text{COOH}$, or

 This acid is formed: 1. By boiling chloracrylic acid with silver oxide and water $\text{C}^3\text{H}^3\text{ClO}^2 + \text{AgHO} = \text{AgCl} + \text{C}^3\text{H}^4\text{O}^3$ (Beckurts a. Otto, *Ber. x.* 265). 2. By the action of strong sulphuric acid at 40° – 50° on tartaric acid: $\text{C}^4\text{H}^4\text{O}^6 = \text{CO}^2 + \text{H}^2\text{O} + \text{C}^3\text{H}^4\text{O}^3$ (Bouchardat, *Compt. rend.* lxxxix. 99). 3. By the dry distillation of glyceric acid (Böttlinger, *Liebig's Annalen*, cxevi. 92):

4. By mixing acetyl cyanide with an equivalent quantity of hydrochloric acid, sp. gr. 1.2, whereby it is converted into acetyl-formamide, and decomposing the latter with a slight excess of dilute hydrochloric acid (Claisen a. Shadwell, *Ber. xi.* 1563):

and

The first two of these modes of formation are consistent with either of the formulae above given for the acid; the third is most readily explained by the first formula, and the fourth may be regarded as decisive in its favour.

Reactions. 1. *Decomposition by Heat.*—Pyroracemic acid, boiled for about eight hours in a reflux apparatus, gives off carbon dioxide, becomes continually thicker, and darker in colour, and on cooling solidifies to a resin from which boiling water extracts pyrotartaric, uvic, and a small quantity of acetic acid, the greater part, however, remaining undissolved. Hence it is probable that the pyrotartaric acid produced in the dry distillation of tartaric acid is a further product of decomposition of pyrорacemic acid, formed, in the first instance, according to the equation above given (Böttinger, *Ber.* ix. 670).

2. With *Phosphorus Pentachloride*.—When pyrорacemic acid is gradually run into 5 pts. of the pentachloride, hydrochloric acid, carbon dioxide, carbon monoxide, and a small quantity of acetyl chloride are produced; and on completing the dissolution of the pentachloride by warming, then distilling, pouring the portion which goes over at 130° into alcohol, and adding common salt, ethylic α -dichloropropionate, $\text{CH}^3\text{CCl}^2\text{COOC}^2\text{H}^5$ (m. p. 155°–160°), is obtained (Beckurts a. Otto, xi. 386; comp. Böttinger, vii. 1038).

3. With *Zinc*.—When an alcoholic solution of pyrорacemic acid is treated with zinc (and a small quantity of hydrochloric acid), or with zinc-dust, the following reaction takes place, resulting in the formation of dimethyl-tartaric acid, $\text{C}^6\text{H}^{10}\text{O}^6$, which is related to pyrорacemic acid in the same way as pinacone to acetone:

The zinc-salt of dimethylpyrotartaric acid separates during the reaction as a white precipitate quite insoluble in cold water, while zinc lactate and a salt apparently belonging to a modified pyrорacemic acid remain in solution (Böttinger, *Ber.* ix. 1064). These two reactions afford farther confirmation of the formula $\text{CH}^3\text{CO.CO}^2\text{H}$ for pyrорacemic acid.

4. With *Hydrocyanic acid*.—When pyrорacemic acid is left in contact for some time with highly concentrated hydrocyanic acid and a few drops of strong hydrochloric acid, an additive cyanogen-product is formed, which may be extracted from the liquid by ether. The residue left on evaporating the ether does not crystallise, and its aqueous solution forms no precipitate with silver nitrate, but gives off ammonia when boiled with alkalis. On heating it for two days with strong hydrochloric acid, carbon dioxide is given off, and ordinary lactic acid is formed. When large quantities of pyrорacemic acid, absolute hydrocyanic acid, and hydrochloric acid were heated together on the water-bath, a very violent reaction took place, and the product, when shaken with ether, yielded ordinary pyrotartaric acid, $\text{CH}^3\text{CH}(\text{CO}^2\text{H}).\text{CH}^2\text{COOH}$, together with mesaconic acid, $\text{CO}^2\text{H}.\text{CH}=\text{CH}.\text{CH}^2\text{CO}^2\text{H}$ (Böttinger, *Ber.* ix. 1621).

5. With *Chromic acid mixture*.—Pyrорacemic acid, diluted with water and dropped into a cooled mixture of 10 grams potassium dichromate, 10 c.c. strong sulphuric acid, and 60 c.c. water, is completely resolved into acetic and carbonic acids, $\text{C}^2\text{H}^4\text{O}^3 + \text{O} = \text{C}^2\text{H}^4\text{O}^2 + \text{CO}^2$ (Böttinger, *Ber.* viii. 713).

6. With *Barium Hydrate*.—Pyrорacemic acid, boiled with excess of barium hydrate, yields, according to Finck (iv. 770), uvitic acid, $\text{C}^6\text{H}^8\text{O}^4$, and uvitonic acid, $\text{C}^6\text{H}^{12}\text{O}^7$ (?), together with acetic, oxalic, and carbonic acids; with a quantity of barium hydrate, on the other hand, not sufficient to neutralise it, it yields uvic, pyrotartaric, acetic, carbonic acid, and two acids the nature of which has not been ascertained (Böttinger, *Ber.* vi. 787, 893). Further, when neutral barium pyrорacemate is heated for several days in a reflux apparatus, carbon dioxide escapes, the liquid after a while becomes acid, then again neutral, and a precipitate is formed, consisting of barium carbonate and oxalate. From the brownish filtrate hydrochloric acid throws down a mixture of uvic and uvitic acids, which may be separated by distillation with steam; and the same filtrate yields to ether, pyrotartaric, acetic, and a small quantity of uvic acid, still retaining a large amount of pyrotartaric and (probably) uvitonic acid. The products of decomposition of pyrotartaric acid in neutral solution consist, therefore, of the sum of those obtained in acid and in alkaline solution (Böttinger, viii. 957).

7. With *Ammonia*.—Gaseous ammonia acts very violently on pyrорacemic acid, eliminating carbon dioxide; and on treating the product with milk of lime, acetic acid is formed, together with modified pyrорacemic acid. Aqueous ammonia, heated with pyrорacemic acid, does not yield any product of decomposition. Alcoholic ammonia

yields—together with acetic acid and carbon dioxide—a precipitate consisting of the acid ammonium salt of an acid, $C^8H^9NO^4$, called by Böttinger uvitoninic acid (*Ber.* x. 362).

8. With *Aniline*.—On bringing this base in contact with pyroracemic acid, anilopyroracemic acid, $C^9H^9NO^2 = CH^3.C \begin{smallmatrix} \nearrow NC^6H^5 \\ \searrow COOH \end{smallmatrix}$ separates as a crystalline body which melts at 122° , and when dissolved in water is converted into an isomeric body which has not been obtained pure. The solution when heated yields pyroracemic acid, aniline, and acid bodies which are further acted on by the aniline, and ultimately a crystalline product is obtained, probably having the composition $C^{10}H^{10}N^2O^4$; it exhibits basic properties, combining with acids, and forming a platinochloride (Böttinger, *Ber.* x. 818).

9. With *Anthranilic acid* or [1 : 2] *Amidobenzoic acid*.—This acid acts violently on pyroracemic acid, forming a yellow powder which continuously gives off carbon dioxide at 135° , turns blue when exposed to light or suspended in water, and is perhaps constituted according to the formula:

(Böttinger, *Ber.* x. 1517; *Liebig's Annalen*, clxxxviii. 293).

10. With *Urea*.—Pyroracemic acid and urea, heated together at 100° , yield pyroracemic carbamides or ureides (p. 1720).

11. Silver pyroracemate, decomposed by *hydrogen sulphide*, yields thiolactic acid, $C^8H^6SO^2$ (Böttinger, *Ber.* ix. 404).

Dibromopyroracemic Acid, $C^8H^2Br^2O^3$, is formed when the dibromolactic acid, $C^8H^2Br^2O^3$, which Wislicenus obtained by the action of bromine on pyroracemic acid (vi. 771), is heated in a stream of chlorine. It crystallises in rather large rhombic plates melting at 98° (Ph. Clermont, *Bull. Soc. Chim.* [2], xix. 103).

Tribromopyroracemic Acid, $C^8HBr^3O^3 = CBr^3.CO.CO^2H$ (Grimaux, *Bull. Soc. Chim.* [2], xxi. 390). This acid is formed, together with the dibrominated acid, by the action of bromine on pyroracemic acid. 1 pt. of the acid and 1 pt. water are introduced into a flask with vertical condensing tube, heated in a water-bath, and 4 pts. bromine are slowly added. The contents of the flask solidify on cooling to a crystalline mass, and the formation of *small* crystals may be promoted by external cooling and stirring. The crystals are freed by the filter-pump from the mother-liquor (which also contains the dibrominated acid), mixed with a small quantity of cold water, and once recrystallised from water at 80° .

Pure tribromopyroracemic acid thus obtained forms laminae resembling naphthalene, having the composition $C^8HBr^3O^3 + 2H^2O$, and melting at 104° . It does not part with its water of crystallisation either in the air or in a vacuum, or even to the smallest amount when heated for several days at 50° – 60° , but the whole of it is given off at 100° . The dehydrated acid melts at 90° . The acid is sparingly soluble in cold, easily in hot water, also in alcohol and in ether. It decomposes quickly when boiled in aqueous solution, a dense liquid passing over with the steam, which boils above 140° , and appears to consist of bromoform. At the same time oxalic, carbonic, and hydrobromic acids are formed, together with a solid body which reduces ammoniacal silver solution. Ammonia and lead acetate also readily decompose tribromopyroracemic acid, with formation of oxalic acid. The tribrominated acid precipitates calcium salts at ordinary temperatures, and forms with silver nitrate an immediate precipitate of silver bromide. It reduces auric chloride and mercuric chloride; it is not acted on by acetyl chloride.

The same tribromopyroracemic acid is formed by the action of bromine on ordinary lactic acid, and this reaction, which is perfectly analogous to the formation of tetrabromacetone from pseudopropyl alcohol, observed by Friedel (*Compt. rend.* lx. 346), affords a further confirmation of Wichelhaus's formula for pyroracemic acid:

Compounds of Pyroracemic Acid with Alkaline Sulphites (Clewing, *J. pr. Chem.* [2], xvii. 241). 1. *Sodium salts*.—A mixture of pyroracemic acid with a recently prepared solution of normal sodium sulphite yields crystals of the salt $C^8H^9O^3Na.HSO^3Na + H^2O$, easily soluble in cold water (100 pts. water dissolve 26.6

of the dry salt). The solution is not precipitated by barium chloride, except on addition of ammonia. Strong acids liberate sulphurous acid from it. Under somewhat different circumstances, the salt $2(\text{C}^3\text{H}^3\text{O}^3\text{Na}, \text{HSO}^3\text{Na}) + 3\text{H}^2\text{O}$ was obtained in prisms several centimeters long; it is less soluble than the former salt, and does not give off its water of crystallisation so readily. Pyrорacemic acid and *acid sodium sulphite* yield the salt $\text{C}^3\text{H}^3\text{O}^3, \text{HSO}^3\text{Na}$, which decomposes when boiled with water, giving off sulphur dioxide. It is not converted into a disodic salt by addition of the corresponding quantity of soda-ley, the mixture being rather disposed to deposit normal sodium sulphite.

2. *Potassium salts*.—A concentrated solution of normal potassium sulphite mixed with excess of pyrорacemic acid deposits, after a few days, strongly refracting octohedrons of the salt $\text{C}^3\text{H}^3\text{O}^3, \text{HSO}^3\text{K}$, of which 100 pts. water at 17° dissolve 44.9 pts. Its solution when boiled gives off sulphur dioxide, and leaves a thick syrup, which, after prolonged sojourn in a vacuum over sulphuric acid, has the composition $2\text{C}^3\text{H}^3\text{O}^3\text{K}, \text{HSO}^3\text{K}$. The mother-liquor of the former salt, mixed with a large excess of normal potassium sulphite, deposited, after about a week, crystals of the salt $\text{C}^3\text{H}^3\text{O}^3\text{K}, \text{HSO}^3\text{K} + \text{H}^2\text{O}$; 100 pts. water at 17.5° dissolve 32.6 pts. of the dry salt. A mixture of acid potassium sulphite with excess of pyrорacemic acid deposits, when concentrated, the salt $\text{C}^3\text{H}^3\text{O}^3, \text{HSO}^3\text{K}$; when dilute, the salt $\text{C}^3\text{H}^3\text{O}^3\text{K}, \text{HSO}^3\text{K}$.

3. *Calcium salts*.—When sulphur dioxide is passed into a mixture of dissolved and precipitated calcium pyrорacemate—such as is obtained by adding levigated calcium carbonate to pyrорacemic acid—till the whole is dissolved, and the solution is left to evaporate in a vacuum, the salt $2(\text{C}^3\text{H}^3\text{O}^3, \text{Ca}, \text{SO}^3\text{H}) + 3\text{H}^2\text{O}$ is obtained. This salt is very soluble in water and very stable, not being acted upon by sulphuric acid of 50 per cent.; on adding acid of 66 per cent., calcium sulphite separates out, but the odour of sulphurous acid does not become perceptible till the liquid is warmed. No precipitate is formed by barium chloride. When sulphur dioxide was passed into a clear dilute solution of calcium pyrорacemate, nodular groups of granules separated, consisting of the salt $(\text{C}^3\text{H}^3\text{O}^3)^2\text{Ca} + \frac{1}{2}(\text{C}^3\text{H}^3\text{O}^3, \text{Ca}, \text{SO}^3\text{H}) + 2\text{H}^2\text{O}$, and slender needles of the salt $(\text{SO}^3\text{H})^2\text{Ca} + 4(\text{C}^3\text{H}^3\text{O}^3, \text{Ca}, \text{SO}^3\text{H}) + 15\text{H}^2\text{O}$, which could be separated by cold water, 100 pts. water at 17° dissolving 4.1 pts. of the former and 143 pts. of the latter.

4. The *Strontium salt*, $\text{C}^3\text{H}^3\text{O}^3, \text{Sr}, \text{SO}^3\text{H} + 5\text{H}^2\text{O}$, separates as a bulky crystalline pulp on passing sulphur dioxide into a solution of strontium pyrорacemate, and may be obtained in small octohedrons by recrystallisation from warm water. It is much more soluble in hot than in cold water; the solution is not decomposed by boiling, and does not form any precipitate with barium chloride; concentrated acids, however, decompose it, with evolution of sulphur dioxide.

5. *Barium salt*.—When sulphur dioxide is passed into a solution of barium pyrорacemate no precipitate is formed, but the solution when evaporated leaves a thick syrup which, when dissolved in boiling water, yields on cooling crystals of the salt $\text{C}^3\text{H}^3\text{O}^3, \text{Ba}, \text{SO}^3\text{H}$. This salt is very permanent; 100 pts. water dissolve 1.7 pts. of it at 17° and 7.5 pts. at 100° . Clewing regards the formation of these compounds, and especially of the salts $\text{C}^3\text{H}^3\text{O}^3, \text{HSO}^3\text{Na}$ and $\text{C}^3\text{H}^3\text{O}^3, \text{HSO}^3\text{K}$, as demonstrative of the analogy of pyrорacemic acid to the ketones and aldehydes in its behaviour to acid sulphites.

Pyrорacemic Ethers. The pyrорacemates of Ethyl and Methyl have been already described (vii. 1034).

Pyrорacemic Glyceride, or *Pyruvin*, $\text{C}^6\text{H}^{10}\text{O}^3 = \text{C}^3\text{H}^3(\text{OH})(\text{OC}^3\text{H}^3\text{O}^3)$, is formed by heating tartaric acid with glycerin to a temperature higher than that which is required for the formation of glycerotartaric acids; if the mixture be heated in a retort, the pyruvin collects in fine crystals in the neck of the receiver. Pyruvin sublimes in shining laminae, melts at 78° , boils with decomposition at 242° , dissolves in alcohol, ether, carbon sulphide, and benzene, and with especial facility in chloroform, but is decomposed by water (Schlagdenhauffen, *Ann. Chim. Phys.* [4], xxvi. 139).

PYRORACEMIC CARBAMIDES or UREIDES (Grimaux, *Compt. rend.* lxxix. 526, 1304, 1478; lxxx. 53; *Ann. Chim. Phys.* [5], xi. 356). Pyrорacemic acid and urea, heated together at 100° , yield, according to the proportions in which they are mixed, the following compounds:

Pyrорacemic Dicarbamide or Pyruvil	$\text{C}^6\text{H}^8\text{N}^4\text{O}^3$
Dipyrорacemic Tricarbamide	$\text{C}^9\text{H}^{12}\text{N}^6\text{O}^3$
Tripyrорacemic Tetracarbamide	$\text{C}^{13}\text{H}^{16}\text{N}^8\text{O}^7$
Tetrapyrорacemic Tetracarbamide	$\text{C}^{16}\text{H}^{16}\text{N}^8\text{O}^8$

1 pt. pyroracemic acid is heated for an hour or two with 2 pts. urea, whereupon carbon dioxide is evolved, and the mass, which is at first liquid, becomes solid; and on exhausting this mass with hot alcohol, urea and ammonium pyroracemate are dissolved, while pyvuril remains behind, and may be purified by recrystallisation from about ten times its weight of boiling water, from which it separates in small shining rhombic plates.

Pyvuril may be heated to 145° without loss of weight, but when heated for several days at 155° – 160° , it is converted, with loss of about 25 per cent., into a brown-yellow amorphous substance and tetrapyracemic tetracarbamide. By boiling with baryta-water, pyvuril is resolved into urea, oxalic acid, and probably uvitic acid. Its solutions, mixed with potassium hydrate, give precipitates with the nitrates of silver and mercury. Pyvuril is resolved by dilute hydrochloric acid into urea and dipyracemic tricarbamide, and, by heating with strong hydrochloric acid, it is converted into

this compound in the pure state, the liquid is evaporated to dryness on the water-bath; the gummy residue is drenched with alcohol and left at rest for twenty-four hours; and the mass, which has now become crystalline and has been freed from urea by the alcohol, is recrystallised once or twice from boiling water. The monocarbamide is thus obtained as a white, very light, and indistinctly crystalline powder.

Nitropyracemic Carbamide, $\text{C}^4\text{H}^3(\text{NO}^2)\text{N}^2\text{O}^2$, is formed, together with nitrate of urea, on dissolving pyvuril in 4 or 5 pts. of moderately warm nitric acid of ordinary strength; and, on evaporating the solution to a pasty consistence, washing the residue with cold water, and crystallising it from 25 pts. of hot water, the nitrocarbamide is obtained in shining pale-yellow scales. It has a sweet taste, may be heated to 140° without loss of weight, and is converted at 160° into an amorphous substance which, by treatment with hot water, is reconverted into the original compound. The crystals decompose at 200° , and dissolve in alkalis with yellow colour, which disappears on addition of acids. The nitro-compound is quickly decomposed by heating with potash-ley; when boiled with lime- or baryta-water, it yields soluble yellow salts; the *silver salt*, $\text{C}^4\text{H}(\text{NO}^2)\text{N}^2\text{O}^2\text{Ag}^2$, and the *lead salt* form bulky jellies. On dissolving the nitro-compound in water and distilling the solution, after addition of bromine, bromopicrin passes over, and oxalyi-carbamide (parabanic acid) remains:

Dipyracemic Tricarbamide,

This compound is formed, by heating equal weights of urea and pyroracemic acid, as a clear liquid which gradually thickens and finally solidifies; and on exhausting the solid mass with 200 to 250 times its volume of boiling water, a solution is obtained which on cooling yields the tricarbamide in the form of a thick gelatinous mass of slender needles. It is nearly insoluble in cold water, but dissolves easily in alkalis, without, however, entering into combination with them; acids, including carbonic acid, precipitate it from its solutions as a jelly. The alkaline solutions give with silver nitrate a white precipitate; the aqueous solutions form such a precipitate only with mercury nitrate. It is decomposed by boiling with alkalis or with baryta-water, yielding, in the latter case, pyvuril, urea, and pyroracemic acid. Heated with nitric acid, it yields urea and the nitromonocarbamide above described; with pyroracemic acid at 100° , an amorphous substance.

By the action of heat on pyvuril, or by treating urea with excess of pyroracemic acid, *condensed carbamides* are formed, richer in carbon and less rich in nitrogen than the preceding; they are amorphous, insoluble in water, easily dissolved by alkalis, and reprecipitated by acids; decomposing without previous fusion when heated; not attacked by acids.

Tripyracemic Tetracarbamide, $\text{C}^{13}\text{H}^{16}\text{N}^8\text{O}^7 = 3\text{C}^3\text{H}^4\text{O}^2 + 4\text{CH}^1\text{N}^2\text{O} - 6\text{H}^2\text{O}$, formed simultaneously with dipyracemic tricarbamide, is a white powder which dissolves in alkalis without previous gelatinisation.

Tetrapyroracemic Tetracarbamide,

is precipitated by acids from its solutions in alkalis as a bulky jelly which dries up to a granular mass; it is not attacked by boiling potash-ley or by nitric acid.

Tribromanhydropyvvuril, $C^3H^3Br^3N^4O^2$, is formed by heating equal parts of bromopyroracemic acid and urea at 100° , the mixture first liquefying and then solidifying after a few hours. By washing the mass with cold water and recrystallising it from hot water, the tribromanhydropyvvuril is obtained in light needles, which melt with decomposition at 180° . It has a sharp taste, provokes sneezing, dissolves in hot water, alcohol, ether, and ether-alcohol. Its solution gives with silver nitrate a precipitate containing silver and bromine. Dibromopyroracemic acid acts upon urea in the same manner as the tribrominated acid.

PYROSCLERITE (iv. 770). The following analysis, by J. Ebert, of pyrosclerite from the limestone cleft of St. Philipp, near St. Marie aux Mines, Alsace, has been published by A. Knop (*Jahrb. f. Min.* 1870, 70):

SiO ²	Al ² O ³	CaO	MgO	FeO	H ² O
38.7	16.1	6.1	25.9	0.5	12.8 = 100.1

The carbonic acid present is not sufficient to allow of the whole of the lime being regarded as admixed limestone.

A rhombic silicate (possibly pyrosclerite) of greyish and occasionally bronze-yellow colour, and sp. gr. 2.558, occurring as a contact product between talc and gymnite on the Bare Hills near Baltimore, has been analysed by A. R. Leeds (*Sill. Am. J.* [3], vi. 24):

SiO ²	Al ² O ³	Fe ² O ³	FeO	MgO	Na ² O Li ² O	H ² O
36.03	9.19	5.48	0.94	33.05	0.41	14.66 = 99.76
35.84	9.85	5.21	1.21	32.93	0.41	14.53 = 99.98

PYROSMALITE. Wöhler (*Liebig's Annalen*, clvi. 85), from three analyses made by himself, and an older analysis by Hisinger (iv. 771), gives for this mineral the following composition:

SiO ²	FeO	MnO	Fe ² O ³	Fe ² Cl ⁶	H ² O
36.42	22.91	22.52	5.10	9.73	3.32 = 100

and deduces therefrom the formula $(Fe^2Cl^6, Fe^2O^3) + 10(FeO, SiO^2 + MnO, SiO^2) + 8H^2O$.

E. Ludwig (*Min. Mitth.* 1875, 211) gives analyses of pyrosmalite from Nordmarken, from which he deduces the empirical formula:

	SiO ²	FeO	MnO	CaO	MgO	H ² O	Cl	Total	O*	Residue
Analysis	34.66	27.05	25.60	0.52	0.93	8.31	4.88	= 101.95	1.10	100.85
Calculation	34.88	26.16	25.80	—	—	9.16	5.16			

* To be deducted as equivalent to the chlorine.

PYROSULPHURIC ACID, $S^2H^2O^7 = 2SO^3, H^2O$. See SULPHUR, OXYGEN-ACIDS OF.

PYROTARTARIC ACIDS, $C^5H^8O^4$. Theory indicates the existence of four of these acids, all of which are now known, viz.:

1. **Normal Pyrotartaric, Homosuccinic, or Glutaric Acid**, $CH^2(CH^2.CO^2H)^2$. This acid, identical with the deoxyglutanic acid which Dittmar obtained (*J. pr. Chem.* [2], v. 338) by heating glutanic acid, $C^5H^8O^5$, with hydriodic acid (vii. 362), is also produced: α. By saponification of normal propylene cyanide, $CH^2(CH^2.CN)^2$, prepared by the action of potassium cyanide on normal propylene bromide in presence of alcohol (Julie Lermontoff, *Ber.* ix. 1441; Reboul, *Bull. Soc. Chim.* [2], xxv. 386). β. By treating ethyl sodaceto-acetate with ethylic β-iodopropionate, whereby ethylic aceto-glutanate is formed, according to the equation:

and decomposing this ether with alcoholic potash (Wislicenus a. Limpach, *Liebig's Annalen*, xcii. 128).

Glutaric acid crystallises very easily from aqueous solution in large transparent four-sided prisms, melts at 97° (Dittmar), at 97.5° (Markownikoff), at 96° (corr. Reboul) and boils at 291° (corr. 299° , Reboul), at 302° (Markownikoff).^{*} When glutaric acid (8.5 grams) is heated with bromine (21 g.) and water (10 c.c.) at 145° , it yields nothing but HBr, CO, and CO^2 ; at 118° – 120° the bromine disappears more slowly, with evolution of CO^2 and HBr, and the liquid on cooling deposits crystals of dibromosuccinic acid. With 7.2 g. glutaric acid, 18 g. bromine, and 15 c.c. water heated at 100° for ninety hours, the products are tetrabromethane and dibromoglutaric acid (Bourgoin a. Reboul, *Compt. rend.* lxxxiv. 556).

Calcium glutarate, $\text{C}^5\text{H}^3\text{O}^4\text{Ca} + 4\text{H}^2\text{O}$, crystallises in stellate groups of slender needles, more soluble in cold than in hot water. The magnesium salt is very soluble, and partly separates from very concentrated solutions in microscopic four-sided plates, the greater part, however, drying up to an amorphous mass; from dilute alcohol it crystallises in small needles. The zinc salt, $\text{C}^5\text{H}^3\text{O}^4\text{Zn}$, is but very slightly soluble in cold water (1 pt. in 102 pts. water at 18°), and still less in hot water. The solution prepared at ordinary temperatures deposits, when heated, microscopic rectangular plates with re-entering angles on the shorter sides of the rectangle.

Diethyl glutarate, $\text{CH}^2(\text{CH}^2.\text{COOC}^2\text{H}^5)^2$, is prepared by passing hydrogen chloride to saturation into a solution of the acid in absolute alcohol, distilling, collecting the portion which goes over between 240° and 260° , freeing this distillate from unetherified glutaric acid by digestion with potassium carbonate, and redistilling. The pure ether is a colourless liquid having a disagreeable odour, a density of 1.025 at 21° , and boiling without decomposition at 236.5 – 237° (corr.) (Reboul, *Ann. Chim. Phys.* [5], xiv. 510).

Normal Pyrotartaric or Glutaric Anhydride,

When glutaric acid is slowly distilled, either alone or in contact with phosphoric anhydride, water passes over first, and afterwards, at 282° – 285° , a crystalline mass which melts at 80° – 85° , and consists of a mixture of acid and anhydride. It is difficult, however, to obtain the pure anhydride in this way, and a better product is obtained by the action of acetyl chloride in ethereal solution on silver glutarate:

Glutaric anhydride crystallises in white slender needles, melts at 56° – 57° , and boils, with decomposition, at 282° – 287° . By prolonged contact with alcohol, it is converted into ethyl-hydrogen glutarate (Markownikoff, *Ber.* x. 972, 1102).

Glutaric chloride, $\text{CH}^2(\text{CH}^2.\text{COCl})^2$, obtained by the action of 2 mol. PCl^5 on 1 mol. of the acid, is a heavy liquid having an irritating odour, boiling, with perceptible decomposition, at 216° – 218° , and converted by water into hydrochloric and glutaric acids (Reboul, *Ann. Chim. Phys.* [5], xiv. 510).

Normal Hydroxypyrotartaric Acid, $\text{C}^5\text{H}^4\text{O}^5$.—There are two modifications of this acid, viz.:

^{*} Markownikoff found that the acid prepared from glutaric acid boiled at 302° , whereas that prepared from propylene cyanide boiled at 215° , and he attributes the difference to some diversity in the circumstances of the distillation. As, however, the higher boiling point agrees nearly with that determined by Reboul, it may safely be regarded as nearer to the truth than the lower. According to Dittmar, the acid decomposes at temperatures above 280° into water and the anhydride.

The symmetrical modification was discovered in 1862 by Maxwell Simpson, who obtained it by heating symmetrical dichlorhydrin, $\text{CH}^2\text{Cl}.\text{CH}^2\text{OH}.\text{CH}^2\text{Cl}$, with potassium cyanide in alcoholic solution, and saponifying the resulting dicyanhydrin with alcoholic potash. It forms hard crystals very soluble in cold water, slightly soluble in alcohol and ether (vii. 886).

The unsymmetrical modification, called glutamic acid, obtained by the action of nitrous acid on glutamic acid, $\text{C}^5\text{H}^9\text{NO}_4$, was discovered by Ritthausen (vi. 637), and has been further examined by Markownikoff (*Liebig's Annalen*, clxxxii. 347). It may be prepared by passing nitrous gas into a solution of glutamic acid in nitric acid, or more advantageously by mixing a solution of glutamic acid in hydrochloric acid with an equivalent quantity of potassium nitrite. It is difficult to obtain in well-defined crystals. It melts at $72^\circ\text{--}73^\circ$, and solidifies, on cooling, to a clear amorphous mass. It appears to form with bases two classes of neutral salts differing in solubility.

The *zinc salt*, obtained by saturating the acid with zinc carbonate, crystallises from a syrupy solution, on standing, in transparent four-sided tables, which when dissolved in hot water are transformed into a pulverulent sparingly soluble salt. From a hot saturated solution it crystallises in nodules agreeing in composition with the formula $\text{C}^5\text{H}^9\text{O}^5\text{Zn} + 3\text{H}^2\text{O}$. The *magnesium salt*, $\text{C}^5\text{H}^9\text{O}^5\text{Mg} + 4\text{H}^2\text{O}$, obtained in the same manner as the zinc salt, is sparingly soluble in cold water, and crystallises from hot solutions in transparent microscopic rhombic tables.

Glutamic acid, when heated to 190° , is converted into an anhydride, which dissolves in water, reproducing the acid. By reduction it yields glutaric acid (p. 1721).

2. Ordinary Pyrotartaric or Methyl-succinic Acid, $\text{CH}^3.\text{CH} \begin{smallmatrix} \text{COOH} \\ \text{CH}.\text{COOH} \end{smallmatrix}$

This acid, originally obtained by the dry distillation of tartaric acid (iv. 771), is also produced: (1). By the action of boiling aqueous potash on the ethylic ethers of α - and β -methylacetosuccinic acid, which are obtained in the same way as the corresponding ethers of α - and β -ethylacetosuccinic acid, using methyl instead of ethyl iodide in the case of the α -ether, and ethylic α -bromopropionate instead of the α -bromobutyrate in that of the β -ether (see ACETO-ACETIC ETHERS, pp. 15, 16). The reactions by which methylsuccinic acid is formed from these ethers are represented by the following equations:

(Conrad, *Liebig's Annalen*, clxxxviii. 217; Kressner, *ibid.* xcii. 135).

(2). By the action of boiling aqueous potash on the dicyanide obtained by heating allyl iodide in a sealed tube with 2 mols. potassium cyanide and a little alcohol (Claus, *Ber.* v. 612; viii. 100).

Electrolysis.—When a concentrated solution of pyrotartaric acid is electrolysed, hydrogen appears at the negative pole, and oxygen, mixed with CO and CO₂, at the positive pole. A solution of potassium pyrotartrate when electrolysed deposits on the positive pole crystals of the acid salt, which disappear after some time, the solution then containing free pyrotartaric acid. Solutions containing excess of alkali give off considerable quantities of gas, consisting of carbon dioxide, carbon monoxide, and oxygen (Reboul a. Bourgoin, *Compt. rend.* lxxxiv. 1231).

Reaction with Bromine.—When pyrotartaric acid is treated with bromine (1 mol.) in a closed vessel at 120° , the chief product obtained is bromocitrapyrotartaric anhydride, together with very small quantities of an apparently monobrominated acid. With 2 mols. bromine, the product consists of bromocitraconic anhydride. *Bromocitrapyrotartaric anhydride* melts at $104^\circ\text{--}105^\circ$, has a sp. gr. of 1.935 at 23° , dissolves readily in alcohol and ether, sparingly in chloroform, and when heated with water in sealed tubes at 130° yields carbon dioxide and allylene. When pyrotartaric acid is heated with 4 mols. bromine at $130^\circ\text{--}132^\circ$, carbon dioxide is given off, and a tetra-

bromide of acetylene, $\text{C}^2\text{H}^2\text{Br}^4$, is formed, which has a density of 2.93 at 0° , boils with partial decomposition at about 200° , and solidifies at -17° , whereby it is distinguished from the other known acetylene tetrabromides, one of which remains liquid at -17° (p. 35), while the other is solid at ordinary temperatures, and melts at 54.5° (Bourgoin, *Ann. Chim. Phys.* [5], xii. 419).

Bromopyrotartaric acids, $\text{C}^3\text{H}^7\text{BrO}^4$.—The crystalline forms of these isomeric acids (vi. 49, 980) have been determined by Arzruni (*Zeitschr. Kryst.* i. 439). *Citra-bromopyrotartaric acid* crystallises in the monoclinic system with the axial ratio $a : b : c = 0.7504 : 1 : 1.1175$; $\beta = 84^\circ 5'$. Principal forms, 0P , ∞P , ∞P , $- \text{P}$, $+ \text{P}$, ∞P , ∞P . Angle $\infty \text{P} : \infty \text{P} = 36^\circ 53'$. Cleavage perfect parallel to ∞P and ∞P . Plane of optic axes perpendicular to the plane of symmetry. *Itabromopyrotartaric acid* is also monoclinic. Axial ratio $a : b : c = 0.2914 : 1 : 0.4101$; $\beta = 65^\circ 38'$. Forms ∞P , P , ∞P .

3 and 4. **Ethylmalonic** and **Dimethylmalonic acid** have already been described as **MALONIC ETHERS**.

The following tabular view of the properties of the isomeric pyrotartaric acids is given by Markownikoff (*Liebig's Annalen*, clxxxii. 324):

	Glutaric or Homosuccinic acid	Pyrotartaric or Methyl-succinic acid	α -Isopyrotartaric or Ethyl-malonic acid	β -Isopyrotartaric or Dimethyl-malonic acid
Acid.	Large flat plates, easily soluble in water; melts at 97° ; boils, almost without decomposition, at 302° .	Four-sided prisms; easily soluble in water; melts at 112° ; boils at about 200° , being converted into the anhydride.	Short four-sided prisms, easily soluble in water; melts at 111.5° ; decomposes without subliming, at 160° .	Short four-sided prisms, easily soluble in water; melts, with decomposition, at 170° ; sublimes at 120° .
Calcium salt.	Easily soluble in cold, less easily in hot water. Crystallises with difficulty.	Somewhat sparingly soluble in cold water. Crystallises with $2\text{H}^2\text{O}$.	Slightly soluble in hot, easily in cold water. Crystallises in prisms with $1\text{H}^2\text{O}$.	Less soluble in hot than in cold water. Crystallises in nodules.
Zinc salt.	Microscopic twins, soluble in 102 pts. water at 18° .	Easily soluble.	Microscopic six-sided plates. Soluble in 456 pts. water. Contains $2\frac{1}{2}\text{H}^2\text{O}$.	Like the α -salt. Dissolves in 106 pts. water. Contains $3\text{H}^2\text{O}$.
Lead salt.		White precipitate.	White precipitate, becoming granular on boiling.	White precipitate, converted on boiling into shining scales.

PYROTEREBIC ACID. See TEREBIC ACID.

PYROTRITARTARIC or **UVIC ACID**, $\text{C}^7\text{H}^5\text{O}^3$. This acid, which Wislicenus a. Stadnicki obtained, together with pyrotartaric acid, by the dry distillation of tartaric acid (vi. 981), is also produced: 1. By heating pyroracemic acid with a quantity of barium hydrate less than sufficient to neutralise it. 40 to 50 grams of pyroracemic acid and 25 to 30 grams of crystallised barium hydrate are boiled together for six hours in a flask with vertical condenser and then left to cool, whereupon the liquid acquires a dark-red colour and deposits uvic acid (7 p. c. of the pyroracemic acid) in small interlaced needles, while pyrotartaric acid remains dissolved, together with acetic acid and small quantities of other acids not determined (Böttinger, *Liebig's Annalen*, clxxii. 239). 2. By the action of dilute sulphuric acid on ethylic diacetosuccinate. 20 grams of this ether are boiled with 150 g. dilute sulphuric acid (1 : 10) in a reflux apparatus as long as carbon dioxide continues to be evolved, after which the liquid is distilled in a current of steam. Alcohol then passes over, together

with the water, and an oil which smells like anise, and after repeated distillation boils at 208°–209°. This oil is the ethylic ether of pyrotritartaric acid, and yields the acid by saponification. The residue of the distillation contains carbopyrotritartaric acid, $C^8H^8O^5 = C^7H^8O^3 + CO^2$, partly in the free state, partly in the form of ethylic ether (G. H. Harrow, *Chem. Soc. J.* xxxv. 425).

The formation of these acids from ethylic diacetosuccinate may be represented by the following equations:

Böttger represents uvic acid by the formula:

but Harrow points out that this formula will not explain the formation of the acid from ethylic diacetosuccinate, and, moreover, that Wislicenus a. Stadnicki have shown that uvic acid does not contain a second hydroxyl-group.

Uvic acid is nearly insoluble in cold water, but dissolves to a considerable amount in boiling water; it is soluble also in ether, and crystallises therefrom in prismatic needles melting at 135° (Harrow). According to Böttger, it separates from boiling water in crystals having a vitreous lustre, sparingly soluble in cold water, melting at 133°, and resolidifying at 126°. It volatilises with vapour of water, and sublimes in smooth rectangular prisms, joined together like steps, and melting at 134°. On mixing a very small quantity of it on a watch-glass with 2 drops of fuming hydrochloric acid, then heating slightly, adding about 6 drops of strong sulphuric acid, and again gently warming, a fine cherry-red colour is produced (Harrow).

Uvic acid is monobasic. Its *sodium salt*, $C^7H^7NaO^3$, is a white crystalline mass, easily soluble in water (Harrow). The *silver salt*, $C^7H^7AgO^3$, is thrown down by silver nitrate from a solution of the acid neutralised with soda or ammonia, as a white precipitate which quickly turns greyish-yellow on exposure to light, but may be converted by crystallisation into small transparent prisms possessing greater stability. The *barium salt*, $(C^7H^7O^3)^2Ba + 5H^2O$, prepared from the acid by means of barium hydrate and carbon dioxide, forms indistinct crystalline geodes. The *calcium salt*, $(C^7H^7O^3)^2Ca + 3H^2O$, crystallises in radiate needles. The *zinc salt*, $(C^7H^7O^3)^2Zn + 4H^2O$, is more readily soluble in cold than in boiling water. It is prepared by nearly neutralising a moderately warm solution of the acid with zinc oxide, and leaving it for some time in the exsiccator; the solution then first deposits a small quantity of the free acid, and afterwards the zinc salt in large round geodes. With *mercurous nitrate*, a solution of uvic acid forms a white precipitate which is not altered by boiling with water (Böttger).

The *ethylic ether*, $C^7H^7O^3.C^2H^5$, is obtained, as above mentioned, by boiling ethylic diacetosuccinate with sulphuric acid, also by decomposing the silver salt with ethyl iodide. When purified by repeated distillation, it melts at 208°–209° (Harrow).

Carbopyrotritartaric Acid, $C^8H^8O^5$, remains, as above stated, as the residue of the distillation in the preparation of pyrotritartaric acid, partly in the free state, partly as ethylic ether, which may be saponified by prolonged boiling with dilute sulphuric acid. The acid crystallises from boiling water in which it is moderately soluble, in long very slender needles, which melt at 230°–231°, especially in presence

of a small quantity of sulphuric acid. It is nearly insoluble in cold water. The sodium salt, $C^8H^7NaO^6 + 3H^2O$ (?), crystallises from water in long needles. It dissolves easily in water, sparingly in alcohol, and, like the ammonium salt, has a persistent bitter taste. The silver salt, $C^8H^7AgO^6$, is obtained as a dense precipitate, and crystallises from boiling water in slender needles, turning grey when exposed to light. When heated, it yields carbopyrotritartaric and pyrotritartaric acids. The ethylic ether, $C^8H^7O^6.C^2H^5$, forms needles melting at $80^{\circ}-81^{\circ}$.

Carbopyrotritartaric acid is resolved by heat into pyrotritartaric acid and carbon dioxide. It is neutralised by 1 equivalent of sodium hydroxide, NaOH, and is therefore monobasic; but, if heated for some time with 2 mols. sodium hydroxide, it yields a solution from which silver nitrate throws down no longer a brown precipitate of silver oxide, but a white precipitate of a *diargentic salt*, having the composition $C^8H^3Ag^2O^6$. The acid reprecipitated from this salt by dilute nitric acid is unaltered carbopyrotritartaric acid. From this result, and the fact that carbopyrotritartaric acid splits up on heating into CO^2 and pyrotritartaric acid, which undoubtedly contains a carboxyl-group, it may be inferred that it belongs to the class of etheric anhydrides.

Carbopyrotritartaric acid is not altered by boiling with strong aqueous potash, even for several hours, but by fusion with potassium hydroxide, it is resolved into acetic and succinic acids, according to the equation :

(Harrow, *Chem. Soc. J.* xxxv. 435).

PYROUSNIC ACID, $C^{12}H^{12}O^5$. See USNIC ACID.

PYROVANADATES. See VANADIUM.

PYROXANTHIN, $C^{12}H^{12}O^3$. The action of bromine on this substance (contained in crude wood-spirit, and produced by the action of potash on one of the constituents of wood-tar oil (iv. 776*)) has been examined by H. B. Hill (*Ber.* xi. 456). When dissolved in carbon sulphide and treated with a solution of bromine in the same liquid, it is slowly converted into dibromopyroxanthin tetrabromide, $C^{12}H^{10}Br^2O^3.Br^4$, which crystallises from solution in benzene in small white triclinic needles, and is converted by boiling with absolute alcohol and metallic antimony into dibromopyroxanthin, $C^{12}H^{10}Br^2O^3$, soluble in alcohol and crystallising therefrom in bright yellow well-defined monoclinic needles; this latter compound is not produced by the direct action of bromine on pyroxanthin. Pyroxanthin boiled with zinc-dust and acetic acid containing a little alcohol is converted into hydropyroxanthin.

PYROXENE or **AUGITE**, $R'SiO^3$. The following analyses of augites have been made by C. Doelter (*Min. Mitth.* 1877, 279): 1. Black augite from Vesuvius: crystals of the form $\infty P . \infty P \infty . \infty R \infty . P$, from a sanidin bomb. 2. Dark green from Vesuvius: crystals of the same form, likewise from a bomb. 3. Yellow augite from Vesuvius: crystals having the form $2P$, together with those above mentioned; also from a bomb. 4. Simple crystals and twins of the ordinary form from Lipari. 5. Simple crystals and twins of the ordinary form from a basaltic lava from Cuglieri in Sardinia. 6. Augite in prismatic crystals from Greenwood furnace. 7. Augite of the combination $\infty P . \infty P \infty . \infty P \infty . 0P . \frac{1}{2}P \infty$, from the melaphyre of the Buforeberg, South Tyrol. 9. Dark green, and 10. Colourless portions of a variously coloured diopside crystal from Ala:

	SiO ^a	CaO	MgO	FeO	Fe ² O ³	Al ² O ³	Sp. gr.
1.	46.95	19.02	16.04	4.09	4.47	9.75 = 100.32	3.275
2.	51.01	20.80	16.58	3.16	3.51	4.84 = 99.90	3.203
3.	50.41	22.75	12.92	6.78	1.09	6.07 = 100.02	3.298
4.	48.45	20.30	14.35	6.94	3.57	6.68 = 100.29	3.225
5.	45.65	21.09	13.60	5.05	6.32	8.61 = 100.32	3.299
6.	49.18	20.62	16.83	2.55	5.05	5.09 = 99.32	3.295
7.	49.01	20.01	14.55	7.74	3.77	5.09 = 100.17	3.299
8.	44.76	24.90	13.65	2.09	5.01	10.10 = 100.51	3.979
9.	54.28	25.04	17.30	1.91	0.98	0.51 = 100.02	
10.	54.74	26.03	17.02	2.91	—	— = 100.70	

From these analyses, Doelter endeavours to decide between the views of Rammelsberg and Tschermak respecting the constitution of aluminiferous augites, the former

* The empirical formula $C^8H^8O^2$ there given is erroneous; it should be C^8H^4O .

regarding them as isomorphous mixtures of RSiO^3 with Al^2O^3 and Fe^2O^3 , whereas the latter assumes for the admixture of aluminium and sesquivalent iron, the formulæ $\text{MgAl}^2\text{SiO}^6$ and $\text{MgFe}^2\text{SiO}^6$. Doelter concludes that all his analyses conform to the fundamental condition of Tschermak's hypothesis, inasmuch as, for all the aluminiferous augites analysed, $\text{Ca} < \text{Mg} + \text{Fe}$, the difference being considerable in most cases, small only in No. 3. Doelter further shows that, with the exception of Nos. 3, 5, and 7, the analytical results may be represented by the formula $x(\text{MgCaSi}^2\text{O}^6) + y(\text{FeCaSi}^2\text{O}^6) + z(\text{MgFe}^2\text{SiO}^6) + y'(\text{MgAl}^2\text{SiO}^6)$, thus;

	$\text{MgCaSi}^2\text{O}^6$	$\text{FeCaSi}^2\text{O}^6$	$\text{MgFe}^2\text{SiO}^6$	$\text{MgAl}^2\text{SiO}^6$
in 1 = 10	:	2	:	1
2 = 16	:	2	:	1
4 = 12	:	4	:	1
6 = 19	:	2	:	2
8 = 84	:	5	:	1

Varieties of Pyroxene.—A. R. Leeds (*Zeitschr. f. Kryst.* ii. 642) has analysed hypersthene (No. 1) and diallage (No. 2) from the norites of the Adirondacks Mountain, New York: sp. gr. 3.459:

SiO^2	TiO^2	Al^2O^3	Fe^2O^3	FeO	MnO	CaO	MgO	H^2O	
50.33	0.07	3.36	1.03	19.40	0.71	2.77	21.40	1.14	= 100.21
46.28	0.59	7.38	2.21	14.80	—	18.78	8.91	1.115	= 100.065

A brown pyroxene (A), nearly related to bronzite, and a chrome-diopside (B), from the olivine-nodules of the Lützelberg, Kaiserstuhl range (p. 1435), have been analysed by A. Knap (*Jahrb. f. Min.* 1877, 697). The bronzite contained about 1.5 per cent. chrome iron ore mechanically mixed, being itself free from chromium whereas in the chrome-diopside no such admixture was perceptible:

SiO^2	X *	Al^2O^3	Cr^2O^3	FeO	MnO	MgO	CaO	
52.50	2.00	2.29	—	6.07	—	32.23	4.35	= 99.44
51.89	2.30	4.76	1.09	4.40	0.54	15.47	19.73	= 100.18

* Residue left on dissolving the separated silica in soda-ley; possibly containing niobic and titanic acids, which, however, could not be detected, owing to the small quantity of the available material.

K. Oebbecke (*Inaug. Dissert.* Würzburg, 1877, 21; *Jahrb. f. Min.* 1877, 844) found in chrome-diopside from the paleoepicrite of the Black rocks, Nassau:

SiO^2	Al^2O^3	Cr^2O^3	FeO	MgO	CaO	Sp. gr.
50.443	5.105	1.403	9.696	17.418	14.629	= 98.694 3.202

Salite from Albrechtsberg in Lower Austria has been analysed by E. v. Ramberger. It occurs in granular limestone, forming groups of crystals of various length up to 12 centimeters. A. analysis. B. calculation from the formula $\text{MgCaSi}^2\text{O}^6$:

	SiO^2	Al^2O^3	FeO	CaO	MgO	Sp. gr.
A.	55.60	0.16	0.56	26.77	18.34	= 101.43 3.167
B.	55.56	—	—	25.92	18.52	= 100

Fassaite, from the Fassa and Fleims valleys, has been analysed by C. Doelter (*Jahrb. f. Min.* 1877, 647) with especial attention to the separation of the two oxides of iron.

1. Pure crystals from the Toal della Foga. 2. Crystallo-granular variety from the same locality. 3. Grass-green crystals from the northern declivity of the Mal Inverno:

	SiO^2	Al^2O^3	Fe^2O^3	FeO	MgO	CaO	H^2O	
1.	43.81	9.97	7.01	1.52	12.51	25.10	0.51	= 100.43
2.	44.06	10.43	5.91	1.67	13.10	25.20	0.15	= 100.52
3.	41.97	10.63	7.36	0.55	10.29	26.60	2.70	= 100.10

These analyses show that fassaite is more nearly related to the aluminiferous augites than to diopside, but that it is specially characterised by the predominance of ferric over ferrous oxide, and of lime over magnesia.

PYRRHOTIN, Fe^2S^4 . *Magnetic Pyrites. Pentlandite.*—This mineral occurs, together with native iron, in the dolerite of Greenland, in masses varying from small grains to blocks of considerable size. It differs in appearance and structure from troilite, which is found in large nodules in meteorites. Its analysis gave:

S	Fe	Ni	Co	Cu	Sp. gr.
38.38	58.48	1.05	0.55	1.58	= 100.04 4.46

It is lighter than troilite (sp. gr. 4.9) and much more magnetic (J. L. Smith, *Ann. Chim. Phys.* [5], xvii. 452).

FURAL-DERIVATIVES, p. 836). This base is formed in considerable quantity when diethylamine is passed through a tube heated to low redness (O. A. Bell); in small quantity, together with ammonium cyanide, when acetylene containing small quantities of ethylene is passed, together with ammonia, through a red-hot tube (Dewar, *Proc. Roy. Soc.* xxvi. 65).

Acetyl-pyrroline, $C^4H^4(C^2H^3O)N$, formed by the action of acetic anhydride on pyrroline, is a liquid boiling at 133° . It is not attacked by ethyl iodide or by alkali-metals, and therefore does not contain an NH^2 -group; in other words, the nitrogen-atom in it is directly associated with only 1 atom of hydrogen, as represented by the above formula. Bromine converts it into dibromacetyl-pyrroline, $C^2H^3O.N(CH-CHBr)^2$ (R. Schiff, *Ber.* x. 1500).

Alcoholic or Alkyl Derivatives of Pyrroline, and Alkyl-pyrrolamides (O. A. Bell, *Ber.* x. 1861; xi. 1810).—When the mucates of primary amines of the fatty series are heated in a paraffin-bath, there are produced: (1). *Alkyl-pyrrolines*, and (2). *Alkylamides of the mono- and di-carboxylated derivatives of these pyrrolines*. Ethylamine mucate, for example, is decomposed as follows:

and the nascent ethylamine resulting from the first reaction acts further on the ethylamine mucate, producing triethyldicarbopyrrolamide, $C^4H^4N^3O^2$, thus:

Methylamine mucate undergoes a change similar to that represented in the last equation, but the amylamine salt is apparently decomposed as in (1) and (2).

Methyl-, Ethyl-, and Amyl-pyrroline are colourless liquids boiling at 112° – 113° , 131° , and 180° – 184° respectively (pyrroline boils at 133°). The first two resemble pyrroline; the last has a powerful and characteristic odour. They dissolve in strong acids, and exhibit the pyrroline reactions with fir-wood, mercuric chloride, &c. When boiled with strong hydrochloric acid they do not, however, deposit any solid substance as pyrroline does. Potassium does not act on them; whereas with pyrroline, hydrogen is evolved, and potassium-pyrroline, C^4H^4KN , is formed. According to Lubavin (*Zeitschr. f. Chem.* [2], v. 399), ethyl iodide reacts with potassium-pyrroline, forming an ethyl-pyrroline boiling at 155° – 175° , and having peculiar properties. This, however, is not the case, the product of the reaction being the ethyl-pyrroline described above.

Dimethyl-, Diethyl-, and Diamyl-carbopyrrolamide are beautifully crystalline bodies, melting at 89° – 90° , 43° – 44° , and 77° respectively. Heated at 120° with strong alcoholic potash, the first two yield fatty amines and *methyl- and ethyl-carbopyrrollic acids*, $C^4H^4(CH^3)N.COOH$ and $C^4H^4(C^2H^5)N.COOH$, melting at 135° and 78° respectively.

The third amide, however, only gives potassium carbonate, amylamine, and amyl-pyrroline, the corresponding acid being probably very unstable. Methyl- and ethyl-carbopyrrollic acids are also unstable, a solution of the latter in water behaving like supersaturated carbonic acid water, and rapidly giving off carbon dioxide in contact with rough surfaces. Dilute acids, boiling water, and sublimation also decompose these acids; their salts are generally very soluble.

Triethyl-dicarbopyrrolamide (from reaction 3) is crystalline and very stable, and melts at 229° – 230° . Strong alcoholic potash at 130° decomposes it into ethylamine and *ethyl-dicarbopyrrollic acid*, $C^4H^4(C^2H^5)N(COOH)^2$. This acid sublimes without melting at 250° , partially decomposing into pyrroline and carbon dioxide. It is quite insoluble in water. Weak acids do not act on it: strong acids slowly decompose it.

Boiling with dilute hydrochloric acid slowly dissolves ethyl-pyrroline, forming an insoluble amorphous base, which yields soluble uncrystallisable salts, and possibly has the composition $C^4H^4N^2O^2$, being formed by the reaction:

Bromine-water produces with ethyl-pyrroline a *substitution-product*, $C^4Br^4N.C^2H^5$, melting at 90° . With diethyl-carbopyrrolamide it forms a *substitution-product*, $C^4Br^2N(C^2H^5)CO.NH.C^2H^5$, and a soluble crystallisable oxidation-product having acid

characters and, probably, the constitution $C^4Br^2O(OH).CO.NH.C^6H^5$. The dimethyl-amide yields similar bodies. In no case was an addition-product obtained analogous to Schiff's dibromacetylpyrroline (p. 1728).

The mucates of secondary and tertiary amines do not yield derivatives of pyrroline by distillation, but give off nearly the whole of their bases in the free state, leaving tarry residues. This fact, and the indifference of the alkyl-pyrroline bases to potassium and acid chlorides, confirm Baeyer's pyrroline formula above given. During the distillation of ammonium mucate, pyrroline is probably formed by the action of ammonia on two of the hydroxyl-groups of the mucic acid, water and the imide-residue (NH) being produced, while one of the carboxyl-groups may remain attached to the pyrroline-nucleus, and so give rise to carboxypyrrolamine. When the mucates of the fatty amines are decomposed, one or both of the carboxyl-groups may remain attached as shown above.

Pyrroline and some of its homologues from bone-tar have quite recently been examined by Weidel a. Ciamician (*Ber.* xiii. 65-85). The tar was several times distilled, then treated with acids to remove amine-bases, and the remaining oil was separated by repeated fractional distillation into three portions, boiling between 93° and 150° ; 150° - 220° ; and 220° to above 360° . Pyrroline was obtained from the first fraction, together with toluene, ethyl-benzene, and several acids and nitrils of the fatty series; while the second fraction yielded homologues of pyrroline represented by the empirical formulæ C^6H^7N and C^6H^8N . (For the methods of separating all these bodies, see *Tar.*)

Pyrroline thus prepared is a perfectly colourless, highly dispersive liquid, which, when quite pure, remains colourless for several days; it has a sp. gr. of 0.9752 at 12.5° , and boils under a pressure of 7465 mm. at 126.2° . This last is the only property in which it differs from the pyrroline obtained by Anderson, who found it to boil at 133° (*iv.* 783); in spite of this difference, however, Weidel a. Ciamician regard their pyrroline as identical with that obtained by Anderson.

The second of the above-mentioned fractions (b. p. 150° - 220°) was found to contain two substitution-derivatives of pyrroline, represented empirically by the formulæ C^6H^7N and C^6H^8N . The first of these, called homopyrroline, is a colourless oil which smells like chloroform, and boils at 145.5° under a pressure of 742.8 mm. When exposed to air and light, it changes more quickly than pyrroline, but is less readily acted on by acids, being merely converted into a viscid resinous mass, whereas pyrroline is strongly attacked by acids, and converted into a solid brittle resin. It unites with mercuric chloride, forming a white curdy-looking compound.

Homopyrroline has the same empirical composition as Bell's methyl-pyrroline (p. 1728), but differs from it considerably in boiling point, methyl-pyrroline boiling at 112° - 113° . Moreover, the mode of formation of the latter shows that the methyl-group in it takes the place of the hydrogen in the NH-group, whereas in homopyrroline the CH^3 -group is not united directly to the nitrogen, but takes the place of one of the hydrogen-atoms in the C^4H^4 -group, inasmuch as it is converted into an acetyl-derivative, $C^4H^3(CH^3)N-C^2H^3O$, by prolonged contact with acetic anhydride in presence of sodium acetate.

The oil boiling at 165° has the composition C^6H^8N , and may be provisionally formulated as dimethyl-pyrroline, $C^4H^2(CH^3)^2N$. It has an unpleasant biting odour, without the sweetish after-scent of homopyrroline. It unites with mercuric chloride, forming a white insoluble compound. It is very slowly attacked by acids, forming soft red masses not obtainable in definite form. It forms an acetyl-derivative, and therefore has both the methyl-groups included in the C^4H^4 nucleus, the formula of that derivative being $C^4H^3(CH^3)^2N(C^2H^3O)$. Acetyl-dimethylpyrroline is a thickish, and at first colourless liquid, which is not quite insoluble in water, and does not solidify at -20° . It has a mild odour like that of bitter almond oil, becomes dark-coloured on standing, and after a certain time solidifies. By boiling with potash it is resolved into its constituents.

A small fraction was obtained boiling above 165° , and probably containing still higher homologues of pyrroline.

Anderson described under the name 'Pyrrol-red' a substance having the composition $C^{12}H^{14}N^2O$, and formed according to the equation $3C^4H^5N + H^2O = C^{12}H^{14}N^2O + NH^3$. Wiedel a. Ciamician have tested this equation, and found it correct so far as regards the quantity of ammonia evolved; but they have not been able to obtain the pyrrol-red of constant composition, as it continually absorbs oxygen during washing and drying, changing colour at the same time.

The following table shows the distinguishing characteristics of pyrroline, and of homopyrroline, methyl-pyrroline, ethyl-pyrroline, and dimethylpyrroline.

Characters of Pyrroline and its Homologues.

	Pyrroline, C^4H^5N	Homo- pyrroline, $C^4H^5(CH^3)NH$	Methyl- pyrroline, $C^4H^5N(CH^3)$	Dimethyl- pyrroline, $C^4H^5(CH^3)_2NH$	Ethyl- pyrroline, $C^4H^5N(C^2H^5)$
Boilingpoint	126·2°.	145·5°.	112°–113°.	165°.	131°.
Action of: HCl.	Converted, with great rise of tem- perature, into a brit- tle resin.	Very slowly converted into a soft resin.	Unaltered.	Converted, after pro- longed boil- ing, into a soft resin- ous mass.	Remains unaltered.
HgCl ₂ .	White precipitate.		—	White pre- cipitate.	
KOH.	—	Unaltered.	Resolved into pyrroline and methyl alcohol.	Unaltered.	
(C ² H ⁵ O) ₂ O.	Forms an acetyl-deri- vative melt- ing at 90° (R. Schiff).	Forms an acetyl-deri- vative soli- difying be- low 0° and melting at 4°–6°.	No action.	Forms an acetyl-deri- vative re- maining liquid at –20°.	No action.

Q.

QUARTZ. *Occurrence and Formation.*—Quartz has been found, together with iron-glance, in the clefts of a trachytic lava from Lipari, in small crystals exhibiting all the marks of volcanic sublimation (G. vom Rath, *Pogg. Ann.* cxlvii. 279).

Th. Hübener (*Pogg. Ann.* cl. 643), on treating lignite from Göltz with potassium chlorate and nitric acid, and then with ammonia and alcohol, found in the residue a number of small quartz-crystals (about 3 grams from 1 kilo. of the lignite). He attributes their formation to the action of humic acid produced in the lignite on a solution of silicates which had penetrated into it. Direct experiments made with the view of obtaining quartz by prolonged digestion of humic acid with silicates, yielded, however, merely negative results.

Quartz may be formed from amorphous silica and from tridymite by the agency of sodium tungstate. For this purpose, silica and fused sodium tungstate are alternately heated and cooled between the temperatures 800° and 950°. The silica, when heated, combines with the soda, but on cooling it is precipitated by the tungstic acid, at first as tridymite, but below 850° as quartz. The amorphous silica disappears after several hours of alternate heating and cooling, being replaced by thin plates of tridymite, amongst which are very small crystals of quartz. The number and size of the latter increase considerably if the action of the fused salt be long continued. The crystals have the density and polyhedral forms characteristic of quartz, different forms being obtained according to the method of preparation adopted (Hautefeuille, *Compt. rend.* lxxxvi. 1133, 1194).

Quartz as Pseudomorph after Crocidolite.—The brown fibrous quartz from the Orange River, analysed by Klaproth is a mixture of pure white fibrous quartz with göthite (Fe²O³.H²O), which may be dissolved out by hydrochloric acid. Blue fibrous quartz is essentially a mixture of white fibrous quartz with crocidolite. Both varieties are pseudomorphs after crocidolite, the brown being the product of a slow and complete transformation, the blue of an incomplete and rapid transformation. The amount of alteration in each case is shown by the following analyses :

Transformation of Crocidolite into Quartz.

	Asbestos-like crocidolite from the Cape. Stromeyer	Brown fibrous quartz. F. Wibel	Blue fibrous quartz. F. Wibel
SiO ₂ . . .	50·81	57·46	97·27
FeO . . .	33·88	Fe ₂ O ₃ 37·56	FeO 1·67
MnO . . .	0·17	—	—
MgO . . .	2·32	—	—
CaO . . .	0·02	—	0·15
Na ₂ O . . .	7·03	—	0·15
H ₂ O . . .	5·58	5·15	0·76
	99·81	100·17	100·00

In the formation of the brown fibrous quartz, the decomposition of the crocidolite mass appears to have been accompanied by an almost simultaneous washing out of the soda, magnesia, &c., and by an oxidation and hydration of the ferrous oxide. The 33·88 p. c. FeO of the original crocidolite is exactly equivalent to the 37·56 p. c. Fe₂O₃ of the brown fibrous quartz. This shows that no iron has been carried away by the decomposing liquid, the whole of it having been oxidised *in situ*, and deposited as goëthite, Fe₂O₃·H₂O; and consequently that the circulation of the decomposing liquid and of the products of decomposition must have been very slow. This slow decomposition, indeed, has enabled the delicate fibres of crocidolite, while undergoing so complete a change of composition, to retain their form instead of being converted into a dense structureless mass of quartz. On the other hand, in the more rapid action which has produced the blue fibrous quartz, nearly all the ferrous oxide has been carried away, together with the other monoxides, leaving quartz together with about 2·5 per cent. of unaltered crocidolite.

These conclusions are confirmed by the microscopic examination of thin sections of the two varieties. The brown variety exhibits, both in longitudinal and in transverse sections, a complete and tolerably uniform impregnation with ferric hydrate, each individual fibre appearing more or less brown. In the blue mineral, on the other hand, a longitudinal section exhibits a white homogeneous matrix traversed by blue or sometimes brownish fibres, with sharp edges, running parallel to one another at various distances, and of various diameters; and in accordance with this, the transverse section appears as a snow-white substance dotted with dark points. Under the polarising microscope, the white mass exhibits double refraction, with a brilliant play of colours.

The quartzes which accompany crocidolite in a few other localities (Golling in Salzburg, Rudka in Moravia, &c.) must also be regarded, not as primary quartzes coloured by crocidolite, but likewise as secondary products resulting from an incomplete but very rapid decomposition of that mineral. The same is true with regard to the blue iron ore of Klapproth. Quartz, indeed, in spite of its prismatic habit, appears to be incapable of *originally* assuming the fibrous form of aggregation.

On the crystalline forms of Quartz from various localities, see *Jahrb. f. Min.* 1874, 81, 113, 190; 1875, 415; 1876, 264; *Jahresb. f. Chem.* 1874, 1243; 1875, 1205; 1876, 1226.

On Quartz-diorite from Yosemite, see A. Schmidt (*Jahrb. f. Min.* 1878, 716; *Chem. Soc. J.* 1879, 512). Quartz-hornblende andesite from Wöllan in Styria; R. v. Drasche (*Jahrb. f. Min.* 1873, 768; *Jahresb. f. Chem.* 1873, 1219).

QUASSIA. Goldschmidt a. Weidel (*Wien. Akad. Ber.* lxxiv. 389), by exhausting the bark and wood of *Quassia amara* with water, obtained a yellow resinous body from which they did not succeed in separating the crystalline *quassin* described by Winckler and afterwards by Wiggers (v. 2). The resin darkens in colour on exposure to the air, and splits up into acetic and protocatechuic acids when fused with potash.

QUEBRACHO. The wood of the *Quebracho colorado*, an Anacardiaceae tree growing in the northern part of the Argentine Republic, has a sp. gr. of 1·11 to 1·13. It is very hard, and of a light or dark brownish-red colour, and contains, according to Jean (*Bull. Soc. Chim.* xxviii. 6), 15·7 per cent. of a tannic acid not identical with that of oak-bark or chestnut wood, and 2·8 per cent. of another astringent acid, which behaves with reagents like gallic acid, and is not fixed by animal skins. Arnaudon has found in it a colouring matter which gives a fine yellow dye. The watery decoction of the wood is slightly acid. Quebracho is as suitable as sumach

for the preparation of morocco leather, especially in the production of dark colours (*Dingl. pol. J.* ccxxxi. 451).

On the gum of *Quebracho colorado*, see GUM (p. 916).

QUERCETAGETIN, $C^{27}H^{20}O^{13}$. A yellow colouring matter extracted from the flowers of the common marigold (*Tagetes patula*). Its reactions in alcoholic solution are the same as those of quercetin, but it differs from the latter in crystalline form and solubility in alcohol. The crystals contain 4 mols. water, which they give off at 100° . If quercetin be regarded as $C^{27}H^{20}O^{12}$ (*infra*), quercetagenin will be quercetin + H^2O (Latour a. Magnier de la Source, *Bull. Soc. Chim.* [2], xxviii. 337).

QUERCETIN. See QUERCITRIN.

QUERCITOL, $C^6H^{12}O^5$. *Quercite*.—This saccharine substance, obtained from acorns, was discovered in 1849 by Branconnot, who found that it does not ferment in contact with yeast. Dessaignes, in 1851, determined its composition, and showed that it is isomeric with mannitan and dulcitan, that is to say, that it contains the elements of mannitol, $C^6H^{14}O^8$, minus H^2O . Berthelot in 1855 showed that it is a polyatomic alcohol, and described several of its compound ethers. The results of all these investigations have already been described (v. 6).

A more complete examination of quercitol has lately been made by Prunier (*Ann. Chim. Phys.* 1878, [5], xv. 5–91), who has especially investigated the derivatives obtained from it by the action of the haloïd acids and of acetic and butyric acid.

Prunier prepares quercitol by mixing the cold concentrated infusion of acorns with basic lead acetate, which throws down most of the impurities and colouring matter. The liquid is then fermented with yeast, freed from lead by means of sulphuric or carbonic acid and hydrogen sulphide, and evaporated. The white crystals thus obtained are finally purified by recrystallisation from dilute hydrochloric acid.

Quercitol crystallises in monoclinic prisms exhibiting, according to Sénarmont (*Jahresb. f. Chem.* 1857, 505), the combination $\infty P. \infty P \infty. 0P. + P. P \infty$, having the axial ratio $a : b : c = 0.8001 : 1 : 0.7662$, and the angle $ac = 68^\circ 57'$. Angle $\infty P : \infty P$ in the clinodiagonal principal section = $106^\circ 30'$; $P \infty : P \infty$ in the same = $108^\circ 52'$; $0P : + P \infty = 126^\circ 17'$; $0P : \infty P = 106^\circ 44'$.

Quercitol is optically dextrogyrate; $[\alpha]_D = 24.17^\circ$; has a density of 1.5845 at 13° ; dissolves in about 11 pts. of water at 12° , and in about 9 pts. at 20° ; is insoluble in alcohol, ether, benzene, and chloroform; melts at 225° . When heated at 100° for some days, quercitol gradually loses water and approximates to the composition $4C^6H^{12}O^5 - H^2O$. When heated to 240° in a vacuum it yields about three-fourths of its weight of an anhydride, $C^{12}H^{22}O^9 = 2C^6H^{12}O^5 - H^2O = (C^6H^{10}O^4)(C^6H^{12}O^5)$. This anhydride (which may be regarded as a compound of quercitol and quercitan) melts at 228° – 230° , dissolves much less freely than quercitol in water, and is nearly insoluble in alcohol and ether. Between 250° and 275° quercitol loses more water, and yields a sublimate of white, highly refracting, tabular crystals melting at 101° – 102° , the nature of which has not yet been determined. At 280° – 290° a totally different reaction takes place: the fused mass swells up enormously, giving off hydrogen, and the retort becomes filled with yellowish-green vapours of quinhydrone and quinol (hydroquinone), the latter of which condenses in long yellowish needles melting at 160° . This reaction may perhaps be explained as follows: a molecule of quercitol losing 3 mols. of water is first converted into quinol, $C^6H^{12}O^5 - 3H^2O = C^6H^6O^2$; and the quinol by loss of H^2 gives rise to quinone, which combines with more quinol to form quinhydrone, $C^6H^4O^2.C^6H^6O^2$.

Quercitol, when fused with potash, evolves hydrogen and yields quinol and quinhydrone, together with pyrogallol (or an isomeric substance), and oxalic and malonic acids.

Acetoquercitols.—*Monoacetoquercitol*, $C^6H^{11}(C^2H^3O)O^5$, formed on heating quercitol at 100° with glacial acetic acid in sealed tubes, is a white solid substance, difficult to crystallise. *Triacetoquercitol*, $C^6H^9(C^2H^3O)^3O^5$, is readily formed on heating quercitol at 130° – 140° with excess of glacial acetic acid containing 1 or 2 per cent. of acetic anhydride. It is a colourless amorphous solid, of bitter taste and faint aromatic odour, insoluble in water, soluble in alcohol and ether. *Pentacetoquercitol*, $C^6H^7(C^2H^3O)^5O^5$, is obtained by heating quercitol at 150° for many hours with excess of acetic anhydride. It is a colourless amorphous solid body, of very bitter taste, soluble in alcohol and ether, and very sparingly in water. The acetoquercitols are more volatile than quercitol. When submitted to dry distillation they appear to yield *monoacetoquercitan*.

Butyroquercitols.—*Monobutyroquercitol*, $C^6H^{11}(C^4H^7O)O^5$, formed on heating quercitol at 100° – 115° with butyric acid, is a semi-solid colourless body, of bitter taste, soluble in ether and less freely in alcohol and water. *Tributyroquercitol*,

$C^6H^9(C^4H^7O)^3O^3$, is formed on heating quercitol at 150° – 160° for many hours with excess of butyric acid. It is a syrupy uncrystallisable body, soluble in alcohol and ether. *Pentabutyroquercitol*, $C^6H^7(C^4H^7O)^5O^3$, is produced on heating the preceding compounds at 180° with a large excess of butyric acid. It forms a syrupy liquid of bitter taste, soluble in alcohol and ether, but scarcely so in water.

Quercitolchlorhydrins.—Quercitol treated with dilute hydrochloric acid, even at 100° , is simply dissolved in large quantity; but the concentrated acid attacks it in such a manner as to substitute HCl for the elements of water, whilst the strongest acid (saturated at 0°) exerts at the same time a dehydrating action, resulting in the formation of quercitan and its chlorhydro-derivatives.

Quercitol-monochlorhydrin, $C^6H^{11}ClO^4$, is formed on heating quercitol in the water-bath with excess of hydrochloric acid saturated at 10° . It is a white crystalline substance, soluble in ether and in alcohol, and melting at 198° – 200° . The mother-liquor contains *quercitan-monochlorhydrin*, $C^6H^9ClO^3$, a viscid uncrystallisable body soluble in absolute alcohol. *Quercitol-trichlorhydrin*, $C^6H^7Cl^3O^2$, formed on heating quercitol at 120° – 140° with excess of hydrochloric acid, crystallises in long flattened needles melting at 155° . *Quercitol-pentachlorhydrin*, $C^6H^5Cl^5$, obtained by heating the last compound afresh with hydrochloric acid, crystallises in slender yellow needles, fusible at about 102° . The mother-liquor contains quercitan-chlorhydrin, which is, indeed, the chief product, corresponding in quantity with two-thirds of the quercitol employed:

Quercitan, $C^6H^{10}O^4$, is obtained by saponifying with baryta the chlorhydrin just mentioned, neutralising exactly with sulphuric acid, and evaporating. It is a colourless uncrystallisable and slightly deliquescent substance, soluble in water and in alcohol, insoluble in ether. When dissolved in 85 per cent. spirit it gradually takes up water, becoming converted into quercitol.

Action of Hydrobromic Acid on Quercitol.—Hydrobromic acid (sp. gr. 1.7) appears to act on quercitol at 100° in the same manner as hydrochloric acid, producing a white crystalline substance soluble in water, and having the composition of *quercitol-monobromhydrin*. But at higher temperatures the action is entirely different, the products being aromatic bodies, including benzene, phenol, quinol, quinquhydrone, quinone, and brominated derivatives of these last, which are still under examination.

Action of Hydriodic Acid on Quercitol.—Quercitol when distilled with hydriodic acid saturated at 0° , yields benzene (in quantity corresponding with half the quercitol employed), phenol, iodophenol, quinone, quinol, hydroxyquinones, and volatile iodised products transformable into C^6H^{14} . The cold acid dissolves quercite freely, with slight rise of temperature, but no hydriodide has been isolated.

In accordance with the foregoing results, quercitol may be regarded as belonging either to the fatty or to the aromatic series of compounds. On the one hand, its behaviour with acids shows that it is a polyatomic alcohol capable of yielding a series of ethers of the general formula $C^6H^2(H^2O)^5 + nA - nH^2O$, in which A represents a monobasic acid and $n = 1, 3$, or 5 . Its decomposition by heat and by the action of potash, or of hydrobromic or hydriodic acid, indicates, on the other hand, its derivation from benzene: $C^6H^6 - 2H^2 + 2H^2O = C^6H^6O^2$ (quinol); and $C^6H^6O^2 + 3H^2O = C^6H^{12}O^5$ (quercitol). It is the type of a group of bodies forming a connecting link between the two series.

QUERCITRIN and QUERCETIN (J. Löwe, *Zeitschr. anal. Chem.* 233, 247). Quercitrin is usually regarded as a glucoside, since, according to the statements of various chemists (v. 4, 6), it is resolved, on boiling with dilute acids, into sugar and quercetin. Löwe, however, finds that quercitrin is not a glucoside, inasmuch as it differs from quercetin only by a certain number of molecules of water, and may be, for the most part, converted into the latter substance by simply heating its aqueous solution, in which change no sugar is produced.

To prepare quercitrin, Löwe exhausts with alcohol the quercitron-bark of commerce, evaporates the filtered extract, dissolves the residue in water, and shakes the solution repeatedly with ether. The residue left on evaporating the ethereal liquid is taken up with alcohol, and mixed with a large quantity of hot water, to separate the quercitrin. The product, after recrystallisation from boiling water and prolonged drying over sulphuric acid, forms light yellow shining scales, and gives on analysis numbers agreeing with the formula $C^{15}H^{16}O^9$. The crystals lose water at 120° , melt at 130° – 133° without further loss, and solidify to a brownish-yellow mass on cooling. The fused substance gives on analysis numbers agreeing with the formula $C^{13}H^{14}O^8$. The above formula of quercitrin was confirmed by analyses of two lead-salts, which were found to have the formulæ $C^{13}H^{12}O^7 \cdot 2PbO$ and $C^{15}H^{14}O^8 \cdot PbO$.

Quercetin.—Quercitrin suspended in water and heated at 110° for some days in sealed tubes, is resolved for the most part into a body having the properties of quercetin and giving on analysis numbers agreeing with the formula $C^{15}H^{12}O^7$. Quercetin may therefore be regarded as an anhydride of quercitrin. This result accords with the fact previously known, that quercitrin yields quercetin by dry distillation.

Löwe also finds that when an aqueous solution of catechu is shaken up with ether, the ether takes up quercetin, which may thus be shown to exist in all kinds of catechu, though in many varieties the proportion is so small that it can be detected only when several pounds of material are operated on. The existence of this substance, which in itself is almost insoluble in cold water, in a cold extract, is due, according to Löwe, to the presence of catechutannic acid. From sumach, especially the Sicilian variety, Löwe obtained yellow needles or flocks, moderately soluble in hot water, and exhibiting all the reactions of quercitrin.

QUINCE-MUCILAGE. See PLANT-MUCILAGE (p. 1638).

QUINHYDRONE. See QUINONE (p. 1741).

QUINIC ACID, $C^7H^{12}O^6 = C^6H^7(OH)^4.COOH$. Ethyl quinate, treated with acetic anhydride, is converted into ethylic tetracetylquinate, $C^6H^7(OC^2H^3O)^4.COOC^2H^5$, showing that quinic acid contains four hydroxyl-groups. Ethylic tetracetylquinate is almost insoluble in cold, and only sparingly soluble in boiling water, but dissolves easily in hot alcohol and ether. It crystallises from boiling water in plates (m. p. 135°), and can be sublimed without decomposition. By slow evaporation of the ethereal solution, it can be obtained in large colourless rhombic crystals.

Quinic acid, heated with hydrobromic acid in sealed tubes at 130° , yields benzoic and protocatechuic acids, thus:

together with small quantities of parabromophenol and quinol. These facts show that quinic acid is nearly related to hexhydrobenzene and quercite, thus:—

(Fittig a. Hillebrand, *Liebig's Annalen*, cxci. 194).

According to O. Loew (*J. pr. Chem.* [2], xix. 309), quinic acid is a constituent of hay, and the hippuric acid which is present in the urine of herbivorous animals is perhaps one of its products of decomposition.

QUININE, QUINIDINE, and ALLIED BASES. See CINCCHONA-BASES (pp. 489–495).

Oxidation-products of Quinine.—When a solution of quinine sulphate, which has been acidified with sulphuric acid, is oxidised in the cold by potassium permanganate, it splits up into formic acid and *quitenine* or *chitenine*, $C^{10}H^{22}N^2O^4 + 4H^2O$, according to the equation $C^{20}H^{24}N^2O^2 + 2O^2 = C^{10}H^{22}N^2O^4 + CH^2O^2$. Quitenine, which is identical with Kerner's *α-dihydroxyl-quinine* (*Zeitschr. f. Chem.* 1869, 593), is separated from the precipitated manganese dioxide by repeated lixiviation with boiling alcohol. It crystallises in colourless prisms, which are insoluble in ether and in absolute alcohol, but dissolve freely in acids, and in water to which a few drops of ammonia or potash have been added. Quitenine is a weak base, and forms the following compounds:

Quininic acid, $C^{11}H^9NO^3$, is obtained by oxidising quinine with chromic acid, neutralising the product with baryta-water, and decomposing the barium salt with hydrochloric acid. On evaporating the solution, quininic acid separates in prisms. The mother-liquor is treated with lead carbonate, and the lead salt decomposed by sulphuretted hydrogen. A non-crystalline syrupy liquid is thus obtained, which resembles the crystalline acid in its chemical properties (Skraup, *Ber.* xii. 1104).

Periodides of Quinine and Allied Bases. The *sulphato-periodides* of these bases have already been described (pp. 479, 486, 489–491, 493). The following acid periodides have also been described by Jörgensen (*J. pr. Chem.* [2], xv. 65, 418).

Selenato-periodides.—These salts are formed by treating the selenates of alkaloids with a mixture of alcoholic iodine-solution and hydriodic acid. *Selenic Herapathite*, $4C^{20}H^{21}N^2O^2.3H^2SeO^4$, obtained by mixing the calculated quantities of its constituents in hot alcoholic solution, is isomorphous with ordinary herapathite and closely resembles it, but is less soluble; it does not dissolve in carbon sulphide, ether,

or chloroform. The alcoholic solution when shaken up with mercury yields not a trace of mercurous iodide, but a colourless iodine double salt, strongly resembling the corresponding sulphur-compound. Treated in alcoholic solution with tincture of iodine, it yields bronze-yellow needles, probably analogous to the third quinine sulphato-periodide (p. 490), and on dissolving these crystals in hot alcohol, an olive-grey compound separates, resembling the second sulphato-periodide of quinine.

Selenato-periodides of Quinidine.—(1). $2C^{20}H^{24}N^2O^2.H^2SeO^4.2HI.I^4$, prepared with deficient iodine, but with calculated quantities of the other constituents, crystallises in red-brown orthorhombic prisms, resembling the corresponding sulphur-compound. Optical action * || comparatively light; + comparatively dark brown. When shaken in alcoholic solution with mercury, it yields an iodine double salt which does not melt when heated with an insufficient quantity of iodine, like that formed from the sulphate.

(2). $4C^{20}H^{24}N^2O^2.4H^2SeO^4.3HI.I^6$, is prepared like the second sulphato-periodide of quinine (p. 490), which it very much resembles, excepting that it is somewhat darker. Polarisation strong; || opaque; + olive-yellow. Shaken with mercury, it forms an iodine double salt, which melts when heated, and resolidifies amorphous. The formula of this selenato-periodide is probably: †

a view which is supported by the fact that its alcoholic solution, when agitated, yields crystals of the compound:

Selenato-periodide of Cinchonine, $2C^{20}H^{24}N^2O^2.H^2SeO^4.2HI.I^6$, is prepared like the third sulphato-periodide (p. 479), which it closely resembles.

Selenato-periodides of Cinchonidine: (1). $C^{20}H^{24}N^2O^2.9H^2SeO^4.8HI.I^{24} + 8H^2O$, is prepared like the sulphur-compound (p. 486), which it closely resembles; it must be washed with strong alcohol. Optical character: || opaque; + very faint olive-green.

(2). $2C^{20}H^{24}N^2O^2.H^2SeO^4.HI.I^4 + H^2O$, formed, with separation of H^2SeO^4 and HI , by the action of dilute alcohol on the last compound. When recrystallised from dilute alcohol, it forms red-brown needles resembling the fourth sulphato-periodide (p. 486).

Phosphato-periodide of Cinchonidine, $2C^{20}H^{24}N^2O^2.2PH^3O^4.HI.I^4$, separates from an alcoholic solution of calculated quantities of its constituents, in long dark-brown shining needles which have a bluish reflex and polarise slightly: || lighter, + darker brown. It contains unaltered cinchonidine. The hot alcoholic solution, shaken up with mercury, yields mercurous iodide and a double salt. There is also at least one more phosphato-periodide of cinchonidine, obtained under circumstances not definitely known, in dark brown laminæ with violet reflex, probably having the composition $4C^{20}H^{24}N^2O^2.3PH^3O^4.4HI.I^2$.

Arsenato-periodide of Cinchonine, $2C^{20}H^{24}N^2O^2.2AsH^3O^4.HI.I^4$, exactly resembles the corresponding phosphate.

Oxalato-periodide of Cinchinine, $4C^{20}H^{24}N^2O^2.2C^2H^2O^4.4HI.I^6$, is formed when 1 mol. cinchonine, dissolved in 20 c.c. normal oxalic acid and alcohol, is mixed with 1 mol. HI and 3 at. I , and separates in the purest state from dilute solutions; it forms black, shining, apparently orthorhombic prisms, mostly quite opaque. When shaken up with mercury, it yields indistinct yellow granules of a double salt, together with mercurous iodide.

Oxalato-periodide of Cinchonidine, $2C^{20}H^{24}N^2O^2.C^2H^2O^4.2HI.I^4$, separates from the hot alcoholic solution of calculated quantities of its constituents in thin red-brown needles. Polarisation || yellow; + brown to opaque. Rational formula:

When agitated with mercury, it yields no mercurous iodide, but only a double salt in slender pale yellow needles.

Oxalato-periodides of Methylquinine.—Several of these salts appear to be producible, but they are all very much alike in physical properties and solubility; two which crystallise in black prisms appear to be represented by the formulæ $2C^{20}H^{24}N^2O^2.CH^3I.2C^2H^2O^4.I^5$ and $2C^{20}H^{24}N^2O^2.CH^3I.2C^2H^2O^4.I^6$.

* || with parallel Nicols; + with crossed Nicols.

† $M = C^{20}H^{24}N^2O^2.H.SeO^4$; $Qu = C^{20}H^{24}N^2O^2$.

‡ $Cl = C^{20}H^{24}N^2O^2$.

Tartrato-periodide of Cinchonidine, $2C^{20}H^{24}N^2O^6, C^4H^6O^6, HI, I^2$, is formed when 1 mol. cinchonidine is dissolved with at least 2 mol. tartaric acid, and 1 mol. HI in 100 c.c. strong alcohol, and the solution is mixed with 1 at. iodine. It forms long thin red-brown prisms which, when shaken with mercury, yield no mercurous iodide, but an oily, yellow, gummy double salt.

Hydrochloro periodides of Quinine: (1). $3C^{20}H^{24}N^2O^6, 8HCl, 4HI, I^2$, crystallises in blackish-green flat needles when pure quinine (1 mol.) is heated with a large excess of dilute hydrochloric acid and alcohol, and an alcoholic solution of 2 mols. iodine is then added. The crystals polarise strongly: || brown to brownish-yellow; + opaque. By agitating it with mercury, a large quantity of mercurous iodide is formed, together with an amorphous double salt. (2). $4C^{20}H^{24}N^2O^6, 3HCl, 5HI, I^4$, is formed in light brown crystals when 1 mol. quinine is brought in contact with 3 mols. hydrochloric acid, and 3 mols. potassium iodide in solution; it must be quickly filtered off and dried. The polarising power of this salt is very feeble. When dry, it requires a temperature above 100° to melt it, but under boiling water it melts easily with separation of iodine.

Hydrochloro-periodide of Cinchonine, obtained like the quinine-compound, crystallises in long brown shining prisms, and when shaken with mercury, yields no iodide, but only a pale-yellow, oily, mercury double salt.

Jørgensen considers that the iodine in all these compounds is present in two different forms, viz., as hydrogen iodide, and in a looser form of combination, in which it may be called 'molecular iodine,' since it exhibits many of the properties of free iodine, acting, for example, on polarised light like the tourmaline, a property which Jørgensen has shown to be possessed by crystallised iodine.

QUINIRETIN. This name is given by Flückiger (*Pharm. J. Trans.* [3], viii. 885) to a substance, probably isomeric with quinine, which is produced by the action of light on quinine in solution. A clear solution of 1 pt. quinine in 2000 pts. water, exposed to summer sunshine, assumed a yellowish or brownish coloration, and after a few days deposited a flocculent brown precipitate, only a very small trace of alkaloid being left in solution. This change takes place when quinine dissolved in water previously freed from air by boiling is exposed to sunlight, also on exposing a solution of quinine to the direct rays of the sun in an atmosphere of hydrogen. Quiniretin has no alkaline reaction, neither does it neutralise acids, in which, however, it is freely soluble; it has a very bitter taste, and is insoluble in alcohol, ether, and water. The hydrochloric acid solution is precipitated by ammonia, but not by tannin. Nessler's solution produces a precipitate. It is dissolved by chlorine-water, the solution yielding a green precipitate when treated with ammonia. Quinine in the dry state is not so readily transformed as when it is dissolved in water or alcohol. The other cinchona alkaloids, being more sparingly soluble in water, are not so easily changed. Solutions of quinic acid, concentrated or dilute, are scarcely affected by exposure. Aqueous solutions of morphine or strychnine are only slightly coloured, whilst codeine or brucine are coloured very strongly. The solubility of the alkaloid seems to play a prominent part in the transformation, but the subject requires further investigation.

QUINIZARIN, $C^{14}H^8O^4 = C^6H^4 \begin{smallmatrix} CO \\ CO \end{smallmatrix} C^6H^2(OH)^2$ (Liebermann a. Giescl, *Ber.*

x. 606). This isomeric of alizarin, which Grimm obtained by heating quinol with sulphuric acid and phthalic anhydride (p. 102), is likewise produced when a mixture of phthalic anhydride and parachlorophenol, in equal numbers of molecules, is heated for some hours at 110° with a quantity of sulphuric acid equal to ten times the weight of the chlorophenol. In this way 8 to 10 per cent. of the chlorophenol is converted into quinizarin. A certain quantity of purpurin is formed at the same time, but can be easily separated, as quinizarin is almost insoluble in a cold solution of sodium carbonate.

Reduction-products.—Quinizarin, boiled with dilute hydriodic acid and phosphorus, or heated with hydrochloric acid and stannous chloride, is reduced to hydroquinizarin, $C^{14}H^{10}O^4$, which crystallises from alcohol in yellow needles. It forms an insoluble yellow barium salt, and its alkaline, yellow, fluorescent solution readily absorbs oxygen, and is reconverted into quinizarin. Sometimes if the reaction is carried on longer it goes further, producing quinizarol, $C^{14}H^{12}O^2$, which resembles hydroquinizarin.

When quinizarin is boiled for an hour with hydriodic acid of sp. gr. 1.8, and an excess of phosphorus, it yields hydroanthracene-quinol, $C^{14}H^{12}O^2$, which is readily soluble in alcohol, ether, and acetic acid, and crystallises in yellowish-white rhombic plates melting at 99° ; its solutions show a strong greenish-yellow fluorescence; it volatilises with steam; the alcoholic solution is coloured green by ferric chloride. It forms a crystalline potassium salt, $C^{14}H^{11}O^2K$, and insoluble yellow lead and copper

salts, which are obtained by precipitating the alcoholic solution containing a little ammonia with the corresponding acetates, the lead compound, $(C^{14}H^{10}O^2)_2Pb$, forming microscopic needles. On heating the quinol with a mixture of acetyl chloride and acetic anhydride, the compound $C^{14}H^{10}O^2.C^2H^3O$ is obtained, forming pale yellow warty crystals, which melt at $136^\circ-138^\circ$.

An ammonia-compound could not be obtained, but ethylamine acts readily on the quinol, yielding the compound $C^{14}H^{10} \begin{smallmatrix} OH \\ \diagup \\ NH(C^2H^5) \end{smallmatrix}$, which crystallises in lemon-yellow silky needles, melting at 162° and decomposed by boiling alkalis. When the quinol is boiled with acetic acid, manganese dioxide, and sulphuric acid, it is oxidised to $C^{14}H^8O^2$, which crystallises in orange-coloured needles melting at 191° .

The constitution of the preceding compounds is expressed by the formulæ:

QUINOL, $C^6H^8O^2 = C^6(OH).H.H.OH.H.H$. *Paradihydroxybenzene* (hitherto called *Hydroquinone*: see NOMENCLATURE, p. 1420).

Formation and Preparation.—1. Together with phenoquinone (vii. 1036) by adding quinone to a solution of phenol, the phenoquinone dissolving while the quinol separates out:

(Wichelhaus, *Ber.* v. 248).

2. By boiling an aqueous solution of diazophenol sulphate with 10–15 per cent. strong sulphuric acid:

The quinol may be extracted from the product by ether after cooling. The yield amounts to 46.2 per cent. If no sulphuric acid is added, resinsation takes place on boiling. Strong hydrochloric acid may also be added instead of sulphuric acid, in which case from 30 to 36 per cent. quinol is obtained, together with resin (Weselsky a. Schuler, *Ber.* ix. 1159).

3. By the action of hydroxylamine hydrochloride on a dilute aqueous solution of nitrosophenol. No action takes place in the cold, but on gently heating the liquid, torrents of nitrogen are given off, and the solution is found to contain quinol. Probably diazophenol is first formed, according to the equation:

and then converted into quinol in the manner above explained (E. Hepp, *Ber.* x. 1654).

4. By reducing the methylic ether of paranitrophenol with tin and hydrochloric acid, converting the resulting paranitranisidine by the action of nitrous acid into paradiazo-anisole, and decomposing the sulphate of this base with water. The salts of paradiazo-anisole are but slowly decomposed by boiling with water or dilute acids, and it is therefore better to heat the solution for some hours in a sealed tube at about 140° . The greater part of the diazo-compound is thereby converted into a brown viscid substance, probably consisting for the most part of methyl-quinol, while a small portion is converted into quinol, which may be extracted from the watery liquid in the tube by agitation with ether (H. Salkowski, *Ber.* vii. 1008).

5. From bromosalicylic acid, $C^6.OH.CO^2H.H.Br.H.H$. (which, when heated, yields [1 : 4] bromophenol), by fusion with sodium hydroxide, whereby it is converted into the corresponding hydroxysalicylic acid, $[OH : CO^2H : OH = 1 : 2 : 4]$, m. p. $196^\circ-197^\circ$, and heating this latter in a sulphuric acid bath at 215° , whereupon pure quinol sublimes; if the acid be distilled from a retort over an open flame, catechol (pyrocatechin) will pass over, though in subordinate quantity, together with the quinol (Rakowski a. Leppert, *Ber.* viii. 788).

6. Together with quinone and other products by heating quercitol above 280° (p. 1740).

7. By passing a current of air for three or four hours through an alkaline solution of ethyl succinosuccinate (see SUCCINIC ETHERS), mixing the resulting brown liquid with excess of acetic acid, filtering, and treating the filtrate with sulphuric acid, which throws down a yellow crystalline body, containing, together with other products,

quinol-dicarboxylic acid, $C^6H^4O^2(COOH)^2$, which, when heated with potassium hydroxide, yields quinol (F. Herrmann, *Ber.* x. 107).

8. Quinol may be prepared from aniline by the following process. 1 pt. of aniline is dissolved in 8 pts. of sulphuric acid diluted with twice its bulk of water, and to this solution, after cooling, a saturated solution of $2\frac{1}{2}$ pts. of potassium bichromate is added gradually, too great a rise of temperature being avoided. The thick pulpy mass of aniline-black produced at first changes after a time to a dirty-brown solution, which is then to be treated with sulphur dioxide in excess, and afterwards agitated with ether. The ethereal liquid, when distilled, leaves a brownish crystalline residue of crude quinol, amounting to 16 per cent. of the aniline employed.

Toluquinol may be prepared in the same manner from orthotoluidine (Nietzki *Ber.* x. 1934).

Crystalline Form.—According to O. Lehmann (*Zeitschr. f. Kryst.* i. 44), quinol is dimorphous, one of its modifications being the ordinary stable form which the compound assumes when crystallised from water, the other the unstable form produced on sublimation. This latter takes the form of laminar monoclinic crystals, in which $a : b : c = 2.605 : 1 : 1.558$ and $ac = 73^\circ$. The measurements (only approximate) give the faces OP , ∞P , ∞ , $+P$, and the angle $+P : -P = 112^\circ 4'$. The plane of the optic axes is the plane of symmetry. On a plate inclined to the median line, the angle of the optic axes in oil is 92° . The stable modification is hexagonal (rhombohedral-hemihedral). Axes $a : c = 1 : 0.6591$. The crystals are elongated prisms of the second order, with the face $\infty P2$, at the end of which there occurs only $+R$ or $-R$, as well as $-R$. The observed angles are $-R : -R = 62^\circ 57'$; $+R : +R = 58^\circ 22'$. Double refraction slightly positive. The crystals of the unstable modification appear to change into the stable modification when left to cool slowly after their formation.

Melting Point.—Hasiwetz a. Habermann (*Ber.* viii. 684) find, in opposition to all previous statements, that the true melting point of quinol is 169° —a result which establishes its identity with pyrogentic acid, the product obtained by the action of heat on gentisic acid (p. 860).

Reaction with Nitrous acid.—When nitrous gas is passed into a solution of quinol (in ether?), cooled with ice as long as it continues to be absorbed, small golden-yellow needles separate, probably consisting of dinitrodihydroxyquinone, $C^6(NO^2)O^2(OH)^2$, the quantity increasing on addition of water, and red fumes being at the same time evolved (Nietzki, *Ber.* x. 2147).

Derivatives of Methyl- and Ethyl-quinols. *Dichlorodimethylquinol*, $C^6H^2Cl^2(OCH^3)^2$, separates in colourless needle-shaped crystals when chlorine-gas is passed into a solution of dimethyl-quinol in glacial acetic acid. It melts at 126° , dissolves in ether, alcohol, and hot glacial acetic acid, but is insoluble in water. *Tetrachlorodimethylquinol*, $C^6Cl^4(OCH^3)^2$, is formed on saturating the mother-liquor of the dichloro-compound with chlorine, and separates in yellowish-white needles which melt at 153° – 154° , but begin to sublime at a lower temperature. It dissolves easily in alcohol and ether. The filtrate from the tetrachloroquinol contains tetrachloroquinone and another chloro-compound, which is very soluble in alcohol, and sublimates in violet crystals melting at 79° (Habermann, *Ber.* xi. 1034).

Dibromodimethylquinol, prepared by slowly adding bromine to a solution of dimethylquinol in hot glacial acetic acid, forms colourless crystals, which melt at 142° , and sublime without decomposition. It is soluble in boiling glacial acetic acid, and insoluble in water (Habermann).

Nitrodimethylquinol, $C^6H^4(NO^2)(OCH^3)^2$, separates in golden-yellow crystals, when strong nitric acid is added to an emulsion of dimethylquinol and warm water; it melts at 70° – 71° , sublimates at higher temperatures, and dissolves in alcohol.

Dinitrodimethylquinol is obtained by mixing a solution of dimethylquinol in glacial acetic acid with an equal volume of strong nitric acid, leaving the mixture at rest for a quarter of an hour, and then adding water, which precipitates the nitro-compound in the form of a yellow crystalline powder. It is soluble in alcohol and glacial acetic acid, but insoluble in water; melts at 169° – 170° , and sublimates readily.

Trinitrodimethylquinol is formed on adding a solution of dimethylquinol or of dinitrodimethylquinol in glacial acetic acid, to a well-cooled mixture of sulphuric and fuming nitric acids. On dilution with water, a yellow precipitate is produced, which dissolves in hot alcohol, and is deposited from the alcoholic solution in yellow brittle prisms (Habermann).

Nitrodietethylquinols (Nietzki, *Ber.* xi. 1448; xii. 38).—The *mononitro-compound*, $C^6H^2(NO^2)(OC^2H^5)^2$, prepared by mixing a solution of diethylquinol in 5 pts. glacial acetic acid with an equal volume of nitric acid sp. gr. 1.25, crystallises from

an alcoholic solution in golden-yellow needles melting at 49° . By the further action of nitric acid, it is converted into two *dinitro-derivatives*, $\text{C}^6\text{H}^2(\text{NO}^2)^2(\text{OC}^2\text{H}^3)^2$, one melting at 176° , the other melting at 180° , and dissolving freely in alcohol (Nietzki, *Ber.* xii. 38). The first of these compounds is also formed, together with a trinitro-derivative, by adding a solution of diethylquinol in acetic acid to fuming nitric acid, and without admixture of the trinitro-compound, by treating diethylquinol with weaker nitric acid. As thus obtained, it forms lemon-yellow laminæ, insoluble in water, easily soluble in alcohol, melting at 172° .

Trinitrodiethylquinol, $\text{C}^6\text{H}(\text{NO}^2)^3(\text{OC}^2\text{H}^3)^2$, obtained by the action of a mixture of nitric and sulphuric acids on diethylquinol, crystallises from alcohol in long pale straw-yellow needles melting at 133° , and turning orange-yellow when exposed to light. Heated in sealed tubes with alcoholic ammonia, it is converted into a red compound, $\text{C}^6\text{H}^9\text{N}^4\text{O}^4$, or probably $\text{C}^6\text{H}(\text{NO}^2)^2(\text{NH}^2)^2(\text{OC}^2\text{H}^3)^2$, formed by replacement of the ethoxyl-group by NH^2 , and of the nitro-group by another NH^2 -group. This compound is neither acid nor basic; but when boiled with potash it gives off ammonia, and is converted into a bibasic acid, $\text{C}^6\text{H}^8\text{N}^2\text{O}^7$, or $\text{C}^6\text{H}(\text{NO}^2)^2(\text{OH})^2(\text{OC}^2\text{H}^3)^2$, which crystallises from alcohol in golden-yellow needles having a violet reflex, melts with decomposition at 143° , dissolves sparingly in water, easily in alcohol, ammonia, and alkalis. Its alkali-salts are easily soluble; the barium salt forms sparingly soluble orange-coloured needles.

Diamidodiethylquinol, obtained by the action of tin and hydrochloric acid on the dinitro compound, is converted by nitrous acid into a body having the composition $\text{C}^6\text{H}^3\text{N}^3\text{O}^2$; thus: $\text{C}^6\text{H}^{12}(\text{NH}^2)^2\text{O}^2 + \text{NO}^2\text{H} = 2\text{H}^2\text{O} + \text{C}^{10}\text{H}^{13}\text{N}^3\text{O}^2$. This compound crystallises in colourless needles, melts at 233° , dissolves in absolute alcohol and glacial acetic acid; also in caustic alkalis, and is precipitated therefrom by acids (Nietzki).

Azo-diethylquinol, $\text{C}^{10}\text{H}^{26}\text{N}^2\text{O}^4 = (\text{C}^2\text{H}^3\text{O})^2\text{C}^6\text{H}^3\text{—N=N—C}^6\text{H}^3(\text{OC}^2\text{H}^3)^2$, is formed, together with a hydrazo derivative, by treating a solution of mononitrodiethylquinol in alcoholic potash with a small quantity of zinc-dust. The liquid, which at first assumes a deep-red colour, is decolorised by prolonged boiling with zinc-dust, but quickly recovers its red colour on exposure to the air; and on pouring the decolorised solution into water, a crystalline product separates, which appears, on examination with the microscope, to be a mixture of two bodies, viz. colourless needles of the hydrazo- and deep red laminæ of the azo-compound. These two bodies cannot be separated by fractional crystallisation, on account of the ready oxidisability of the hydrazo-compound; but on washing the mixture with water to remove potash, and then warming it with dilute hydrochloric acid, the hydrazo-compound passes completely into solution, while the azo-compound remains behind, and may be purified by recrystallisation from alcohol. It crystallises in red plates, dissolves in ether, benzene, and hot alcohol—also in strong hydrochloric and sulphuric acids, forming violet solutions from which it is precipitated by water. It melts at 128° , and distils at a higher temperature (Nietzki, *Ber.* xii. 38).

Hydrazotetretethylquinol, $\text{C}^{20}\text{H}^{28}\text{N}^2\text{O}^4 = (\text{C}^2\text{H}^3\text{O})^2\text{C}^6\text{H}^3.\text{NH}.\text{NH}.\text{C}^6\text{H}^3(\text{OC}^2\text{H}^3)^2$, as already observed, is extremely oxidisable, and has not been obtained in the pure state; but the base, $\text{NH}^2.\text{C}^6\text{H}^3(\text{C}^2\text{H}^3\text{O})^2.\text{C}^6\text{H}^3(\text{C}^2\text{H}^3\text{O})^2.\text{NH}^2$, related to it in the same manner as bezazidine to hydrazobenzene, is obtained as hydrochloride by concentrating the acid solution filtered from the azo-compound above mentioned. The hydrochloride, $\text{C}^{20}\text{H}^{28}\text{N}^2\text{O}^4.2\text{HCl}$, then crystallises, especially in presence of an excess of hydrochloric acid, in long slender needles. This salt is but slightly soluble in water, even when hot, and nearly insoluble in moderately strong hydrochloric acid, and on adding hydrochloric acid to its warm saturated solution, every drop produces a gelatinous precipitate: this reaction affords an easy mode of purifying the salt. The aqueous solution of the hydrochloride forms with *platinic chloride* a yellow crystalline precipitate of the platinum salt, $\text{C}^{20}\text{H}^{28}\text{N}^2\text{O}^4.2\text{HCl}.\text{PtCl}^4$.

The base separated from the hydrochloride by alkalis crystallises from alcohol in delicate colourless laminæ, resembling benzidine, and melting at 129° (corr.) Its aqueous solution, when treated with oxidising agents, becomes dark brown and deposits a brownish iridescent precipitate (Nietzki, *Ber.* xii. 40).

QUINOL-CARBOXYLIC ACID. This name is given to the hydroxysalicylic acid, $\text{C}^6.\text{OH}.\text{CO}^2\text{H}.\text{H}.\text{OH}.\text{H}^2$ (m. p. 196° – 197°), obtained by fusing the bromosalicylic acid of corresponding constitution with potassium or sodium hydroxide (p. 289). The acid of the same composition, obtained in like manner from the corresponding iodosalicylic acid, melts at the same temperature, and likewise yields quinol when heated in a sulphuric acid bath at 215° , but appears to differ somewhat in its relations to solvents from the acid obtained from the bromosalicylic acid. When quinolcarb-

oxylic acid in aqueous solution is treated with weak oxidising agents, a product is formed, from which ether extracts a crystallisable acid [quinone-carboxylic acid?], which is instantly decolorised by reducing agents. The acid named by Hesse *carbohydroquinonic acid* (iii. 214), yields, when heated, as observed by Lautemann (iii. 215), not quinol, but catechol (Rakowski a. Leppert, *Ber.* viii. 788, 976).

Quinol-dicarboxylic acid, $C^6H^4O^2(COOH)^2$, is formed, as already stated (p. 1738), by passing a current of air through a solution of ethylic succino-succinate containing an excess of alkali. When precipitated by sulphuric acid and purified by repeated crystallisation from boiling water, it forms tufts of long interlaced needles of light brownish-yellow colour, very soluble in alcohol and ether, sparingly in cold, abundantly in boiling water, the solutions having a light yellow colour, and exhibiting a faint greenish fluorescence; with ferric chloride they yield a pure deep blue colour. The acid is not fusible, and only a very small portion of it sublimes without decomposition. When cautiously fused with potassium hydroxide, it yields quinol (F. Herrmann, *Ber.* x. 107).

QUINOL ETHER. See QUINYL OXIDE.

QUINOL-PHTHALEIN. See PHTHALEINS (p. 1612).

QUINOLSULPHONIC ACID, $C^6H^5SO^3 = C^6H^4 \begin{smallmatrix} OH \\ \diagup \\ O.SO^3H \end{smallmatrix}$. The crystalline form of the potassium salt of this acid, $C^6H^5KSO^3$, has been determined by C. Bodewig (*Zeitschr. f. Kryst.* i. 584). It belongs to the orthorhombic system, $a : b : c = 0.7641 : 1 : 2.0965$. Observed forms $0P, \frac{1}{2}P, P, \infty P$. The crystals are developed tabularly and irregularly in the direction of the basal face. The plane of the optic axes is parallel to ∞P . The axis c is the first median line. Double refraction positive. Apparent angles of the axes in oil:

Li-red 83° 16'	Na-yellow 83° 29'	Tl-green 84° 31'
-------------------	----------------------	---------------------

QUINONE, $C^6H^4O^2 = C^6H^4 \begin{smallmatrix} O \\ \diagup \quad \diagdown \\ \quad \quad O \end{smallmatrix}$ [1 : 4]. This compound is formed by the oxidis-

ing action of manganese dioxide and sulphuric acid on paraphenolsulphonic acid [the meta-acid yields none], and on sulphanilic (*p*-amidobenzenesulphonic) acid (Schröder, *Ber.* viii. 759). According to Prunier (*Bull. Soc. Chim.* [2], xxv. 515; xxviii. 180), quinone occurs, together with quinol, amongst the products of decomposition of quercitol by heat (above 280°) and by hydriodic acid.

Preparation from Aniline.—Powdered potassium dichromate is added to a cold mixture of 1 pt. aniline, 8 of sulphuric acid, and 30 of water, until the precipitate of aniline black which is first formed redissolves, giving a brown solution. About $2\frac{1}{2}$ pts. of potassium dichromate are required for this purpose. If the process is now interrupted by the addition of a sulphite, quinol is obtained, but in order to prepare the quinone, it is necessary, after adding potassium dichromate (1 pt.), again to leave the mixture at rest for some hours, and then heat it to 35°. The quinone is extracted by agitation with ether, as by this means 68 per cent. of the theoretical yield of quinone is obtained, whilst the amount is comparatively small if the quinone is distilled off in the current of steam. Quinone separates from the ethereal solution in golden scales, which generally contain traces of quinhidrone. The mother-liquor from the quinone may be worked up for quinol (Nietzki, *Ber.* xi. 1102).

Detection.—A very delicate test for quinone in aqueous solution is afforded by an alcoholic solution of *hydrocærulignone*. On addition of a drop or two of this liquid, the quinone solution assumes at first a yellowish-red colour, but quickly becomes colourless again, and deposits steel-blue iridescent needles of *cærulignone* (p. 548). This reaction will detect 1 pt. of quinone in 200,000 pts. of water, and the orange coloration is still perceptible with 1 pt. quinone in 1,000,000 pts. of water. With *thymoquinone*, the reaction is either not produced at all or is very indistinct. On the other hand, *hydrocærulignone* may be used as a test for many other oxidising agents.

Tetrabromoquinone, $C^6Br^4O^2$, is formed by the action of bromine in excess on quinone dissolved in hot glacial acetic acid (Saraw, *Ber.* xii. 680).

Trichloroquinone is converted by aniline into *dianilidomonochloroquinone*, $C^6H^3N^2ClO^2$, which crystallises in plates having a metallic lustre (Neuhöffer a. Schultz, *Ber.* x. 1792).

Chlorimidoquinone, $C^6H^4ClNO = C^6H^3Cl \begin{smallmatrix} O \\ \diagup \quad \diagdown \\ NH \end{smallmatrix}$ [O : Cl : NH = 1 : 2 : 4]

(R. Schmitt a. Benewitz, *J. pr. Chem.* [2], viii. 1; R. Schmitt, *ibid.* xix. 312). This

compound, originally regarded as dichlorazophenol, is formed by the action of aqueous chloride of lime on paramidophenol hydrochloride, according to the equation:

and in like manner from paramidophenetol, ethyl chloride being then given off as well as hydrogen chloride:

It is best prepared by dissolving 3 g. paramidophenol hydrochloride in 150 g. water, and dropping in from a burette, with agitation, a strong solution of bleaching powder. A point is then soon reached at which the chlorimidoquinone, which separates in white flocks, no longer redissolves, but increases on further addition of the chlorine-solution, the colour of the liquid at the same time becoming fainter and fainter, till at the moment of completion of the reaction, it suddenly changes from violet to yellow; the addition of the chlorine-solution must then be discontinued. The chlorimidoquinone is easily separated from the liquid by filtration, and may be freed from calcium chloride by washing with a little water, and dried over sulphuric acid, which process, however, is attended with some loss, on account of the volatility of the compound. It may also be purified, though likewise with some loss from decomposition, by distillation with steam.

Chlorimidoquinone is sparingly soluble in cold, easily in hot water, also in alcohol, benzene, ether, and glacial acetic acid, and crystallises from the last-mentioned solvent in tufts of yellow needles often several millimeters long. It melts at 86° , and decomposes with slight detonation when heated a few degrees higher. It smells very much like quinone, and further resembles the latter by the deep brown colour which it imparts to the hands and to organic substances in general. It is readily decomposed by potash-ley and strong sulphuric acid, with formation of brown humus-like substances. By tin and hydrochloric acid it is decolorised, and reconverted into paramidophenol. By sulphurous acid or sodium-hydrogen sulphite it is converted into orthoamidophenolsulphonic acid:

Nitroquinone, $\text{C}^6\text{H}^4(\text{NO}^2)\text{O}^2$, is prepared by dropping chromyl chloride into nitrobenzene at 150° – 160° as long as hydrogen chloride is thereby evolved; then adding water; boiling the aqueous solution with a slight excess of alkali; filtering from chromic oxide; concentrating; adding a small quantity of sulphuric acid; and crystallising the resulting precipitate from boiling water. Nitroquinone is thus obtained in shining scales melting at 232° , subliming at a somewhat higher temperature, and dissolving without alteration in alkalis (Etard, *Compt. rend.* lxxiv. 391).

Dinitro-dihydroxyquinone, or *Nitranilic acid*, $\text{C}^6\text{H}^2\text{N}^2\text{O}^8 = \text{C}^6(\text{NO}^2)^2(\text{OH})^2\text{O}^2$, and *Tetranitroquinone*, or *Nitranilic acid*, $\text{C}^6(\text{NO}^2)^4\text{O}^2$ (Nietzki, *Ber.* x. 2147).—When nitrous acid is passed into a well-cooled solution of quinol, a crystalline mass of quinhedrone is formed at first by oxidation of the quinol. Subsequently, however, this body disappears, and small golden-yellow needles separate, easily soluble in ether, but insoluble in water. These needles are converted by potash into sulphur-yellow potassium-nitranilate, $\text{C}^6(\text{NO}^2)^2(\text{OK})^2\text{O}^2$.

The yellow crystals soluble in ether probably consist of tetranitroquinone or nitranilic acid, as they are readily decomposed in ethereal solution by addition of water, with evolution of red fumes, and formation of nitranilic acid.

Nitranilic acid crystallises in golden-yellow prisms exhibiting a bluish dichroism; it melts in its water of crystallisation at a little above 100° , and when anhydrous, decomposes without melting at 170° . It has a strong, sour, astringent, ferruginous taste, and forms well crystallised salts with most of the metals, giving crystalline precipitates with barium chloride, calcium chloride, and silver nitrate.

In addition to nitranilic acid, other nitro-compounds seem to be formed in the reaction above described, together with a considerable quantity of oxalic acid.

Quinhedrone. This body was originally regarded by Wöhler and by Laurent as a compound of 1 mol. quinol and 1 mol. quinone: $\text{C}^6\text{H}^4\text{O}^2 + \text{C}^6\text{H}^4\text{O}^2 = \text{C}^{12}\text{H}^{10}\text{O}^4$. Wichelhaus, on the other hand, regards it as a compound of 2 mols. quinone and 1 mol. quinol: $\text{C}^6\text{H}^4\text{O}^2 + 2\text{C}^6\text{H}^4\text{O}^2 = \text{C}^{18}\text{H}^{14}\text{O}^8$ (vii. 1037). Liebermann, however, has shown (*Ber.* x. 1614, 2000) that quinone and quinol, when brought together in equal numbers of molecules, combine *without residue*, and produce quinhedrone, whereas when 2 mols. quinol and 1 mol. quinone are mixed, half the quinone remains uncombined, and quinhedrone is formed in quantity corresponding with the quinol. These results are in complete accordance with the older formula of quinhedrone, viz.

$C^{12}H^{10}O^4$; and this formula is further corroborated by the experiments of Nietzki (*Ber.* x. 2003), who has tested it by reducing quinhedrone with sulphurous acid, and titrating the excess of the latter with iodine solution. Wichelhaus, however (*ibid.* 1781), still endeavours to defend his own formula.

QUINYL OXIDE, $C^{12}H^{10}O^3 = (C^6H^4OH)^2O$. *Quinolic Ether*.—This compound is formed by the action of chromyl chloride on phenol, and decomposition of the product with an aqueous alkali. Chromyl chloride acts on phenol with great violence, but the action may be moderated by dissolving the two substances (1 pt. C^6H^4O : 5 pts. CrO^2Cl^2) in carbon sulphide. When the action is finished, water is added, and the aqueous solution is boiled with a slight excess of alkali, then filtered, concentrated, and mixed with a small quantity of sulphuric acid. Quinyl oxide is a white amorphous powder, which softens at 100° , and is converted by chromic acid mixture into quinone (Etard, *Compt. rend.* lxxxiv. 391).

R.

RADICLES. A. Cayley has estimated the number of possible isomeric alcohol-radicles of the fatty series as far as C^{13} , and finds 1 Methyl, 1 Ethyl, 2 Propyls, 4 Butyls, 8 Pentyls, 17 Hexyls, 39 Heptyls, 89 Octyls, 211 Nonyls, 507 Decyls, 1238 Undecyls, 3057 Dodecyls, 7638 Tridecyls (*Phil. Mag.* [4], xlvii. 444; [5], iii. 34).

RAFFINOSE, $C^{18}H^{32}O^{16}, 5H^2O$. A substance found in the molasses of the sugar-beet. It is crystalline, colourless, easily soluble in water, sparingly in alcohol, has a very faint sweet taste, gives off water when heated (D. Loiseau, *Compt. rend.* lxxxii. 4058).

RAIZ DEL INDICO. The root of a plant growing in California, and used there in medicine; it contains chrysophanic acid, aporetin, phæoretin, erythrorutin, calcium malate and oxalate, starch, gum, sugar, tannin, and albumin (F. G. Voelcker, *Pharm. J. Trans.* [3], vi. 781).

RATANHINE, $C^{10}H^{13}NO^3$. This substance, homologous with tyrosine, first obtained by Wittstein from rhatany-root, and described by Kuge (v. 77), has been further examined by Gintl (*Wien. Akad. Ber.* [2], lx. 668). It unites both with bases and with acids. The *potassium* and *sodium salts*, $C^{10}H^{11}K^2NO^3$ and $C^{10}H^{11}Na^2NO^3$, are amorphous deliquescent masses, partly soluble in alcohol, decomposed by carbonic acid. The *barium salt*, $(C^{10}H^{11}NO^3)^2Ba + 2H^2O$, is a gummy mass having a faint yellow colour. The *strontium salt*, $(C^{10}H^{11}NO^3)^2Sr + 2H^2O$, the *calcium salt*, $(C^{10}H^{11}NO^3)^2Ca (+aq?)$, and the *magnesium salt*, $(C^{10}H^{11}NO^3)^2Mg$, are likewise amorphous. No definite compounds were obtained with aluminium, iron, or lead. The *silver salt*, $C^{10}H^{11}Ag^2NO^3$, prepared like silver-tyrosine (v. 933), is a heavy white precipitate, consisting of microscopic spiculæ, slightly soluble in cold water, dissolving with partial decomposition in hot water, easily soluble in ammonia and nitric acid. The ammoniacal solution quickly decomposes, with separation of metallic silver. It remains unaltered at 110° , but burns away at a higher temperature, with a glimmering light, leaving a mixture of silver carbide and spongy charcoal.

Ratanhine is dissolved by organic acids, but soon separates from the solutions. All its compounds with acids are decomposed by alcohol, especially on addition of ether. It dissolves in cold dilute nitric acid, forming the compound $C^{10}H^{13}NO^3.H^+H$; strong nitric acid converts it into a resinous body which detonates when heated in the dry state. The colour-reaction with nitric acid (red, changing to indigo-blue, v. 78) is most strikingly exhibited with red fuming nitric acid. The product is decolorised by hydrogen sulphide in weak alkaline solution, the characteristic red colour being restored on addition of acids. The *hydrochloride*, $C^{10}H^{13}NO^3.HCl$, crystallises in monoclinic prisms, dissolves at a gentle heat in a small quantity of water, but is decomposed by a larger quantity. The *platinochloride*, $(C^{10}H^{13}NO^3.HCl)^2PtCl_4$, is obtained by slow evaporation of a solution of the hydrochloride mixed with excess of platinum chloride, in small reddish-yellow crystals resembling potassium dichromate; it is permanent in the air, and dissolves without decomposition in water and in alcohol, sparingly also in ether. The *sulphate*, $C^{10}H^{13}NO^3.SO^4H^2$, is obtained in colourless rhombic crystals, by dissolving ratanhine in dilute sulphuric acid and evaporating; it may also be prepared by the action of strong sulphuric acid at ordinary temperatures. The *phosphate*, $C^{10}H^{13}NO^3.PO^4H^2$, is obtained in small prisms,

apparently rhombic, by dissolving ratanhine in moderately concentrated phosphoric acid, evaporating the solution to a syrup, and leaving it at rest for a considerable time.

Ratanhine is not decomposed by nascent hydrogen, either in acid or in alkaline solution (Gintl).

B. Kreitmair (*Liebig's Annalen*, clxxvi. 64) has examined numerous samples of rhatany-extract, some occurring in commerce, others prepared by himself, and has found ratanhine in only one, to the amount of 7 per cent.

RAUTE. A zeolite from the island of Lamö, near Brevig in Norway. It is related to thomsonite, and has probably been formed by decomposition of elæolite. It is greyish-black, fine-grained, exhibits no crystalline forms. Hardness 5. Sp. gr. 2.48 at 13°. The mineral encloses small quantities of hornblende, &c. Its analysis gave:

SiO ²	Al ² O ³	Fe ² O ³	CaO	Na ² O	H ² O
39.21	31.79	0.57	5.07	11.55	11.71 = 99.90

numbers which may be represented by the formula (Na²,Ca)O,Al²O³,2SiO²,2H²O, in which Na² : Ca = 2 : 1 (Paykull, *Ber.* vii. 1334).

REICHARDTITE. This name is given by G. Krause (*Arch. Pharm.* [3], vi. 41) to a massive variety of magnesium sulphate, MgSO⁴ + 7H²O, occurring at Stassfurt.

RESINS. The behaviour of the more important resins, gum-resins, and balsams with various reagents, has been examined by E. Hirschsohn (*Russ. Zeitschr. Pharm.* xvi. 1, 33, 65, 97; *Arch. Pharm.* [3], x. 481; xi. 54, 152, 247, 312, 434), with the following results:

Alcohol of 95 per cent. dissolves completely:

Benzoin, Caranna, Resins and Balsams from Conifers, Dragon's-blood, Guajacum, Peruvian guajacum, Mani-resin, Mastic from Alexandria, Mastic from Bombay, Black Peru-balsam, Podocarpus-resin, Sandarac, Tolu-balsam, Xanthorrhæa-resins.

Alcohol of 95 per cent. dissolves incompletely:

Ammoniacum, Asa fœtida, Bdellium, Canada-balsam, Ceradia-resin, Copaiba-balsam, Copal, Dammar, Elemi, Euphorbium, Resin of *Euphorbia Tirocalli*, Euryops-resin, Galbanum, Gamboge, Shellac, Liquidambar-balsam, common Mastic, Mecca-balsam, Myrrh, Olibanum, Opoponax, white Peru-balsam, Sagapenum, Sonora-lac, Liquid Storax.

Ether dissolves completely:

Caranna, Canada-balsam, Conifer-resins and balsams, Copaiba-balsam, Dragon's-blood, Elemi, Guajac-resin, Peruvian guaiac, Mani-resin, Mastic, Podocarpus-resin, Sandarac.

Ether dissolves incompletely:

Ammoniacum, Asa fœtida, Bdellium, Benzoin, Ceradia-resin, Copal, Dammar, Euphorbium, Resin of *Euphorbium Tirocalli*, Euryops-resin, Galbanum, Shellac, Gamboge, Liquidambar-balsam, Mecca-balsam, Myrrh, Olibanum, Opoponax, black Peru-balsam, white Peru-balsam, Sagapenum, Sonora-lac, Liquid Storax, Tolu-balsam, Xanthorrhæa-resins.

Ethereal solution clouded by addition of Alcohol:

Canada-balsam, Brazilian Copal, Copaiba-balsam from Maranham and from Para, Dammar, Resin of *Euphorbium Tirocalli*, Euryops-resin, Liquidambar-balsam, common Mastic, white Peru-balsam, Sonora-lac, Liquid Storax.

Ethereal solution forms a clear mixture with Alcohol:

Ammoniacum, Asa fœtida, Bdellium, Benzoin, Caranna, Ceradia-resin, Conifer-resins and balsams, Copaiba-balsam from Brazil, Copal, Dragon's-blood, Elemi, Euphorbium, Guajacum, Peruvian guajacum, Galbanum, Shellac, Gamboge, Balsam of *Liquidambar styraciflua*, Mani-resin, Mastic from Bombay, Mastic from Alexandria, Mecca-balsam, Myrrh, Opoponax, black Peru-balsam, Podocarpus-resin, Sandarac, Sagapenum, Tolu-balsam, Xanthorrhæa-resins.

Chloroform dissolves completely:

Benzoin, Canada-balsam, Caranna, Ceradia-resin, Conifer resins and balsams, Copaiba-balsam, Brazilian Copal, Dammar, Dragon's-blood (not all varieties), Guajac-resin, Peruvian guajac, Mani-resin, Mastic, Mecca-balsam, black and white Peru-balsam, Tolu-balsam.

Chloroform dissolves imperfectly or not at all:

Ammoniacum, Asa fetida, Bdellium, Copal, Dragon's-blood from *Pterocarpus Draco*, Euphorbium, Resin of *Euphorbia Tiocalli*, Euryops-resin, Galbanum, Shellac, Gamboge, Liquidambar-balsam, Myrrh, Olibanum, Opoponax, Podocarpus-resin, Sagapenum, Sandarac, Sonora-lac, Liquid Storax, Xanthorrhæa-resins.

Lead Acetate gives with the Alcoholic solution a precipitate which does not dissolve or dissolves only partially on boiling:

Ammoniacum, common Asa fetida, Benzoin, Canada-balsam, Caranna, Ceradia-resin, Conifer-resins and balsams, Copal, Dammar (certain East Indian samples), Galbanum, Euphorbium, Resin of *Euphorbia Tiocalli*, Dragon's-blood from *Pterocarpus Draco*, Shellac, Guajacum, Mani-resin, Mastie from Bombay, common Myrrh, black Peru-balsam, Sandarac, Sonora-lac, Liquid Storax, Tolu-balsam, Resin of *Xanthorrhæa arborea*, yellow Xanthorrhæa-resin.

Lead Acetate gives a turbidity which disappears on heating:

African Bdellium, Copaiba-balsam, Dammar (certain East Indian samples), Peruvian Guajacum, Balsam of *Liquidambar styraciflua*, common Mastie, Mastie from Alexandria, Mecca-balsam.

Lead Acetate gives no turbidity:

Asa fetida from *Perula alliacea* Boiss, Indian Bdellium, Caranna (*Aceyta americana*), Dammar, Dragon's-blood (some sorts), Elemi, Gamboge, Liquid-ambar-balsam, Indian Myrrh, Olibanum, Podocarpus-resin, white Peru-balsam, Resin of *Xanthorrhæa quadrangularis*.

Ferric Chloride gives with the Alcoholic solution a turbidity or a precipitate which disappears on heating, and dissolves in ether:

Canada-balsam, Dammar (some East Indian sorts).

Ferric Chloride gives a precipitate which neither disappears on heating nor dissolves in ether:

Copal, Sonora-lac.

Ferric Chloride gives no precipitate, but colours the solution:

(a). *Blue*: Caranna (*Aceyta americana*), Guajacum. (b). *Black, brown-black, or greenish-black*: Gamboge, Xanthorrhæa-resins, Shellac. (c). *Dark green*: Asa fetida (some sorts), Benzoin. (d). *Black*: Peru-balsam, Storax-balsam, Opoponax, Sagapenum.

The other resins are coloured by ferric chloride either greenish, brownish, or not at all.

Aqueous Ammonia forms with the Alcoholic solution a clear mixture:

Caranna, Ceradia-resin, Conifer-resins (some sorts), Copal, Dragon's-blood from *Pterocarpus Draco*, Euryops-resin, Shellac, Guajacum, Gamboge, Podocarpus-resin, Sandarac, Sonora-lac, Xanthorrhæa-resins.

Aqueous Ammonia forms a turbid mixture:

The remaining Resins.

Chloride of Lime Solution gives an orange-yellow colour with: Persian ammoniacum; no colour with any of the other resins.

Alcohol containing Hydrochloric acid is coloured brick-red by: white Peru-balsam, Ceradia-resin; *red to violet by:* Caranna (one sample), common Myrrh, Euryops-resin; *blue to violet by:* Elemi (some sorts); *yellowish-brown to green:* Guajacum-resin; *yellow changing through red-brown to cherry-red:* Benzoin, Tolu-balsam; *crimson:* Resin of *Xanthorrhæa arborea* and *X. quadrangularis*; *greenish changing to dingy violet:* common Asa fetida; *yellow:* Gamboge, Caranna; *light rose-coloured:* Podocarpus-resin; *brown changing into various shades:* the remaining resins.

Concentrated Sulphuric acid dissolves with cherry-red colour: Benzoin from Siam, Tolu-balsam; *yellow:* Gamboge; *with yellowish-brown fluorescence:* common Asa fetida; *brown changing to various shades:* the rest.

The solution in Sulphuric acid gives with Alcohol a clear violet mixture: Benzoin from Siam, benzoin from Sumatra (more red-violet), Euryops-resin, Levant Galbanum, Tolu-balsam; *blue-violet changing to blue:* Levant Sagapenum; *a clear cherry-red mixture:* red Xanthorrhæa-resin; *a clear green mixture:* Guajacum, yellow Xanthorrhæa-resin; *a turbid dingy violet mixture:* Myrrh, black Peru-balsam; *a turbid brown mixture:* the other resins.

Water added to the sulphuric acid solution throws down resin in flocks, and

exhibits a violet colour: Benzoin from Siam; *dingy red-violet*: black Peru-balsam, Galbanum, African Ammoniacum, Sagapenum, Benzoin from Sumatra, Tolu-balsam, red Xanthorrhæa-resin; *yellow*: Gamboge; *blue-green or black-blue*: Guajacum; *brown*: the other resins.

Bromine-solution, added to the chloroform extract, produces either immediately or after some time a *red colour*: Peruvian Guajacum; *cherry-red*: white Peru-balsam; *red-violet*: common Myrrh, Caranna (one sample), resin of *Xanthorrhæa arborea*; *yellowish changing to violet and blue*: Copaiba-balsam from Maranham and Para; *blue*: Guajacum, Caranna, Ceradia-resin, Euryops-resin; *brown*: the rest.

Bromine-solution, added to the chloroform-extract, throws down the resin in flocks: Shellac, Australian Copal.

Sodium Carbonate solution at ordinary temperatures is coloured *violet* by Shellac; *crimson* by Sonora-lac; *yellowish or yellow-red* by common Asa fetida, Dragon's-blood from *Pterocarpus Draco*, Euphorbium, Guajacum (*greenish* at first), Gamboge, Xanthorrhæa-resins; *yellowish, brownish, or not at all* by the rest.

Sodium Carbonate solution at boiling heat is coloured *violet* by Shellac; *yellow* by Asa fetida, Benzoin, Euphorbium, Dragon's-blood, Guajacum, black Peru-balsam, Sandarac, Storax-balsam, Xanthorrhæa-resins; *yellowish, brownish, or not at all* by the rest.

From the extracts obtained with sodium carbonate at ordinary temperatures, *Acetic acid* throws down flocks: Conifer-resins and balsams, Guajacum, Gamboge, Podocarpus-resin, Sandarac, Xanthorrhæa-resins. *Acetic acid* throws down nothing or produces only a slight turbidity: the rest.

Umbelliferone is obtained by the dry distillation of: Asa fetida, African Ammoniacum, Galbanum, Sagapenum.

Sulphur may be detected in Asa fetida, Bdellium, some sorts of Caranna and Dragon's-blood.

Cinnamic acid is contained in Benzoin from Sumatra, Dragon's-blood, Liquidambar-balsam, black Peru-balsam, Tolu-balsam, red Xanthorrhæa-resin.

The *Petroleum-ether extract* is coloured *deep yellow* in the case of: Gamboge, Euryops-resin; *dark brown*: Mani-resin; *yellowish or colourless*: the rest.

Iodine-solution gives with the petroleum-ether extract a *clear violet mixture*: Benzoin, Indian Bdellium, Dragon's-blood, Shellac, Guajacum, Galbanum, Peruvian Guajacum, Indian Myrrh, yellow Xanthorrhæa-resin, resin of *Xanthorrhæa quadrangularis*; *red violet mixture*, clear at first, but afterwards becoming turbid: Copal, Dammara (some samples), Mastic, Gamboge, black Peru-balsam, Podocarpus-resin, Sandarac, Storax-balsam, resin of *Xanthorrhæa arboracea*; *brown and turbid mixtures*: the rest.

Sulphuric acid colours the evaporation-residue of the Petroleum-ether extract *crimson*: Benzoin from Siam, Guajacum; *no coloration*: Shellac, Podocarpus-resin; *yellow or brown*: the rest.

*Chloral-reagent** colours the residue gradually *violet*: common Myrrh, Caranna, Euryops-resin; *crimson changing to violet*: white Peru-balsam; *rose-coloured changing to violet*: Levantine Galbanum (old commercial sample), Levantine Sagapenum; *yellowish or greenish changing to red-violet*: Canada-balsam, Conifer-resins and balsams; *yellow*: Caranna, Gamboge; *green*: Dammara viridis, Persian Galbanum, Mecca-balsam, Persian Sagapenum; *dull green with rose-coloured edges*: Levantine Galbanum (sort at present occurring in commerce); *greenish*: Asa fetida, Indian Bdellium, Benzoin from Sumatra, Persian Ammoniacum, Liquidambar-balsam, black Peru-balsam; *blue into violet*: balsam of Liquidambar styraciflua; *no coloration or very faint*: the rest.

The *evaporation-residue after being heated to 120°* is either *soft or fluid*: Asa fetida, Benzoin from Sumatra, Liquidambar-balsam, Opoponax, black Peru-balsam, Tolu-balsam, Sagapenum, Storax-balsam.

Colophony. Processes for separating common resin, or colophony, from fatty acids, are described by C. Barfoed (*Zeitschr. anal. Chem.* 1876, 20; *Chem. Soc. J.* xxix. 771). For qualitative examination, the following methods may be adopted: 1. The mixture is dissolved, with aid of heat, in alcohol of 70 per cent. and then left to cool, whereupon the fatty acids separate out while the resin remains dissolved. 2. The mixture is heated with an alcoholic solution of sodium carbonate (7 vols. spirit of 30 per cent. and 1 vol. of a solution of 1 pt. crystallised sodium carbonate in 3 pts. water) till it is dissolved, and then left to cool, whereupon the sodium salts of the

* An impure chloral hydrate obtained by saturating alcohol with chlorine, mixing the product with 4 vols. strong sulphuric acid, stirring up the solid mass which separates with one-third of its weight of water, and distilling.

fatty acids separate, while the sodium resinate remains dissolved. 3. The mixture dissolved in alcohol is mixed with an alcoholic solution of calcium chloride and ammonia. The fatty acids then separate as calcium salts, while the calcium resinate remains dissolved in the alcohol. 4. The mixture is dissolved in the requisite quantity of soda-ley, the solution evaporated to dryness on the water-bath, and the residue treated with a mixture of 1 vol. alcohol of 98 per cent. and 5 vols. ether; in this case only the sodium resinate is dissolved. If any notable quantity of oleic acid is present, together with the stearic and palmitic acids, complete separation can be effected only by the fourth method, care being taken also that the solution containing soda be evaporated to complete dryness, and that the ether-mixture be prepared with absolute alcohol and ether.

The fourth method may be advantageously employed for quantitative estimation.

Colophthalin, $C^{11}H^{10}$. This name is given by P. Curie (*Chem. News*, xxx. 189) to a solid hydrocarbon occurring amongst the products of the dry distillation of colophony. It is prepared by heating 100 pts. colophony with 50 pts. sulphur at 400° , and purifying the distillate with cold alcohol. Pure colophthalin is a white flocculent body having a faint balsamic odour, easily soluble in benzene, turpentine-oil, carbon bisulphide, ether, boiling alcohol, and boiling glacial acetic acid; it melts at 70° and boils at 400° . By oxidising agents it is converted into oxycolophthalin, $C^{11}H^8O$, by chlorine into chlorocolophthalin, $C^{11}H^8Cl^2$; by hot nitric acid into nitrocolophthalin, which, when boiled with alkaline leys, gives off all its nitrogen as ammonia, and is converted into a compound called by Curie, colophulmic acid. These derivatives of colophthalin, when fused with caustic potash, yield a substance resembling alumina, and called colophalumina, which is insoluble in water, alcohol, and ether, infusible, non-volatile, and is said not to be decomposed by chloride or nitrate of potassium even at 1000° . Curie represents its composition by the formula $C^{10}H^6O^2$. By chlorine at a red heat, it is converted into *chlorocolophalumina*, $C^{10}H^4Cl^2O^2$, and by fusion with potash into *colophaluminoic acid*, $C^{10}H^4O^4$.

RESORCINOL, $C^6H^4(OH)^2$ [1 : 3]. This compound is formed by the action of melting potash on all the three modifications of monobromophenol (Fittig a. Mager, *Ber.* viii. 362), in like manner from *p*-chlorophenol (Faust, *Ber.* vi. 1022), and from *p*-iodophenol at temperatures above 165° (Nölting a. Wrzesinski, *ibid.* 820). Its formation from para- and ortho-derivatives must take place by atomic transposition, and shows that resorcinol is the most stable of the three modifications of dihydroxybenzene. Nölting a. Wrzesinski find, indeed, that para-iodophenol, when fused with potash, yields quinol at 165° , and resorcinol at higher temperatures. Resorcinol is also formed by the action of sodium-amalgam on paramorin, and, together with the latter, by the dry distillation of morin (p. 1337); further, together with protocathechuic acid and volatile fatty acids, by the action of melting potash on hydrocarotin (Brimmer, *N. Rep. Pharm.* xxiv. 641).

On the preparation of Resorcinol from Brazilin, see vii. 1040.

On the manufacture of Resorcinol, Eosin, and other resorcinol-derivatives, see Bindschedler a. Busch (*Chem. News*, xxxviii. 226; *Chem. Soc. J.* xxxvi. 291).

Resorcinol is most readily purified by crystallisation from pure anhydrous benzene. It dissolves easily therein when heated, and crystallises almost completely on cooling in large transparent perfectly colourless needles, or by spontaneous evaporation in very large well-developed rhombic prisms, having the aspect of crystals of nitre or urea (Fittig a. Mager, *Ber.* vii. 1177; viii. 365).

According to Caldeyron (*Compt. rend.* lxxxiv. 779), the crystals of resorcinol are orthorhombic, and exhibit the combination $\infty P. \bar{P} \infty$; or sometimes $\infty P. \infty \bar{P} 2. \bar{P} \infty$. Axes $a : b : c = 0.912326 : 1 : 1.0587577$. The crystals are often elongated in the direction of the axis a , and have sometimes the appearance of a perfect octohedron. Resorcinol melts at 118° , boils at 276.5° under a pressure of 759.7 mm., between 200° and 210° under a pressure of 7 mm., and decomposes at 300° . Its vapour-density, determined by Dumas' method under reduced pressure, gave, as a mean of two experiments, 3.862 instead of the theoretical number 3.8078. The density of solid resorcinol, taken in carbon sulphide, was found to be 1.2728 at 0° , 1.2717 at 15° . Coefficient of expansion, 0.00007868 between 0° and 15° ; for the liquid between 118° and 178° , uniformly 0.0007114. The molecular volume calculated for liquid resorcinol between 118° and 178° varies from 92.26 (at 118°) to 96.196 (at 178°). Calculation gives for the molecular volume of liquid resorcinol at 0° , the number 86.43, and for the solid 85.13, showing a difference of 1.3; the molecular volume at the boiling point is 103.17. A comparison of the molecular volumes of resorcinol, phenol, and benzene at 100° gives the following results:

	Sp. gr.	Mol. volume
Benzene	0.7938	98.26
Phenol	1.0128	92.9
Resorcinol	1.2076	9.109

For the densities of solutions of resorcinol containing $\frac{1}{2}$, 1, and $1\frac{1}{2}$ eq. in a litre, Calderon (*Compt. rend.* lxxxiv. 1164) finds the following numbers—

Content in 1 l.	at 0°	at 10°	Density at 100°
$\frac{1}{2}$ eq.	1011.48	1011.11	964.05
1 eq.	1023.17	1023.23	976.64
$1\frac{1}{2}$ eq.	1034.06	1033.32	987.41

Reactions. 1. *Oxidation*.—Resorcinol is oxidised by fusion with soda, and on dissolving the melt in dilute sulphuric acid, exhausting the acid solution with ether, and evaporating the latter, phloroglucinol, $C^6H^6O^3$, crystallises out to the amount of 60–70 per cent. of the resorcinol. The mother-liquor yields with lead acetate a yellow precipitate, which, when decomposed by hydrogen sulphide, yields a syrupy liquid, decomposing when distilled, with formation of catechol. The filtrate from the lead precipitate contained a small quantity of unaltered resorcinol, but consisted chiefly of phloroglucinol and tetroxydiphenyl, $C^{12}H^{10}O^4$, in the form of a crystalline powder or long colourless needle-shaped crystals not melting at 250° (Barth a. Schreder, *Ber.* xii. 503).

2. Resorcinol subjected to exhaustive chlorination in a stream of *chlorine*, with addition of a little *iodine* (p. 1066), yields perchloromethane, CCl_4 , together with carbon dioxide (Ruoff, *Ber.* x. 1483). 3. Treated in aqueous solution with *iodine chloride* till iodine separates out, it is converted into tri-iodoresorcinol, together with a brown substance insoluble in carbon sulphide (Michael a. Norton, *Ber.* ix. 1752). 4. *Sulphuryl chloride*, SO^2Cl_2 , converts resorcinol into mono- and di-chlororesorcinol (p. 1748). 5. With *chloroform* and a caustic alkali, it yields resorcinol aldehydes (p. 1751). 6. Resorcinol, heated to 150°–160° with strong *sulphuric acid*, is converted into resorcinoldisulphonic acid; at 200° with *fuming sulphuric acid*, into resorcinoltrisulphonic acid (Piccard a. Humbert, p. 1752). J. Annaheim (*Ber.* x. 975), by heating resorcinol (22 pts.) with fuming sulphuric acid (9.8 pts.) for an hour or two at 120°–130°, obtained a deep red substance, changing as it cooled to a solid mass having a green metallic reflex. On boiling it with water, the greater part remained undissolved in the form of a resinous sulphuretted body, which dissolved with red colour in alcohol, glacial acetic acid, and alkalis, the solutions, especially that in ammonia, exhibiting a splendid fluorescence. The red colouring matter may be separated from the alcoholic solution by water, and from the alkaline solutions by acids. With bromine and iodine it forms compounds which are likewise fluorescent. 7. When 1 mol. resorcinol and 2 mols. *oxalic acid* are heated together in a sealed tube at 200° for two or three hours, a mass is formed which, when diluted with a little alcohol and poured into water, yields a flocculent precipitate purifiable by solution in alcohol and reprecipitation by water. This substance, which has the composition $C^{13}H^6O^4$, and may perhaps be represented by the constitutional formula $C^6H^3O.CO.C^6H^3(OH)^2$, is a fine red powder, very hygroscopic, easily soluble in alkalis with green fluorescence, soluble also in glacial acetic acid and in alcohol, and precipitated unchanged from its alkaline solution by acids. It has not been obtained in the crystalline state. Acetic anhydride converts it on boiling into an acetyl-derivative, $C^{13}H^7(C^2H^3O)O^4$. A brominated derivative is formed by adding bromine to its alkaline solution (Claus a. Andreæ, *Ber.* x. 1305).

8. Resorcinol, treated with *oxalic acid* in presence of dehydrating agents (sulphuric acid, phosphoric anhydride, glycerol), yields two colouring matters having the composition $C^{14}H^6O^5$, one of which is light yellow, insoluble in alcohol, easily dissolved by potash-ley, forming a solution which exhibits green fluorescence, while the other is a dark brown mass, soluble in alcohol, and dissolving in potash-ley with brown colour but without the slightest fluorescence (Gukassianz, *Ber.* xi. 1184).

9. A solution of resorcinol, mixed with *cupric sulphate*, yields, on addition of ammonia in quantity sufficient to redissolve the precipitate at first produced, a deep black liquid with which wool and silk may be dyed black (R. Wagner, *Dingl. pol. J.* cccx. 96).

10. Resorcinol introduced into the animal organism is converted into a sulphonic acid, which is eliminated in the urine (Baumann a. Herter, *Ber.* ix. 1747; *Zeitschr. physiol. Chem.* i. 244).

Bromoresorcinols. These compounds have been studied by Liebermann a. Dittler (*Ber.* v. 1090, and this Dictionary, vii. 1042), and further details respecting

them are given by the same authors in a later communication (*Liebig's Annalen*, elix. 252).

Pentabromoresorcinol, $C^6HBr^5O^2$, crystallises, according to Rammelsberg's measurements, in the dimetric or quadratic system, exhibiting the combination $\infty P \infty . 0P . P$. Axial ratio $a : c = 0.6076 : 1$. Angle $P : P' = 98^\circ . 58'$; $P' : P = 133^\circ . 30'$; $P : 0P = 113^\circ . 15'$; $P : \infty P \infty = 130^\circ$. The faces $\infty P \infty$ are small and incomplete in number.

The liquid obtained by dissolving colourless pentabromoresorcinol in cold alcohol is yellow, as if from separated bromine, and on adding to it an aqueous solution of potassium iodide and then carbon sulphide, the latter immediately becomes purple, as from separated iodine. When an alcoholic solution of silver nitrate is added by drops to an alcoholic solution of pentabromoresorcinol, rather more than 1 mol. bromine is thrown down as silver bromide from 1 mol. pentabromoresorcinol.

Tribromoresorcinone, $C^6HBr^3O^2$ (vii. 1042), formed by heating pentabromoresorcinol at 150° – 160° , is insoluble in water, easily soluble in alcohol, sparingly in ether, carbon sulphide, benzene, and chloroform, and crystallises therefrom in needles. It decomposes at 190° , but remains for the most part unaltered when treated with sodium-amalgam, or when sulphur dioxide is passed into its alcoholic solution heated to 50° – 60° . It resinises when heated with aqueous sulphurous acid at 140° , and with hydriodic acid at a higher temperature. It unites with 1 mol. bromine, reproducing pentabromoresorcinol (Liebermann & Dittler).

From experiments by H. Claassen (*Ber.* xi. 1438), it appears that of the five bromine-atoms in pentabromoresorcinol, three are more stable or less easily removed than the other two: thus pentabromoresorcinol boiled with *formic acid* yields CO^2 , HBr, free bromine, and tribromoresorcinol; with aldehyde, it yields HBr and tribromoresorcinol; and with *acetic anhydride*, tribromodiacetytresorcinol, $C^6HBr^3(OC^2H^3O)^2$. This fact of the easier removal of two out of the five bromine-atoms in pentabromoresorcinol, renders it probable that this compound is correctly represented by the formula $C^6HBr^3(OBr)^2$.

Pentabromoresorcinol is converted by reduction with *tin* and *hydrochloric acid* first into tribromoresorcinol, $C^6HBr^3(OH)^2$, then into resorcinol; with *aniline* it yields tribromaniline and tribromoresorcinol; with *phenol*, tribromoresorcinol and tribromophenol (Benedikt, *Ber.* xi. 1599).

Tetrabromoresorcinol, $C^6Br^4(OH)^2$, formed by heating pentabromoresorcinol with strong sulphuric acid, melts at 163° , dissolves readily in hot alcohol, ether, chloroform, and alkalis, sparingly in water, and when boiled with acetic anhydride, yields tetrabromodiacetytresorcinol, $C^6Br^4(OC^2H^3O)^2$, which is insoluble in water, easily soluble in hot alcohol and in ether, and melts at 169° .

Tribromomonacetyl-resorcinol, $C^6HBr^3(OH)(OC^2H^3O)$, is prepared by treating 1 pt. diacetyl-resorcinol with 5 pts. bromine and 40 pts. water, and separates from solution in carbon sulphide in small transparent crystals, which melt at 114° , and are converted by boiling with aqueous potash into tribromoresorcinol, and by acetic anhydride into tribromodiacetyl-resorcinol, $C^6HBr^3(OC^2H^3O)^2$.

Tetrabromodiresorcinol, $C^{12}H^2Br^4(OH)^4 = (OH)^2HBr^2C^6 - C^6Br^2H(OH)^2$, prepared by boiling tribromoresorcinone with tin and hydrochloric acid, crystallises from glacial acetic acid in rose-red needles, easily soluble in alcohol and ether, decomposing at 280° , and reduced by sodium-amalgam to an amorphous non-brominated compound which, when distilled over zinc-dust, yields diphenyl (Benedikt, *Ber.* xi. 2168).

Chloro-resorcinols (Reinhard, *J. pr. Chem.* [2], xvii. 321; Claassen, *Ber.* xi. 1438). *Monochlororesorcinol*, $C^6H^3Cl(OH)^2$, formed by adding an equivalent amount of sulphuryl chloride, drop by drop, to resorcinol dissolved in absolute ether, and distilling, is a white crystalline body, melting at 89° , but beginning to sublime at 75° , and distilling at 256° – 256° . It is soluble in water, alcohol, ether, benzene, and carbon bisulphide: its aqueous solution slightly reddens litmus paper. It is attacked by warm dilute nitric acid, with evolution of chlorine and nitrous acid, and formation of a hard resinous mass. With ferric chloride it produces a blue-violet colour, becoming brown on heating. It reduces ammoniacal silver solution, and seems to form a very unstable potassium derivative, $C^6H^3Cl(OK)^2$. No derivatives of it could be obtained by fusion with potassium hydrate or cyanide. The action of bromine upon its aqueous solution at 80° gives rise to *monochlorodibromoresorcinol*, $C^6HBr^2Cl(OH)^2$, which crystallises in slender brilliant needles, melting at 105° . The *benzoyl-derivative*, $C^6H^3Cl(OC^2H^3O)^2$, produced by the action of benzoyl chloride upon monochlororesorcinol, crystallises from hot alcohol in small hexagonal needles, melting at 98° , and, when saponified, yields a benzoate and the original monochlororesorcinol.

Dichlororesorcinol, $C^6H^2Cl^2(OH)^2$, is obtained by rubbing together in a basin resorcinol and sulphuryl chloride, in the proportion of 1 to 2 mols., heating after addition of a very little more sulphuryl chloride, and subliming two or three times. It is very soluble in water and other ordinary solvents, and is obtained by evaporation of its aqueous solution over sulphuric acid, in well-formed rhombic prisms, readily efflorescing in air, melting at 77° , and boiling at 249° . **Dichloromonobromoresorcinol**, $C^6H^3BrCl^2O^2$, is obtained by the action of bromine upon dichlororesorcinol, and the *benzoyl-derivative*, $C^6H^2Cl^2(OC^7H^5O)^2$, by the action of benzoyl chloride: the former melts at 100° , the latter at 127° .

Sulphuryl hydroxychloride, $SO^2Cl(OH)$, acts energetically on dichlororesorcinol with formation of a white solid, consisting of microscopic rhombic crystals, soluble in potash and in potassium carbonate solution (in the latter case with evolution of carbon dioxide), but insoluble in water, alcohol, and ether. This substance has the empirical formula, $C^{12}H^4Cl^4S^2O^8$, and probably the structural formula,

By decomposing a solution of this body in potassium carbonate with hydrochloric acid, evaporating on the water-bath, and crystallising from alcohol, the corresponding acid, $C^6HCl^2(SO^3H)(OH)^2$, was obtained as a white powder, soluble in water and in alcohol, and decomposed by sulphuryl hydroxychloride into the anhydride and water. The insoluble barium salt was obtained by boiling the anhydride with baryta-water, or by precipitating a solution of the anhydride in potassium carbonate with barium chloride.

Trichlororesorcinol, $C^6HCl^3(OH)^2$, is obtained by gradually adding to resorcinol about six times its own weight of sulphuryl chloride, heating for some hours in a flask fitted with a reversed condenser, distilling off the excess of sulphuryl chloride, drying in a vacuum over potash, and repeatedly crystallising from hot water. It forms small brilliant needles, readily soluble in alcohol and in ether, melting at 83° , but subliming only with partial decomposition.

By treating an aqueous solution of resorcinol with excess of chlorine, a trichlororesorcinol was obtained, melting at 73° . Reinhard regards this body as identical with that obtained by the action of excess of sulphuryl chloride upon resorcinol, attributing the difference between the melting points to small amounts of impurities.

Trichlororesorcinol forms a *benzoyl-derivative*, $C^6HCl^3(OC^7H^5O)^2$, which melts at 133° . Sulphuryl chloride, heated with trichlororesorcinol in a sealed tube, reacts upon it at 160° , probably forming tetrachlororesorcinol, which, however, has not yet been obtained in the pure state (Reinhard).

Pentachlororesorcinol, $C^6HCl^5O^2$, is somewhat more stable than the corresponding bromine-compound (p. 1748), not being altered by heating either alone or in contact with aldehyde or formic acid; a strong solution of acid potassium sulphite, however, converts it into a trichlororesorcinol, which crystallises from water in white needles melting at 69° (comp. Reinhard, *supra*), and dissolving readily in alcohol, ether, and hot water (Claassen).

Tri-iodoresorcinol, $C^6HI^3(OH)^2$, is formed, together with a brown substance insoluble in carbon sulphide, when iodine chloride is added to an aqueous solution of resorcinol. It is insoluble in water, moderately soluble in glacial acetic acid, easily in carbon sulphide, alcohol, and ether, and crystallises in long needles having a faint rose-colour, and melting at 145° (uncorr.) When heated above 190° , it sublimes and decomposes, giving off vapours of iodine. By alkalis, alkaline carbonates and aniline, it is dissolved with brown colour and at the same time decomposed (Michael'a. Norton, *Ber. ix.* 1752).

Dinitrosoresorcinol, $C^6H^2(NO)^2(OH)^2$ (A. Fitz, *Ber.* viii. 631). This compound is prepared by adding to 1 mol. resorcinol dissolved in fifty times its weight of water and cooled to 0° , first 2 mols. acetic acid and then rather more than 2 mols. potassium nitrite dissolved in water, whereupon, after a few minutes, the green acid potassium salt of dinitrosoresorcinol begins to separate, perhaps mixed with free dinitrosoresorcinol, to judge by the darkening of the liquid. On pouring the mass, after a quarter of an hour's rest, into 2 mols. dilute sulphuric acid, free dinitrosoresorcinol separates in yellowish flocks, which, after standing for an hour, may be collected on a filter, well washed, and crystallised from water, or better from hot alcohol of 50 per cent. The solution becomes dark from oxidation, and on cooling deposits the nitroso-compound in yellowish-grey, or yellowish-brown, shining crystalline laminae, which have the composition $C^6H^2(NO)^2(OH)^2 + 2H^2O$, suffer but little loss of weight at 100° , but detonate at 115° . They are but sparingly soluble in cold water, alcohol, methyl alcohol, or acetone, more soluble in these liquids when hot, insoluble in ether and in benzene. From hot alcohol, dinitrosoresorcinol separates in the amorphous state. The hot solutions oxidise very readily when exposed to the air.

Dinitrosoresorcinol is a moderately strong acid, decomposing carbonates completely and acetates partially. Its salts are amorphous, excepting those of potassium, sodium, ammonium, and calcium. The *acid sodium salt* is prepared by drenching dinitrosoresorcinol with a small quantity of water, adding the requisite quantity of soda-ley, and passing carbon dioxide through the solution for some time; the salt then separates in the form of a slightly soluble dark green crystalline powder. The *ammonium salt*, $C^6H^2(NO)_2(OH)(ONH^4)$, is a greenish-brown powder; the corresponding *potassium salt*, a light green, slightly soluble crystalline powder. The other salts are obtained from the acid sodium salt by precipitation, *barium chloride* giving a green precipitate soluble in dilute acetic acid; *calcium chloride* a greyish-green crystalline precipitate, sparingly soluble in water, soluble in dilute acetic acid; *silver nitrate* a grey flocculent precipitate; *lead acetate* a brown-red flocculent precipitate; *cupric sulphate* a brown-red; *zinc sulphate* a flocculent; *mercurous nitrate* a brown-red; *ferrous sulphate* a blue-green precipitate. *Ferric chloride* gives at first a deep green coloration, then a dark green precipitate. The normal alkali-salts are easily soluble; the other salts, both normal and basic, are amorphous and sparingly soluble.

Nitric acid, even when dilute and cold, converts dinitrosoresorcinol into trinitroresorcinol; potassium ferricyanide and permanganate raise it to a higher stage of oxidation or burn it up completely. By tin and hydrochloric acid, on the other hand, it is very easily reduced to diamidoresorcinol (*infra*). With acetic anhydride, aniline, alcohol and glacial acetic acid, alcoholic hydrochloric acid, and with resorcinol and strong sulphuric or glacial acetic acid when heated, dinitrosoresorcinol forms brown resinous products. Its alcoholic solution is coloured a deeper yellow by nitrous acid, but the compound itself remains unaltered.

Diamidoresorcinol, $C^6H^2(NH^2)^2OH$, is formed, as above mentioned, by reducing the dinitroso-compound with tin and hydrochloric acid. The resulting hydrochloride, which acquires a dark brown colour, is best converted into the more stable sulphate, which separates on addition of sulphuric acid, and more quickly if alcohol be likewise added, in slightly coloured needle-shaped crystals having the composition $C^6H^2(NH^2)^2(OH)^2SO^4H^2 + 1\frac{1}{2}H^2O$, and giving off their water at 100° . The base, when separated by alkalis, immediately turns brown and decomposes on exposure to the air. With ferric chloride it produces a fine blue colour, quickly changing to dirty brown (Fitz).

Trinitroresorcinol, or Styphnic Acid, $C^6H(NO^3)^3(OH)^2$, is formed, together with three dinitrobenzoic acids, when orthonitrobenzoic acid is gradually added to a warm mixture of equal parts of fuming nitric and sulphuric acids (Griess, p. 267). The styphnic acid thus obtained agrees in its melting point (175°) and the composition of its barium salt, $C^6H(NO^3)^3O^2Ba + 3H^2O$ (small yellow rhombic prisms very slightly soluble, even in boiling water, and giving off their crystallisation-water at 200°) with that described by Stenhouse (vii. 1044). H. Salkowski (*Ber.* viii. 637), on repeating the nitration of orthonitrobenzoic acid in the manner described by Griess, obtained a barium salt of styphnic acid containing only 1 mol. H^2O , and crystallising in small orange-coloured scales, nearly insoluble in water even at the boiling heat.

Merz a. Zetter (*Ber.* xii. 681) prepare trinitroresorcinol by heating resorcinol with excess of sulphuric acid at 100° , and adding to the resulting sulphonic acid first slightly diluted, then concentrated nitric acid, and finally an excess of fuming nitric acid. On pouring the product after a while into cold water, the trinitro-compound is thrown down in the pure state. Trinitroresorcinol is also formed by prolonged boiling of ostruthin with dilute nitric acid (Gorup-Besanez, *Liebigs Annalen*, clxxxiii. 321), and in theoretical quantity by the continued action of strong nitric acid at the boiling heat on metanitrophenol (A. Bantlin, *Ber.* x. 524).

Methyl-resorcinols (J. Habermann, *Ber.* x. 867). The two methyl-ethers of resorcinol are easily prepared by heating an intimate mixture of 1 mol. of resorcinol, 2 mols. of potassium methylsulphate, and 2 mols. of potassium hydroxide with a little absolute alcohol, for four to five hours, at 160° . The product is acidulated with sulphuric acid, and exhausted with ether, and after the latter has been driven off, the residue is distilled with water, the dimethyl-ether then passing over, while resorcinol and the monomethyl-ether remain behind. The two compounds are extracted by ether, and separated by fractional distillation.

Monomethylresorcinol, $C^6H^4(OH)(OCH^3)$, is a colourless or pale yellow, very refractive liquid, which is moderately soluble in cold, more freely in hot water and dilute alcohol, and mixes in almost every proportion with absolute alcohol and ether. It has only a faint odour, but its dilute alcoholic solution has an aromatic but not agreeable smell. Its aqueous solution tastes sweetish and burning, and is coloured violet by ferric chloride. Methyl-resorcinol boils at 243° – 244° , and at -17.5° becomes

viscid, but does not crystallise. With alcoholic potash it forms a thick syrupy mass, which turns reddish-brown when exposed to the air.

Dimethyl-resorcinol, $C^6H^4(OCH^3)^2$, is a colourless refractive oil, very much like the monomethyl-derivative, heavier than water, very slightly soluble therein at ordinary temperatures, but dissolving easily at the boiling heat, and very easily in alcohol and ether. It becomes somewhat more viscid at -17.5° , and boils at $214-215^\circ$. Vapour-density, obs. = 4.7050; calc. 4.7781. Its aqueous solution is not coloured violet by ferric chloride.

Chlorodimethyl-resorcinol, $C^6H^3ClO^2 = C^6H^3Cl(OCH^3)^2$, is produced by passing chlorine gas into a solution of dimethyl-resorcinol in glacial acetic acid, the operation being stopped at the moment when the liquid assumes a deep yellow colour. On leaving the solution to evaporate in a vacuum over quicklime, the monochlorinated compound is obtained in long limpid well-defined needles, which may be purified by filtering, washing with glacial acetic acid, pressure between filter-paper, and recrystallisation from alcohol. This compound melts at 118° , dissolves sparingly in glacial acetic acid and in cold alcohol, easily in ether and in boiling alcohol. *Dichlorodimethyl-resorcinol*, $C^6H^2Cl^2(OCH^3)^2$, produced by the further action of chlorine, is a liquid insoluble in water, somewhat soluble in alcohol, easily soluble in ether and in glacial acetic acid (Hönig, *Ber.* xi. 1039).

Dibromodimethyl-resorcinol, $C^6H^2Br^2(OCH^3)^2$, is obtained by dropping a solution of bromine in glacial acetic acid into dimethyl-resorcinol dissolved in the same acid, till the colour of the bromine-solution no longer disappears. The product, which crystallises out on standing, melts at $137-138^\circ$, dissolves sparingly in alcohol and glacial acetic acid, easily in ether, and forms transparent shining crystals belonging to the orthorhombic system (Hönig).

Dinitrodimethyl-resorcinol, $C^6H^2(NO^2)^2(OCH^3)^2$, is formed by adding to dimethyl-resorcinol diluted with glacial acetic acid, an equal volume of nitric acid of the ordinary strength. On leaving the solution at rest for about ten minutes and then shaking it with ether, the dinitro-compound dissolves in the ether, and may be purified by evaporating the ether, dissolving the residue in alcohol, and precipitating with water. It forms small red-brown crystals insoluble in water, soluble in alcohol and ether, melting at 67° . *Trinitrodimethyl-resorcinol*, $C^6H(NO^2)^3(OCH^3)^2$, prepared with dimethyl-resorcinol, fuming nitric acid, and strong sulphuric acid, crystallises from alcohol in nearly colourless laminae melting at $123-124^\circ$, insoluble in water, easily soluble in alcohol and ether (Hönig).

Aldehydes derived from Resorcinol (Tiemann a. Lewy, *Ber.* x. 2216). These compounds are formed from resorcinol in the same manner as salicylic and paraoxybenzoic aldehydes from phenol, and vanillin from guajacol (pp. 303, 305), namely by the simultaneous action of chloroform and an alkaline hydroxide. The diatomic phenols, however, mostly unite with the aldehydes formed from them, producing colouring matters, much more readily than the monatomic phenols; and to prevent this combination, it is necessary, in preparing aldehydes from these diatomic phenols, to work with more dilute solutions and with a larger excess of alkali and chloroform.

The resorcinol aldehydes are prepared by treating 5 grams of resorcinol with 80 g. sodium hydroxide and 500 to 600 g. water, and then adding 80 g. chloroform, the mixture being heated in a reflux apparatus, gently at first, afterwards more strongly, acidulated with sulphuric acid after all the chloroform has been decomposed, and finally distilled in a current of steam. The distillate then deposits slender needles consisting of

Resorcene-dialdehyde, $C^6H^2(OH)^2(COH)^2$, which dissolves easily in alcohol, ether, benzene, and chloroform, and may be separated from its solution in ether by a solution of acid sodium sulphite. It is nearly insoluble in cold water, crystallises from a large quantity of hot water in thin needles, melts at 127° , and sublimes at 110° . The aqueous solution is coloured red-brown by *ferric chloride*. The dialdehyde dissolves in *alkalis*, forming a yellow solution from which it is precipitated by acids. Its ammoniacal solution gives with *lead acetate* a white precipitate, and with *cupric sulphate* a green precipitate soluble in ammonia. The alcoholic solution of the dialdehyde, mixed with *aniline*, immediately deposits needle-shaped crystals melting at 199° . Melting *potash* converts it into an acid—probably resorcene-dicarboxylic acid—which dissolves easily in water, alcohol, and ether, crystallises from water in white slender needles, and melts at 192° , being resolved at the same time into carbon dioxide and resorcinol.

Resorcylic Aldehyde, $C^6H^3(OH)^2COH$, formed simultaneously with the dialdehyde just described, and remaining in the liquid from which the latter has been

removed by a current of steam, may be extracted from this liquid by ether, after removal of a red amorphous colouring matter—and freed from unaltered resorcinol by combination with acid sodium sulphite, or by recrystallisation from hot benzene. It dissolves readily in water, alcohol, ether, chloroform, and glacial acetic acid, sparingly in benzene, and crystallises from water in yellowish needles melting at 134°–135°. The aqueous solution is coloured red-brown by ferric chloride. Resoreyl aldehyde is extremely unstable, and is converted by dehydrants or by prolonged exposure to the air into red amorphous bodies. Its conversion by oxidation into an acid of corresponding constitution takes place only after the introduction of ethyl into the hydroxyl-groups.

Diethyl-resoreyl Aldehyde, $C^6H^3(OC^2H^5)^2COH$, is easily formed by the action of ethyl iodide (2 mols.) and KOH (2 mols.) on resorcinol (1 mol.). It crystallises in shining plates, melts at 71°–72°, dissolves easily in alcohol and ether. By oxidation with potassium permanganate in aqueous solution, it is readily converted into the corresponding acid, $C^6H^3(OC^2H^5)^2COOH$ (diethyl-resoreyl-carboxylic acid), which crystallises in small needles, melts at 99°, and forms well-crystallised slightly soluble salts with barium and calcium. The *lead salt* is a white amorphous precipitate; the *copper salt* a greenish-blue precipitate easily soluble in ammonia.

Resoreyl aldehyde, heated with sodium acetate (1 pt.) and acetic anhydride (3–5 pts.), is converted into a acetoxycoumarin or β -acetumbelliferone:

which crystallises in large faintly yellowish prisms melting at 140°, distils without decomposition, dissolves but sparingly in water even when hot, easily in alcohol and ether. The aqueous solution exhibits a splendid blue fluorescence, but gives no colour-reaction with ferric chloride.

The formation of acetoxycoumarin renders it very probable that at least one of the hydroxyl-groups in resoreyl-aldehyde occupies the *ortho*-position with respect to the COH-group. This compound is not attacked in the cold by alkaline hydroxides or carbonates, but dissolves in them when heated, the solutions after acidulation yielding to ether a substance which, after purification, forms white needles, having the composition of hydroxycoumarin or β -umbelliferone,* $C^9H^6O^3$; sparingly soluble in water (the solution being coloured brown-red by ferric chloride) and decomposing without fusion at 200°.

RESORCINOL-DYES. See RESORCINOL-PHTHALEINS, under PHTHALEINS (p. 1606).

RESORCINOL-SULPHONIC ACIDS. On the crystalline form of *Potassium Resorcinolmonosulphonate*, $C^6H^4(OH)(OSO^3K)$, see Bodewig (*Zeitschr. f. Kryst. i.* 584; *Jahresb. f. Chem.* 1877, 565).

Resorcinol-disulphonic acid, $C^6H^4S^2O^8 = C^6H^2(OH)^2(SO^3H)^2$, is formed by gradually adding 1 pt. finely pulverised resorcinol to 10 pts. of strong sulphuric acid heated to 150°–160°, dissolving the crystals which separate by further heating at 190°–200°, and leaving the solution to cool. The vessel then becomes half filled with large crystals of the disulphonic acid, which may be collected on a suction-filter and washed with strong sulphuric acid. They are colourless, dissolve easily in water and in alcohol, deliquesce on exposure to the air, and are coloured ruby-red by ferric chloride. On boiling the aqueous solution with lime, a *neutral calcium salt* is obtained the solution of which is precipitated on addition of a certain quantity of alkaline carbonate; and on boiling the acid with milk of lime, a *basic salt* is formed, which, like the potassium salt, is too soluble to crystallise well. Barium chloride added to the solution of either of these calcium salts throws down the *barium salt*, $C^6H^2(O^3Ba)(SO^3)^2Ba + 5H^2O$, as a white crystalline precipitate, which does not give off all its water even at 200°. Its formation is analogous to that of the basic phenol-disulphonate of barium, which Städeler obtained (vi. 927) from phenoldisulphonate and carbonate of barium. An aqueous solution of resorcinol-disulphonic acid absorbs a large quantity of *bromine*, producing colourless silky needles of tribromoresorcinol (Piccard a. Humbert, *Ber.* ix. 1479).

Resorcinol-trisulphonic acid, $C^6H(OH)^2(SO^3H)^3$, is formed by heating resorcinol-disulphonic acid with fuming sulphuric acid at 200°. To separate it, the solution is neutralised with milk of lime, whereby an insoluble basic salt is formed,

* The hydroxycoumarin and acetoxycoumarin obtained as above, not having yet been shown to be identical with the umbelliferone and acetumbelliferone previously known (v. 938; vii. 1186), are provisionally distinguished by the prefix β .

and mixes with the gypsum, whilst any disulphonic acid that may still be present remains dissolved. The liquid is filtered, the residue boiled with hydrochloric acid, and the excess of sulphuric acid precipitated by barium chloride. The strongly acid filtrate, in which the barium resorcinoltrisulphonate remains for a while dissolved, is mixed with ammonia (whereby impurities are precipitated), but not to the point of neutralisation, and then quickly filtered. After a few hours, the clear acid solution begins to deposit the dazzling white crystalline barium salt, the separation of which goes on for two or three days; and a further but less pure salt is deposited on warming. This salt, dried at a very gentle heat, has the composition $[\text{C}^6\text{H}(\text{OH})_2(\text{SO}_3)^3]_2\text{Ba}^2 + 3\frac{1}{2}\text{H}_2\text{O}$. When once deposited, it is no longer soluble in hydrochloric acid. By digesting it at 100° in a sealed tube with ammonium carbonate, ammonium resorcinoltrisulphonate is obtained, which forms, with lead and calcium salts, crystalline precipitates soluble in acetic acid; with barium chloride a precipitate insoluble in acetic acid. With ferric chloride it produces a deep red-violet, very stable coloration (Piccard a. Humbert, *Ber.* x. 55).

RESORCINYL OXIDES or RESORCINOL ETHERS. Boettinger (*Ber.* ix. 182), by treating resorcinol with sodium hydroxide and CO_2 , obtained an acid product consisting mainly of a red substance soluble in alkalis. Barth (*ibid.* 308) obtained the same or a similar substance by treating fused resorcinol with sodium and CO_2 , or with sodium alone,—and in a purer state by the action of hydrochloric acid on resorcinol under pressure. Precipitated from ammoniacal solution by acids, it formed light brown flocks, which when dry exhibited a splendid metallic iridescence, and yielded on trituration a powder having a deep red colour. Heated with zinc dust, it gave off benzene, together with a small quantity of diphenyl formed by a secondary reaction. The compound thus obtained is a dye-stuff imparting a very bright red colour to wool and silk. Barth represents it by the formula $\text{C}^{12}\text{H}^{10}\text{O}^3$, and regards it as a kind of ether of resorcinol. The same substance appears to have been obtained by Barth a. Senhofer (*Liebig's Annalen*, clxiv. 109) by the action of hydriodic acid on diethyl-resorcinol.

The product of the action of hydrochloric acid on resorcinol has been further examined by Barth a. Weidel (*Ber.* x. 1464), who prepare it by heating 20 grams of resorcinol with 25 c.c. strong hydrochloric acid in a sealed tube at 180° , obtaining thereby an acid liquid, together with a resin which has a green reflex, and when subjected to the following treatment yields two lead salts A and B. The air-dried resin is treated with alcohol of 90 per cent., which dissolves it slowly but almost completely, and the residue may be brought into solution by first dissolving it in ammonia, then precipitating with an acid, and treating the precipitate with alcohol. If now the united alcoholic extracts be mixed with an alcoholic solution of neutral lead acetate, the lead salt A separates out first, and the filtered liquid, freed from alcohol by distillation and mixed with water, yields a mixture of the salts A and B. To separate these, they are dried and warmed with alcohol, which dissolves B and leaves A.

The lead salt A is a violet-red powder from which the lead may be removed either by dissolving it in glacial acetic acid, and precipitating with hydrochloric acid, or by suspending it in alcohol and decomposing it with hydrogen sulphide. In either case, the further purification of the substance freed from lead is effected by mixing the filtrate with water, after expelling the alcohol, dissolving the washed and dried precipitate in ammonia, and reprecipitating with hydrochloric acid.

The compound thus obtained is *resorcinyloxyde*,

formed according to the equation $2\text{C}^6\text{H}^4\text{O}^2 = \text{H}_2\text{O} + \text{C}^{12}\text{H}^{10}\text{O}^3$. After washing and drying, it is a brown-red amorphous powder, acquiring by pressure a green metallic lustre. It melts at a rather high temperature, is nearly insoluble in water, very sparingly soluble in ether and in cold alcohol, moderately soluble in hot alcohol and in glacial acetic acid. It dissolves in strong sulphuric acid without alteration, and in aqueous alkalis, forming a solution having an intense dark red colour and green fluorescence. The *acetyl-derivative*, $(\text{C}^6\text{H}^4\cdot\text{OC}^2\text{H}^3\text{O})_2\text{O}$, may be prepared by treating the oxide with acetyl chloride at 100° , and purified by precipitation with water, solution in alcohol, and reprecipitation with water. It dissolves in alkalis at ordinary temperatures without alteration, forming a red-violet liquid; with decomposition when heated. The *tetrabromo-derivative*, $\text{C}^{12}\text{H}^4\text{Br}_4\text{O}^3 = (\text{C}^6\text{H}^2\text{Br}_2\text{OH})_2\text{O}$, is formed by adding bromine in excess to a solution of the oxide in glacial acetic acid, and may be purified by solution in alcohol and reprecipitation with water. Melting potash converts it into resorcinol. When heated with zinc-dust, it does not yield any definite products.

Diresorcinyldioxide.

prepared from the lead salt B by the series of processes above described for A, forms, when dry, a brick-red amorphous powder, melting at a somewhat higher temperature. It dissolves very easily in alcohol, ether, and glacial acetic acid, and is somewhat soluble in water. Aqueous alkalis dissolve it to a brownish-yellow liquid with violet-blue fluorescence. The *acetyl-derivative*, $\text{C}^{24}\text{H}^{18}(\text{C}^2\text{H}_3\text{O})^2\text{O}^5$, prepared like its analogue above described, is a cinnamon-brown powder becoming strongly electric when rubbed, nearly insoluble in alkalis, very easily soluble in alcohol. The *hexbromo-derivative*, $\text{C}^{24}\text{H}^{12}\text{Br}^6\text{O}^5$, prepared as above described, is a light red powder sparingly soluble in alkalis, easily in alcohol and glacial acetic acid. By fusion with potash it yields resorcinol (Barth a. Weidel).

Both of the above-described resorcinyldioxides, when boiled for some time with nitric acid, yield isophthalic acid, a large portion, however, undergoing complete decomposition.

The green fluorescence of monoresorcinyldioxide may serve as a test for the presence of resorcinol. On heating resorcinol with a little hydrochloric acid at 160° – 180° for a few minutes in a sealed tube, then opening the tube, and adding a few drops of ammonia, the green fluorescence will be perceptible even in presence of only $\frac{1}{3}$ mg. of resorcinol (Barth a. Weidel).

RETENE, $\text{C}^{18}\text{H}^{18}$ (Ekstrand, *Bull. Soc. Chim.* [2], xxiv. 53; *Liebig's Annalen*, clxxxv. 75). This hydrocarbon, originally found in scales on fossil pine-stems in beds of peat and lignite (v. 97), occurs also amongst the products of the destructive distillation of wood (vi. 993), and forms a considerable portion of the buttery mass obtained in the latter part of the distillation of wood tar. From this mass it may be obtained in the pure state by pressure at a low temperature, washing with ether, and recrystallisation from alcohol of 95 per cent. with the aid of animal charcoal.

Retene crystallises in white laminae melting at 98.5° . Its sp. gr. in the crystallised state is 1.13; after fusion and resolidification 1.08. Its vapour-density according to W. Knecht (*Ber.* x. 2074), is 8.28 (air = 1); calc. for $\text{C}^{18}\text{H}^{18}$, 8.1. It has neither taste nor smell. 100 pts. boiling alcohol of 95 per cent. dissolve 69 pts., 100 pts. cold alcohol only 3 pts. of retene. Glacial acetic acid dissolves it readily with the aid of heat, and deposits the greater part of it on cooling. It dissolves easily in ligroin, carbon sulphide, benzene, and ether, but is insoluble in water. With *chlorine* and *bromine* at ordinary temperatures it forms addition-products which decompose when heated, yielding products of substitution. Retene is but very slightly attacked by nitric acid at ordinary temperatures, more easily when heated; fuming nitric acid dissolves it at ordinary temperatures, and water added to the solution throws down a yellow precipitate, the solution of which in alcohol or acetic acid leaves resinous products on evaporation.

A compound of retene with *dinitroanthraquinone* is obtained by evaporating a solution of the two bodies in glacial acetic acid, and crystallises in small needles of a dark orange-red colour.

Retene-picric acid, $\text{C}^{18}\text{H}^{18}\cdot\text{C}^6\text{H}_2(\text{NO}_2)^3\text{O}^3$, crystallises from alcoholic solution in orange-yellow needles, melts at 123° , dissolves in 5 pts. boiling alcohol of 95 per cent. in 44 pts. alcohol at 10° , and is decomposed by water.

Sodium-amalgam does not appear to act upon retene in alcoholic solution. Retene also remains for the most part unattacked when heated with hydriodic acid (sp. gr. 1.68) and red phosphorus at 175° – 200° ; combustible gases are, however, formed, probably hydrocarbons of the fatty series. When retene is passed in vapour over heated lead oxide, a considerable portion of it remains unaltered, a small quantity of naphthalene being, however, produced, together with water.

Chlororetene, $\text{C}^{18}\text{H}^{17}\text{Cl}$. When retene is exposed for a month to the action of chlorine at ordinary temperatures, a greenish viscid fuming mass is formed, which melts without dissolving when treated with boiling alcohol; and on digesting this product with alcoholic potash, then washing it with water, dissolving it in ether, and leaving the ether to evaporate, chlororetene separates as a red syrupy substance which decomposes when heated, with carbonisation and evolution of chlorine.

Bromoretenes. When retene is exposed to the action of bromine-vapour, and the product is treated with alcoholic potash, then dissolved in ether, and left to evaporate, a brownish syrup is obtained, containing 34.4 to 34.6 per cent. bromine [intermediate between mono- and di-bromoretene].

Dibromoretene, $\text{C}^{18}\text{H}^{16}\text{Br}^2$, is prepared by heating 1 mol. retene on the water-bath with 2 mols. bromine and water, washing the product with warm dilute potash-ley and with alcohol, treating the grey viscid mass with alcoholic potash, washing it

repeatedly with water and alcohol, then digesting it with ether and crystallising the white powder which remains undissolved from carbon sulphide. It crystallises in colourless plates, melts at 180° , dissolves readily in carbon sulphide and in ligroin, but is nearly insoluble in ether.

Tetrabromoretene, $C^{18}H^{14}Br^4O^4$, is obtained by acting on retene with excess of bromine, treating the product with boiling aqueous potash and with ether, and re-crystallising the residue from carbon sulphide. It forms colourless prisms, melts at 110° – 112° , is insoluble in alcohol, slightly soluble in acetic acid and in ether, more easily in ligroin, very easily in boiling benzene and carbon sulphide.

When 1 mol. retene is heated in a sealed tube placed in a water-bath with 5 mols. bromine, the product treated with potash ley, water, and alcohol, and then boiled with ether, the tetrabromoretene just described remains undissolved, and the ethereal solution when left to evaporate leaves a compound isomeric therewith, in the form of a resinous mass, slightly soluble in ether and in ligroin, very soluble in carbon sulphide. This modification of tetrabromoretene is also formed from the tetrabromide of dibromoretene, $C^{18}H^{16}Br^2$, Br^2 , by the action of alcoholic potash.

Oxidation-products of Retene. When warm solutions of retene and chromic acid in glacial acetic acid are mixed together, a violent action takes place, the liquid on cooling becoming filled with needle-shaped crystals; and on diluting with water, and treating the residue with solution of sodium carbonate, and then with warm ether, which removes a viscid mass, the chief product, $C^{16}H^{14}O^2$ (called dioxyretistene by Wahlfors, vi. 994) remains undissolved. The soda-solution with which the crude product has been treated, yields, when concentrated, yellow scaly crystals the solution of which gives a flocculent precipitate with sulphuric acid. On treating this precipitate with alcohol at 50° , a brown mass remains undissolved, and the liquid on cooling deposits yellowish shining scales. By saturating the mother-liquor of the first-separated scales with sulphuric acid, a brown precipitate is formed which when boiled with water partly dissolves, forming a yellow liquid, from which hydrochloric acid throws down white nearly insoluble flocks; and from this precipitate alcohol extracts the compound $C^{18}H^{18}O^2$, which crystallises in yellow shining scales. When the residue left after the extraction of this last compound is boiled for some time with concentrated baryta-water, a brown-yellow solution is obtained, yielding, on addition of hydrochloric acid, a brown precipitate from which, by repeated crystallisation from boiling alcohol, the compound $C^{18}H^{17}O^2$ is obtained in colourless needles.

Dioxyretistene crystallises on cooling from its hot alcoholic solution in flat, deep orange-coloured prisms, melts at 190° , sublimes in orange-red needles without decomposition when cautiously heated, and is moderately soluble in benzene and acetic acid. 100 pts. boiling alcohol of 95 per cent. dissolve 2.2 to 2.3 pts. of it; cold alcohol only 0.15 pts. It is not attacked by chlorine at ordinary temperatures, but *bromine* acts upon it, with elimination of hydrogen. When heated with ordinary *nitric acid*, it dissolves unaltered, but the fuming acid converts it into a nitro-product. *Sulphuric acid* dissolves it without alteration, but on heating it with the acid on the water-bath, sulphur dioxide is evolved, and on cooling, a red gelatinous mass is formed, which gives red crystalline flocks when boiled with water. By prolonged boiling with *chromic acid* in acetic acid solution it yields oxidation-products soluble in aqueous sodium carbonate. It is not altered by dilute solution of *potassium* or *sodium hydroxide*, but the concentrated alkalis convert it into a greenish resinous mass. When fused with potassium hydroxide, it yields a black mass, forming with water a red solution which yields with sulphuric acid a greenish precipitate consisting of a mixture of several bodies, from which ether extracts a red viscid mass, while the residue dissolves in carbon sulphide or in benzene with a fine blue or greenish-blue colour. Dioxyretistene dissolves with difficulty in solution of *acid sodium sulphite*, and is precipitated therefrom by hydrochloric acid in its original state.

The compound called by Wahlfors '*monobromoretistene*,' obtained by the action of 2 mols. bromine on 1 mol. dioxyretistene, has, according to Ekstrand, the empirical formula $C^{16}H^{11}Br^4O^2$. It crystallises from glacial acetic acid in small red prisms, melts at 234° – 235° , is slightly soluble in alcohol, ether, and carbon sulphide, more soluble in benzene and glacial acetic acid.

When dioxyretistene is heated with 10 pts. *baryta*, there is formed, together with water and combustible gas, a red oil which solidifies after some time, and yields to boiling alcohol a body, $C^{22}H^{21}O$, which crystallises in long flat colourless needles, melts at 89° – 90° , and is insoluble in aqueous sodium carbonate. The residual oil yields by fractional distillation a liquid which has the composition $C^{21}H^{22}$, and boils at 215° – 220° .

Dioxyretistene is not altered by the action of sulphurous acid in alcoholic solution, but when heated with *zinc-dust* and *potash-ley* it partly dissolves, and the solution

yields with hydrochloric acid a green precipitate of a quinol, which on exposure to the air is quickly reoxidised to dioxyretistene. Dioxyretistene, distilled with zinc-dust, yields, together with retene, a small quantity of a hydrocarbon, $C^{14}H^{14}$, which melts at 56° – 57° , and is probably dibenzyl.

The compound $C^{16}H^{16}O^3$ (p. 1755) crystallises in colourless shining scales, melts at 139° , dissolves very easily in alcohol, ether, and glacial acetic acid, sparingly in water, from which it crystallises in shining scales; the solution has an acid reaction. The *sodium salt*, $C^{16}H^{15}NaO^3$, crystallises in shining scales; the *potassium salt* likewise. The *barium salt*, $(C^{16}H^{15}O^3)_2Ba$, forms large colourless laminae. The solution of the sodium salt forms with ferric chloride, after a while, a precipitate consisting of small needles; with lead acetate, a bulky precipitate becoming crystalline after some time; with silver nitrate a precipitate made up of microscopic prisms.

The compound $C^{18}H^{17}O^2$ (p. 1755) melts at 222° , may be sublimed, and dissolves easily in alcohol, ether, and glacial acetic acid. The *sodium salt*, $C^{18}H^{16}NaO^2$, forms large brown-yellow laminae, and dissolves with moderate facility, its solution giving amorphous precipitates with lead acetate and silver nitrate. The *barium salt* forms small shining scales.

RETENESULPHONIC ACIDS (Ekstrand, *Liebigs Annalen*, clxxxv. 86).

Retenedisulphonic acid, $C^{18}H^{16}(SO^2H)^2$.—When retene is gradually added to a mixture of equal volumes of concentrated and fuming sulphuric acid, and the liquid is left to itself for two to three weeks, slender needles of the compound $C^{18}H^{16}(SO^2H)^2 + 5H^2SO^4$ separate out. The free disulphonic acid obtained from the barium or lead salt is very soluble, and separates from a concentrated aqueous solution in small needles and from glacial acetic acid in well-defined needles or prisms. Its concentrated aqueous solution is precipitated by sulphuric acid; and the compound thus formed seems to contain varying quantities of the latter acid. The following salts have been prepared and analysed:

			1 part dissolves
$C^{18}H^{16}(SO^2K)^2$	+	$\frac{1}{2}H^2O$ (at 100°), silky needles,	in 5-6 of water
$C^{18}H^{16}(SO^2Na)^2$	+	$\frac{1}{2}H^2O$ " "	in 2-3 "
$C^{18}H^{16}(SO^2)^2Ba$	+	H^2O	
	+	$6H^2O$ (at 15°) prisms, slowly	in 60-61 "
$C^{18}H^{16}(SO^2)^2Sr$	+	$1\frac{1}{2}H^2O$ (at 100°) "	in 24-25 "
$C^{18}H^{16}(SO^2)^2Ca$	+	$1\frac{1}{2}H^2O$	
	+	$8H^2O$ (at 15°) "	in 20-21 "
$C^{18}H^{16}(SO^2)^2Mg$	+	$2H^2O$ (at 100°), woolly needles,	in 25-26 "
$C^{18}H^{16}(SO^2)^2Cu$	+	$1\frac{1}{2}H^2O$ " pale green	in 3-4 "
	+	$5H^2O$ (at 15°), long needles	
$C^{18}H^{16}(SO^2)^2Pb$	+	H^2O (at 100°), long prisms,	
		slowly in 54-55 "	

Retenedisulphonic dichloride, $C^{18}H^{16}(SO^2Cl)^2$, obtained by the action of phosphorus pentachloride on the potassium salt, crystallises from hot glacial acetic acid in hard prisms, melting at 175° ; it dissolves readily in benzene, sparingly in ether, and is scarcely attacked by boiling water, which does not decompose it completely till the temperature is raised to 160° .

An isomeric retenedisulphonic acid appears to exist.

Retenetrisulphonic acid, $C^{18}H^{15}(SO^2H)^3$, is formed by heating retene with a mixture of common and fuming sulphuric acid on a water-bath; it is readily soluble in water; is not precipitated by sulphuric acid; and is obtained on cooling from a very concentrated aqueous solution as a crystalline mass, which dissolves very readily in water, alcohol, and acetic acid. Its *barium salt*, $[C^{18}H^{15}(SO^2)^3]_2Ba + \begin{cases} 3H^2O \text{ at } 100^{\circ} \\ 18H^2O \text{ at } 15^{\circ} \end{cases}$ differs somewhat in form and solubility according to the manner in which it is prepared (crystallising in needles soluble in 16 pts. water, or in prisms soluble in 11 pts.) The *lead salt*, $[C^{18}H^{15}(SO^2)^3]_2Pb + \begin{cases} 3H^2O \text{ at } 100^{\circ} \\ 18H^2O \text{ at } 15^{\circ} \end{cases}$ forms thin needles.

The acid obtained by treating retene with sulphuric anhydride yields three different barium salts.

REZBANYITE. See COSALITE (p. 572).

RHABDOPHANE. This name has been given to a very rare mineral from Cornwall, consisting essentially of didymium and erbium phosphates (Lettsom, *Compt. rend.* lxxvi. 1028).

RHAGITE. A bismuth arsenate, $5Bi^2O^3, 2As^2O^5 + 8H^2O$, sp. gr. 6.82, occurring together with several uranic arsenates (vii. 1190), in the White Hart Mine, near

Schneeberg in Saxony. Its analysis by C. Winckler (*Jahrb. Min.* 1871, 869; 1874, 682) gave:

Bi ² O ³	As ² O ³	H ² O	Fe ² O ³ , Al ² O ³	CoO	CaO	Matrix
72.8	14.2	4.6	1.6	1.5	0.5	3.3 = 98.5

RHAMNUS. The glucoside of yellow berries (*Rh. infectorius*), called xanthorhamnin by Gellatly, rhamnegin by Schützenberger, and its derivatives, have been examined by Liebermann a. Hörmann (*Ber.* xi. 952, 1618), with results different from those obtained by previous investigators (v. 100; vi. 994; vii. 561).

Xanthorhamnin, boiled with dilute sulphuric acid, readily splits up into rhamnetin, C¹²H¹⁰O⁵, and a sugar, supposed by Liebermann a. Hörmann to be different from all others yet known, and named by them 'rhamnodulecite.' Behrend, however (*Ber.* xi. 1353), has shown that it is identical with isodulcitol, C⁶H¹⁴O⁶ (p. 1131). Xanthorhamnin is also converted into rhamnetin by simply heating it at 130°–160°. Liebermann a. Hörmann assign to xanthorhamnin the formula C⁴²H⁴⁶O²⁹, which agrees nearly with the analysis of the potassium-derivative (*infra*), and represents correctly the resolution of xanthorhamnin into rhamnetin and isodulcitol, these products being formed in the proportion of 1 mol. rhamnetin to 2 mols. dulcitol:

Potassium-xanthorhamnin, C⁴⁸H⁶²K⁴O²⁹, is obtained on mixing an alcoholic solution of xanthorhamnin with a slight excess of alcoholic potash, as a thick yellow precipitate which, after rapid filtration, washing with alcohol, and drying over sulphuric acid, forms a yellow powder, yielding by analysis 11.81 per cent. potassium; calc. 12.40 per cent. It is tolerably permanent when dry, but becomes brown and resinous when moist.

Rhamnetin, C¹²H¹⁰O⁵, crystallises from water containing sulphuric acid in microscopic needles; from phenol in distinct yellow needles.

Dibromorhamnetin, C¹²H⁸Br²O⁵, prepared by adding bromine to finely pulverised rhamnetin suspended in glacial acetic acid, forms beautiful yellow needles, easily soluble in hot alcohol and hot glacial acetic acid, also in benzene; alkalis dissolve it with yellow colour. It dyes like rhamnetin, only with a somewhat redder tint.

Diacetyl-rhamnetin, C¹²H⁸(OC²H³O)²O⁵, is obtained by boiling rhamnetin with acetic anhydride and anhydrous sodium acetate in a vessel with upright condenser, till a portion of the crystallised product is no longer coloured by dilute alkali. It crystallises from alcohol containing one-tenth part of acetic anhydride in white silky needles melting at 185°.

Dibromacetyl-rhamnetin, prepared in like manner from dibromorhamnetin, forms white shining needles which turn yellow at 200°, and melt at 211°–212°.

Dipropionyl-rhamnetin, C¹²H⁸(OC³H⁵O)²O⁵, prepared like the acetyl-compound with sodium propionate and propionic anhydride, crystallises in light yellow needles melting at 158°–162°.

Dibenzoyl-rhamnetin, C¹²H⁸(OC⁷H⁵O)²O⁵, prepared by heating 1 pt. rhamnetin with 4 pts. benzoic anhydride at 150°, crystallises in small silky almost colourless needles, easily soluble in glacial acetic acid, sparingly in chloroform and in alcohol, melting at 210°–212°.

Dimethyl-rhamnetin, C¹²H⁸(CH³)²O⁵, is formed by heating xanthorhamnin at 120°–130°, with potassium methyl-sulphate and absolute methyl alcohol, the xanthorhamnin being first converted, with separation of isodulcitol, into rhamnetin, which then takes up 2 at. methyl. Dimethyl-rhamnetin crystallises in needles having a very faint yellowish tint, and melting at 156°–157°.

RHODIUM. Pulverised rhodium decomposes formic acid, with rise of temperature, into water and carbon dioxide. When the decomposing power slackens, it may be restored by washing the metal and drying it in the air. Alcohol is also decomposed by rhodium in presence of alkalis, at a temperature only a little above that of the air, hydrogen being given off, and an alkaline acetate produced. The same action is produced by iridium, but not by platinum or palladium (Deville a. Debray, *Compt. rend.* lxxviii. 1782).

On *Mercaptide of Rhodium*, see p. 1276.

RHCADINE. On the occurrence of this base in the unripe capsules of the red poppy (*Papaver Rhæas*), see p. 1664.

RHUBARB. From a comparison of observations made in the last few years on the sources of official rhubarb, H. Werner (*Arch. Pharm.* [3], xi. 116) concludes that Russian and Chinese rhubarb are obtained from *Rheum palmatum*, and that this plant

is indigenous in the Upper Hoang-ho in the Highland of West China around Lake Koko-nur.

Comparative analyses of different kinds of rhubarb have been made by Dragendorff (*Pharm. J. Trans.* [3], viii. 826):

I. *Rheum Moscovicum*, imported in 1860 with the last consignment of the Crown rhubarb.

II. *Rheum Chinense*, delivered from the Crown Warehouse, St. Petersburg, 1877.

III. *Rheum palmatum Tanguticum*.

IV. *Rheum anglicum cultum* from Moscow.

V. Rhubarb cultivated in Siberia.

Cathartic acid appears to be the purgative, and tannin and chrysophane the tonic constituents of rhubarb, so that No. I. and II. must be regarded as best adapted for therapeutic purposes.

On the detection of Turmeric in Rhubarb, see TURMERIC.

RICINOLEIC ACID, $C^{18}H^{34}O^2$. This acid may be purified by fractional precipitation of crude castor-oil soap with calcium chloride. If the first fractions, amounting to about a third of the entire precipitation, be rejected, the following $\frac{2}{3}$ will be found to consist of pure calcium ricinole (Claus a. Hilkenkamp, *Ber.* ix. 1916).

Hydriodic acid appears to act but slightly on ricinoleic acid at 100° – 170° ; but on gradually adding phosphorus and iodine to a warm emulsion of ricinoleic acid in a small quantity of water, a yellow oil is obtained, consisting of iodostearidonic acid, $C^{18}H^{32}IO^2$. This acid easily takes up 1 mol. bromine, forming the acid $C^{18}H^{32}Br^2IO^2$, and when treated with nascent hydrogen (zinc-filings and dilute hydrochloric acid) it is converted into stearic acid (Claus a. Hilkenkamp).

RICINUS. The leaves of the castor-oil plant (*Ricinus communis*) have been examined by E. S. Wayne (*Pharm. J. Trans.* [3], iv. 749), who finds in them ricinine and considerable quantities of potassium nitrate. They yielded 24 per cent. ash containing:

CaO	MgO	K ² O	Na ² O	Fe ² O ³	P ² O ⁵	SO ³	Cl	CO ²	Silica and sand	Loss
33.40	6.20	27.15	2.12	0.70	6.68	2.90	1.63	16.20	2.41	0.61 = 100

When castor-oil is distilled under reduced pressure, a colourless oil, amounting to about a third of its volume, passes over, together with a small quantity of a watery liquid, while a spongy saponifiable mass remains in the retort. The oily distillate consists, to about one-half, of cœnanthaldehyde, and, after this has passed over, the thermometer suddenly rises considerably, then remains stationary for some time, and a body collects in the receiver, which solidifies to a crystalline mass, and appears to be a new acid of the oleic series. It melts at 24.5° , boils at 198° – 200° , under a pressure of 90 mm., and gives by analysis numbers agreeing with the formula $C^{11}H^{20}O^2$. It is resolved by fusion with potash into acetic and nonoic acid, ($C^9H^{18}O^2$), and yields with bromine an addition-product, from which hydrobromic acid is readily extracted by alcoholic potash (F. Krafft, *Ber.* x. 2034).

RIPIDOLITE. This mineral from the Zillerthal has been analysed by A. J. Egger (*Min. Mitth.* 1874, 244), with the following results:

SiO^2	Al^2O^2	Fe^2O^2	FeO	CaO	MgO	H^2O	Sp. gr.
26.02	20.16	1.07	28.08	0.44	15.50	9.65 = 100.92	2.955

RIVOTITE. An amorphous mineral of yellow-green to dark grey-green colour, occurring, contaminated with malachite and imbedded in limestone, on the western declivity of the Sierra del Cadi, in the province of Lerida in Spain. It has been analysed by X. Ducloux (*Compt. rend.* lxxviii. 1471), who represents the results by the formula $Sb^2O^5 + 4(Cu, Ag)CO^2$:

Sb^2O^5	CO^2	CuO	Ag^2O	CaO	Sp. gr.
42.00	21.00	39.50	1.18	trace = 103.68	3.55–3.62

ROCELLA FUCIFORMIS. This lichen, which is characterised by an intensely bitter taste, has been examined by Stenhouse & Groves (*Proc. Roy. Soc.* xxv. 60). It was treated with milk of lime, dried and exhausted with hot alcohol; the extracts were freed from alcohol; the residue was boiled several times with small quantities of alcohol, and then with benzene to remove fat and chlorophyll; and the residue then left was dissolved in boiling alcohol and filtered hot. The alcoholic solution on cooling deposited two kinds of crystals—slender feathery crystals of a substance which has not yet been examined, and large shining prisms of a substance having the composition $C^{27}H^{28}N^3O^5$, designated as *Picrorocellin*. This compound melts at 192° – 194° , is moderately soluble in hot alcohol, sparingly in ether and in benzene, nearly insoluble in water, petroleum, and carbon sulphide. By oxidation with chromic acid mixture it yields benzaldehyde and benzoic acid.

Xanthorocellin, $C^{21}H^{17}N^2O^2$, is formed by heating picrorocellin to 220° , or boiling it with dilute hydrochloric or sulphuric acid, or best by dissolving it in acetic acid, and boiling the solution, after adding a few drops of hydrochloric acid. It crystallises in yellow needles, dissolves easily in hot alcohol, and is strongly attacked by hot nitric acid, yielding a substance not yet analysed, which crystallises in hexagonal prisms.

Picrorocellin, boiled with aqueous or alcoholic soda-ley, yields a substance which crystallises in large colourless prisms, melts at 154° , and gives by analysis numbers agreeing nearly with the empirical formula $C^{25}H^{25}N^2O^2$.

ROGERSITE. See NIORATES (p. 1395).

ROMAN CHAMOMILE OIL. The acid product obtained by saponifying this oil—hitherto regarded as a single acid, viz. angelic acid (p. 86)—is now found to be a mixture of two isomeric bodies, $C^8H^8O^2$, viz. angelic acid, melting at 45° – 45.5° , and boiling at 185° (not at 194° as formerly stated), and tiglic acid, melting at 64.5° and boiling at 198.5° , together with small quantities of isobutyric acid, and a fourth acid, not yet isolated, but probably consisting of methacrylic acid (Fittig & Kopp, *Ber.* ix. 1195).

Koebig (*Liebig's Annalen.* cxcv. 92), by submitting the oil to careful fractional distillation, has shown that it consists of a mixture of isobutylic isobutyrate, isobutylic angelate, amylic angelate, and amylic tiglate, together with the angelic and tiglic ethers of a new primary hexyl alcohol (sp. gr. 0.8295 at 15° , b. p. 152 – 153°), and the corresponding ethers of terpene-alcohol or anthemol. Other substances, if present at all, can exist in the oil only in very small quantities.

ROSANILINE, $C^{20}H^{19}N^3$. This base is formed by digesting aurin with alcoholic ammonia at 150° for several days, or with aqueous ammonia at 120° for twenty hours; if the action be longer continued, leucaniline is produced. At 180° the reaction proceeds more quickly, with formation of rosaniline (Dale & Schorlemmer, *Ber.* x. 1016, 1123), see AURIN (p. 136). According to Monnet, Reverdin & Nölting (*Ber.* xii. 445),

the presence of meta-toluidine in commercial toluidine from which rosaniline is prepared, injures the purity of the colours.

Rosenstiehl (*Compt. rend.* lxxxii. 415; *Ann. Chim. Phys.* [5], viii. 176; *Chem. Soc. J.* xxix. 935) describes three isomeric rosanilines obtained: (α) from aniline and paratoluidine; (β) from ortho-toluidine (pseudotoluidine) alone, or from ortho-toluidine and aniline; (γ) from ortho- and para-toluidines, or from a mixture of these two bases with aniline. This modification forms the chief constituent of toluidine-red and of the fuchsines. As β-rostaniline is formed from o-toluidine alone, the latter must first be partly converted by the oxidising agent into aniline. All the three rosanilines are resolved into their components by the action of hydriodic acid.

Diazorosaniline is formed from rosaniline by the action of nitrous acid. Its *aurchloride*, $C^{20}H^{18}N^6Cl^3.H^2O + AuCl^3$, is a light yellow flocculent crystalline precipitate, which detonates when heated, and when boiled with water gives off all its nitrogen in the free state. The *platinchloride*, $(C^{20}H^{18}N^6Cl^3.H^2O)^2.3PtCl^4 + 6H^2O$, likewise gives off all its nitrogen when boiled with water, leaving a residue containing rosolic acid. The *aurchloride of diazohydrocyanorosaniline*, $C^{20}H^{14}(CN)^4N^4Cl^3.3AuCl^3$, is a yellow flocculent precipitate, which, when boiled with water, gives off only 6 ats. nitrogen. The *sulphate* is decomposed by boiling water, yielding hydrocyanorosolic acid (E. a. O. Fischer, *Liebig's Annalen*, exciv. 277).

Diazoleucaniline is formed by passing nitrous gas into leucaniline hydrochloride. Its *hydrochloride* is a light yellow sticky mass, forming with auric chloride the sparingly soluble double salt, $C^{20}H^{18}N^6Cl^3.3AuCl^3 + H^2O$.

When leucaniline is dissolved in strong sulphuric acid, the solution in small portions treated with nitrous acid, and the resulting red liquid added, with stirring, to boiling alcohol, a dark red liquid is obtained, which when neutralised deposits an oil yielding on distillation tolyldiphenylmethane, $C^{20}H^{18} = CH(C^6H^5)(C^6H^5)^2$. Hence it appears that diazoleucaniline is converted by boiling alcohol into tolyldiphenylmethane (E. a. O. Fischer).

Pararosaniline, $C^{19}H^{17}N^3 = \begin{matrix} NH^2.C^6H^4 \\ NH^2.C^6H^4 \end{matrix} > C < \begin{matrix} C^6H^4 \\ NH \end{matrix}$ (E. a. O. Fischer, *Ber.* xi.

195, 473, 612, 1079, 1598; *Liebig's Annalen*, exciv. 242). This base is formed: 1. By oxidising a solution of trinitrotriphenylmethane, $C^{19}H^{19}(NO^2)^3$, in glacial acetic acid with chromic acid, whereby it is converted into trinitro-triphenyl carbinol, $C^{19}H^{12}(NO^2)^3OH$, and reducing the latter with zinc-dust, taking care that the action does not go too far, as otherwise paraleucaniline will be formed. The transformation takes place by two stages, as represented by the following equations:

Diazopararosaniline, produced by the action of nitrous acid on pararosaniline, forms a hydrochloride:

which is decomposed by boiling with water, with formation of aurin or pararosolic acid, $C^{19}H^{14}O^3$. It unites with auric chloride, forming a yellow crystalline double salt slightly soluble in water.

Hydrocyanopararosaniline, $C^{20}H^{18}N^4 = C^{19}H^{17}N^3.ONH$, easily obtained by direct combination, crystallises from hot alcohol, in which it is but slightly soluble, in colourless oblique prisms. Its hydrochloride decomposes at 180° – 190° into HCl, HCN, and parafuchsine. Nitrous acid converts the base into diazohydrocyanopararosaniline, the hydrochloride of which, $C^{20}H^{12}N^7Cl^3 + 2H^2O$, forms slender, colourless, very explosive needles, and is decomposed by boiling with water, yielding a compound identical with the hydrocyano-derivative which Graebe a. Caro obtained from aurin:

Pentamethyl-pararosaniline, $C^{19}H^{12}(CH^3)^3N^3$.—This, according to E. and O. Fischer (*Ber.* xi. 2095), is the constitution of methyl-violet, which is produced by

the oxidising action of manganese dioxide and sulphuric acid on hexmethyl-triamidotriphenyl-methane, the product of the action of 1 mol. chloral on 3 mols. dimethylaniline in presence of zinc chloride. The formation of methyl-violet from this hexmethylated base is represented by the equation :

Paraleucaniline, C¹⁹H¹⁹N³, is produced by the action of nascent hydrogen (Zn and HCl) on pararosaniline, and is precipitated as a hydrochloride, C¹⁹H¹⁹N³.3HCl + H²O. The free base may be obtained by adding zinc-dust to a solution of trinitro-triphenylmethane or trinitrotriphenylcarbinol in glacial acetic acid till the red colour disappears. It is precipitated by ammonia, and converted into pararosaniline by oxidising agents, most readily by heating the free base for a short time with a syrupy solution of arsenic acid at 130°-140°. *Paraleucaniline hydrochloride*, heated at 150°-160°, is partly converted into fuchsine.

Paraleucaniline is converted by nitrous acid into a diazo-compound, the hydrochloride of which, C¹⁹H¹⁹ON²Cl², crystallises with difficulty, and imparts a greenish-blue colour to solutions. By dissolving paraleucaniline in strong sulphuric acid, treating the solution by small portions with nitrous acid, and proceeding in the manner already described for leucaniline (p. 1760), diazoparaleucaniline is first produced, and then converted into triphenylmethane, CH(C⁶H⁵)³.

a. Caro, *Ber.* vi. 1390; *Liebig's Annalen*, clxx. 184; Dale a. Schorlemmer, *Ber.* x. 2230; *Chem. Soc. J.* xxxv. 159). This compound is formed by the action of nitrous acid on rosaniline :

It was formerly supposed to be produced by the action of oxalic acid on phenol in presence of sulphuric acid; but Dale a. Schorlemmer have shown that the product of this reaction is not rosaurin, but its lower homologue, aurin, C¹⁹H¹⁴O³ (p. 1763). At present the reaction above mentioned is the only one by which rosaurin has been obtained. The name 'rosaurin' is proposed by Dale a. Schorlemmer in preference to the older name, rosolic acid, to indicate the homology of the compound to aurin, and the resemblance which it exhibits to aurin in its power of combining with acids.

Preparation.—500 grams of rosaniline (or the corresponding quantity of a rosaniline salt) are dissolved in a mixture of 1500 c.c. of concentrated hydrochloric acid with 1500 c.c. of water, and the brownish-yellow liquid which is formed is diluted, after filtration, with about 150 litres of cold water. A dilute solution of sodium or potassium nitrite is gradually added, with constant stirring, till the rosaniline has almost but not quite disappeared. This point may be determined by placing from time to time a drop or two of the mixture on filter paper, and watching the outside part of the circle formed. As long as rosaniline is present, a red border is produced, and the addition of the nitrite must be continued till this appears very faint, but still perceptible. The liquid is then gradually heated to boiling, and as soon as the evolution of gas ceases, it is quickly filtered. On cooling, tolerably pure rosaurin separates in fine, brilliant, brownish green crystals. To purify this product, it is dissolved in caustic soda, and the solution is saturated with sulphurous acid. The impurities separate in dark brownish-red flocks, and by addition of a mineral acid to the nearly colourless liquid and gentle warming, the rosaurin is obtained in a state of great purity. Obstinate adhering inorganic salts are best got rid of by solution in alcohol and precipitation with hot water. The best way to crystallise rosaurin is from dilute alcohol, or by decomposing a hot saturated alcoholic solution with boiling water. In the first case, ruby-red crystals are slowly formed, while in the second greenish plates with metallic lustre separate out.

Rosaurin dissolves very easily in hot alcohol, somewhat more sparingly in the cold, and is also moderately soluble in glacial acetic acid and ether, but insoluble in benzene and carbon disulphide. Water dissolves it slightly, acids a little more freely. These solutions have a yellowish-red colour. Rosaurin dissolves in alkalis with a red colour, which in thin layers becomes of a bluish-red, in thick layers of a yellowish-red tint. In accordance with this the absorption spectrum is a somewhat deep-coloured solution consists only of a bright band (from 30 to 50 on the scale of the Kirchhoff-Bunsen apparatus). On dilution a violet streak appears; on still further dilution the bright streaks extend, and finally only a broad dark band is seen,

the middle of which is situated at 64 to 65, but at 95 the green is very feeble. Rosaurin does not melt when heated to 270°. On stronger heating a bulky carbonaceous mass is formed, and phenol and water escape.

Reactions.—Rosaurin has but a very feeble acid character, and therefore does not easily form well-characterised salts with bases. The ammonia salt separates in the form of steel-blue needles, and dissolves with difficulty in alcohol, but easily in water. It gradually loses its ammonia on exposure to air as well as by washing. The barium and lead compounds also decompose when washed. *Reducing agents* convert rosaurin into hydrosaurin. A solution of a rosaurin-compound in caustic soda is easily decolorised by warming with zinc-dust. Sodium-amalgam produces the same result. On the other hand, sulphurous acid does not effect this reduction even at 200°. Rosaurin dissolves, with the aid of heat, in *potassium cyanide*, and acids added to the colourless solution throw down hydrocyanorosaurin. *Acid sulphites of the alkalis* dissolve and perfectly decolorise rosaurin, and thus afford a test of its purity.

Oxidising agents act readily on rosaurin, giving rise to compounds which dissolve in alkalis, with formation of the same colour as the acid, and are precipitated of a vermilion colour, but are difficult to crystallise. In such cases a compound containing more oxygen, and answering to the formula $C^{20}H^{14}O^5$, seems to be formed.

When rosaurin is heated with *water* at 220°–250°, a colourless body easily soluble in water is formed, in addition to brownish products of decomposition and phenolic bodies. This colourless compound may be obtained free from admixture, by extraction with boiling water, evaporation, and repeated crystallisation. In its properties and the result of its analysis it agrees with the compound which Liebermann obtained by heating rosaniline with water at 270°. It melts at about 200°, and has a composition which lies between $C^{20}H^{12}O^4$ and $C^{20}H^{16}O^4 + H_2O$. The composition of the derivative obtained by heating it with acetic anhydride to 140°–150° shows that this compound, or at least its chief constituent, has a composition represented by the formula $C^{20}H^{14}O^4$, and that four of its hydrogen-atoms can be replaced by acetyl. This tetracetyl-compound, $C^{20}H^{12}O^4(C^2H^3O)^4$, melts at 148°–150°, is easily soluble in alcohol and acetic acid, insoluble in water, and easily crystallisable in needles. Liebermann failed to obtain rosaurin from rosaniline, because rosaurin is decomposed by hot water.

Rosaurin and *acetic anhydride* heated in sealed tubes to 150°–200° do not give rise to an acetyl-rosaurin; but, according to the temperature, various colourless compounds are formed, and among them triacetyl-leucorosaurin, which can be isolated in the pure state and melts at 148°.

Leucorosaurin, $C^{20}H^{10}O^3$, prepared by warming an alkaline solution of rosaurin with zinc-dust till the liquid becomes colourless, separates from the filtrate in brilliant silky colourless crystals. By recrystallisation from dilute alcohol, columnar or acicular crystals are formed, which generally appear brownish. It is easily soluble, in alcohol and ether, especially on heating, but nearly insoluble in water. It gives with alkalis a colourless solution, which, when treated with potassium ferricyanide, assumes the colour of rosaurin, but contains instead a body richer in oxygen. Ferric chloride acts upon it in the same way.

Triacetyl-leucorosaurin, $C^{20}H^{15}O^3(C^2H^3O)^3$, is formed when leucorosaurin is heated with anhydrous acetic acid or acetyl chloride to 130°–150°. The product of the reaction, when decomposed by water, washed, and crystallised from hot alcohol, deposits triacetyl-leucorosaurin in long needles. This compound is insoluble in water, only slightly soluble in cold alcohol, but moderately soluble in hot alcohol. It melts at 148°–149°, and solidifies to a glassy mass, which, after a long time, becomes crystalline. When boiled with caustic soda, it shows tolerable stability, but gradually dissolves to a red liquid.

Hydrocyanorosaurin, $C^{21}H^{17}NO^3$, is obtained by acting on the potassium or sodium-derivative of rosaurin with excess of potassium cyanide. Acids precipitate hydrocyanorosaurin from the cold solution in white crystalline flocks, but if the solution is hot, the product cakes together in resinous brownish masses, which gradually become crystalline on cooling. It may be purified by recrystallisation from dilute alcohol. Hydrocyanorosaurin dissolves easily in alcohol, ether, and benzene, but with difficulty in water. Alkalis dissolve it easily to colourless liquids, which become faintly red after long boiling. Its melting point cannot be obtained, since it remains solid at 200°, and decomposes when heated above this point. Concentrated sulphuric acid dissolves it slowly in the cold, readily at a gentle heat, with production of a violet colour, which becomes redder on further heating, and brown when boiled. On heating hydrocyanorosaurin with acetic anhydride to 140°–150°, a derivative is obtained, which has the composition of *triacetyl-hydrocyanorosaurin*, $C^{21}H^{11}(C^2H^3O)^3NO^3$, is insoluble in water, easily soluble in acetic acid and alcohol, and crystallises in small

colourless prisms which melt at 143° . By strong sulphuric acid it is coloured in the same way as hydrocyanorosaurin.

Tetrabromorosaurin, $C^{20}H^{12}Br^4O^3$, is formed by dropping an excess of bromine into a solution of rosaurin in warm glacial acetic acid, and separates at once in brownish-green plates having a metallic lustre. The crystals may be freed from rosaurin by boiling with alcohol, but some compounds containing a smaller amount of bromine remain: these can be removed by recrystallisation from glacial acetic acid.

Tetrabromorosaurin crystallises from acetic acid, which dissolves it abundantly on heating, in brilliant green plates. When precipitated from its solution by water, or from an alkaline solution by an acid, it forms red microscopic crystals. It is not soluble in water; dissolves with difficulty in alcohol and ether; with a fine violet colour in the fixed alkalis and in ammonia. The absorption spectrum of a moderately deep-coloured ammoniacal solution shows, in addition to a bright band reaching from 30 to 45 (Kirchhoff-Bunsen scale), a second fainter one from 110 to 125. In dilute solutions a faint dark band appears between 50 and 60, while the part of the spectrum corresponding with the above bright streaks is intensely bright. Reducing agents convert this tetrabromo-compound into the corresponding leuco-compound; potassium cyanide forms a hydrocyano-derivative, and alkaline sulphites give rise to colourless solutions, from which the brominated compound is precipitated by mineral acids in red flocks.

Tetrabromoleucorosaurin, $C^{20}H^{14}Br^4O^3$, obtained by heating the last-described compound with zinc-dust and caustic soda, is easily soluble in alcohol, and crystallises in plates from weak spirit.

Hydrocyanotetrabromorosaurin, prepared like hydrocyanorosaurin, crystallises in colourless plates, insoluble in water, but easily soluble in alcohol and ether. Heated with sulphuric acid, it dissolves with blue colour (Graebe a. Caro).

Aurin, $C^{10}H^{14}O^3 = (C^6H^4OH)^2C \begin{smallmatrix} \diagup O \\ | \\ \diagdown C^6H^4 \end{smallmatrix} .^*$ *Pararosanolic acid*.—This lower homo-

logue of rosaurin is formed: 1. By the action of nitrous acid on pararosaniline (p. 1760):

2. Together with formic acid, by heating phenol with oxalic acid in presence of sulphuric acid:

Pure aurin may also be prepared from the commercial product known by the same name (vii. 117), by passing ammonia-gas into a saturated alcoholic solution of the latter, whereupon steel-blue crystals separate out, consisting of ammonia-aurin, $C^{10}H^{14}O^3 \cdot 2NH^3$; and these, when decomposed by dilute hydrochloric or acetic acid, yield aurin, which, after being well washed and repeatedly crystallised from alcohol, gives by analysis, as a mean result, 78.55 per cent. carbon and 4.96 hydrogen, the formula $C^{10}H^{14}O^3$ requiring 78.62 C, 4.83 H, and 16.55 O.

A further confirmation of this formula of aurin is afforded by its conversion into leucaurin, which is effected by treating it with acetic acid and zinc-dust. The leucaurin thus prepared crystallised from dilute alcohol in large flat glistening needles, and when dried over sulphuric acid at 100° , gave by analysis 77.98 and 78.03 per cent. C, 5.68 and 5.7 H, agreeing with the formula $C^{10}H^{16}O^3$, which requires 78.08 C, 5.48 H, and 16.44 O.

Tetrabromaurin, $C^{10}H^{10}Br^4O^3$, is formed on adding a hot solution of aurin in acetic acid to a mixture of acetic acid and excess of bromine, and separates in small brownish crystals having a bronze lustre. Like tetrabromorosaurin (*supra*), it dissolves in alkalis with violet colour, and in acid solution dyes silk and wool deep violet.

Compound of Aurin with Acetic Anhydride, $C^{10}H^{14}O^3, C^4H^4O^3$.—This compound is best prepared by gently boiling aurin with acetic anhydride, mixing the resulting yellowish solution with alcohol to decompose the excess of the latter, adding hot water till a precipitate begins to form, and leaving the liquid to cool. The compound then separates out in small white plates melting at 168° . It may also be obtained, though less readily, by heating aurin with acetyl chloride and a little acetic acid till all the excess of acetyl chloride is expelled, and then adding water. It may be boiled with alcohol or acetic acid without alteration, but on adding a small quantity of hydrochloric acid, the solution turns yellow, and on cooling deposits stellate groups of brown needles consisting of a compound not yet analysed.

* Formerly represented by the formula $C^{20}H^{14}O^3$, and supposed to be identical with rosanolic acid (see vi. 299; vii. 117, and this volume, p. 136).

Compound with Hydrochloric acid.—When a hot solution of aurin in acetic acid is saturated with gaseous hydrogen chloride, the liquid assumes a light yellowish-red colour, and soon deposits glistening needles, which smell strongly of acetic acid even when dry, and on exposure to the air acquire a steel-blue lustre, and gradually crumble to a brown-red crystalline powder. This compound, crystallised from acetic acid and dried at the ordinary temperature, has the composition $C^{10}H^{14}O^3, HCl + 2C^2H^4O^2$, the acetic acid playing the part of crystallisation-water. On heating the crystals at 110° in a current of dry air, the whole of the acetic acid is given off, leaving the compound $C^{10}H^{14}O^3, HCl$, which is of a dull red colour, and may be heated to 190° in a current of dry air, without alteration, but begins to give off hydrogen chloride at 200° . When hydrochloric acid gas is passed into an alcoholic solution of aurin, similar but smaller needles are obtained, containing alcohol of crystallisation, and represented by the formula $C^{10}H^{14}O^3, HCl + 3C^2H^4O$. The alcohol is wholly given off at 100° , leaving a dull red residue identical with that above mentioned.

With Sulphuric acid.—The compound $C^{10}H^{14}O^3, SO^4H^2$, is formed on adding a little sulphuric acid to a hot saturated solution of aurin in glacial acetic acid, and separates in prismatic crystals, or in flat, strongly glistening red needles containing acetic acid. An alcoholic solution treated in like manner yields small red needles of the compound $(C^{10}H^{14}O^3)_2SO^4H^2$ containing alcohol. Both when heated in a current of dry air give off their acetic acid and alcohol respectively, and leave a dull red powder, which is resolved by water into aurin and sulphuric acid. A crystallised *nitrate* has also been obtained.

With Sulphurous acid.—When sulphur dioxide is passed into a hot alcoholic solution of aurin, bright red crystals are obtained of a compound to which Dale a. Schorlemmer formerly assigned the formula $(C^{10}H^{14}O^3)_2SO^2 + 5\frac{1}{2}H^2O$ (p. 119). Subsequent experiments, however, have shown that its true composition when air-dried is $(C^{10}H^{14}O^3)_2SO^2H^2 + 4H^2O$. When heated in a current of dry air it gives off water and sulphur dioxide. The compounds of aurin with the alkaline bisulphites, $C^{10}H^{14}O^3, SO^2KH$, &c. have been already described (vii. 119).

The compounds of aurin with acids have a red colour like that of aurin itself, whereas those with the acid sulphites and with acetic anhydride are colourless like leucaurin. This seems to show that the members of the two groups differ in constitution.

Corallin. This name is applied to the red product obtained by the action of oxalic and sulphuric acids on commercial phenol (vii. 391). According to Zulkowky (*Liebig's Annalen*, xciv. 109), it is a mixture of crystalline substances (20 p. c.), viz. *rosolic acid with metallic lustre*, $C^{20}H^{16}O^8$ [rosaurin], a *garnet-coloured rosolic acid*, $C^{10}H^{14}O^8$ [aurin], and amorphous substances (80 p. c.), viz. *pseudorosolic acid* (resinous) and *corallin-phthaleïn*. To separate these substances, the corallin is pulverised, suspended in water, and dissolved by heating the liquid after addition of caustic soda. On passing sulphur dioxide in excess into the solution, it becomes decolorised and deposits the amorphous constituents of the corallin, while the crystalline substances remain dissolved. The solution may be freed from the last traces of resinous matter by adding water and leaving it at rest for several days, and on heating the filtrate with hydrochloric acid to 70° – 80° the rosolic acids [aurin and rosaurin] are set free, and may be separated by washing, drying, and fractional crystallisation from alcohol of 60 per cent., and purified by recrystallisation. The rosaurin crystallises out first, together with a violet needle-shaped compound, then aurin, and lastly leucrosaurin. The violet substance, probably $C^{10}H^{14}O^2 + H^2O$, dissolves in alcohol with brownish-yellow colour, in ammonia and fixed alkalis with crimson colour, and melts at 150° to a brittle mass having a green colour and metallic lustre.

The amorphous bodies consist of colourless pseudorosolic acid and corallin-phthaleïn. *Pseudorosolic acid*, $C^{20}H^{16}O^4$, to which corallin owes its resinous consistency, is, when recently prepared, a compact, more or less reddish mass, which melts very easily, acquiring at the same time a deeper red colour. It dissolves in alkalis with violet-red colour, and by treating the resulting solutions with zinc-dust or sodium-amalgam, and then adding hydrochloric acid, a purer product may be obtained.

Corallin-phthaleïn, $C^{20}H^{14}O^4$, isomeric with phenol-phthaleïn, is formed by treating an alkaline solution of pseudorosolic acid with permanganate or ferricyanide of potassium. It is an amorphous, strongly staining powder resembling colcothar, dissolving in alcohol with deep brown-yellow, in alkalis with violet-red colour. In dilute alcoholic solution it has a distinct chamois-coloured fluorescence. It does not melt at 140° . It is a dye-stuff, imparting to mordanted wool and silk a golden-yellow colour, like that produced by annatto. Its solution in glacial acetic acid yields with bromine a light brick-red tetrabromocorallin-phthaleïn, $C^{20}H^{10}Br^4O^4$; with nitric acid, a tetranitro-derivative, $C^{20}H^{10}(NO^2)^4O^4$, which dyes wool like picric acid. By heating

with ammonia, it is converted into a red, with aniline into a blue compound. Its hydro-product, boiled with acetic anhydride, is converted into a white amorphous diacetyl-compound, $C^{20}H^{12}O_8(C^2H^3O)^2$, which melts with partial decomposition at 190° .

ROSCEOLITE. See VANADATES.

ROSE. The ash of the several parts of a species of garden-rose (*Rosa remontana*) has been analysed by R. Andreasch (*J. pr. Chem.* [2], xviii. 204), with the following results:

	Roots	Stalks	Leaves	Flowers

ROSE-OIL. This oil is prepared in India and Cashmere by distilling roses with water in earthenware or metal retorts by a current of steam conveyed by a bamboo pipe, mixing the condensed rose-water with a fresh portion of roses, and distilling a second time. As the distillate cools, a thin layer of rose-oil collects on the surface. The oil, when recently taken off, is greenish-yellow, and in the liquid state, after clarification, light yellow with a bright lustre. At 25° or 28° it solidifies to an inodorous camphor or stearoptene (H. von Schlagintweit-Salkülinski, *N. Rep. Pharm.* xxiv. 129).

According to R. Bauer also (*Dingl. pol. J.* cciv. 253), the characteristic odour of rose-oil belongs to the liquid portion, or elæoptene, whilst the stearoptene is destitute of odour. It is therefore an error to assign the highest value to those samples of the oil which solidify most readily. Rose-oil artificially freed from stearoptene, exhibiting no sign of crystallisation at -15° , and soluble in alcohol of 75 per cent., may be converted into stearoptene by treatment with zinc and alcohol containing a small quantity of strong sulphuric acid. The stearoptene thus obtained melts, like that of natural origin, at 33° .

ROSEMARY-OIL AND CAMPHOR (Bruylants, *J. Pharm.* [4], xxix. 508). The quantity of essential oil yielded by *Rosmarinus officinalis* depends on the latitude in which the plant is grown, that from the neighbourhood of Paris yielding only 1.4 to 1.6 grams per kilo., whilst that grown in the south of France yields 3 grams per kilo. When freshly prepared, it is a colourless liquid, but darkens in colour and becomes thick on keeping; it is miscible in all proportions with alcohol of 85 per cent. It smells strongly of rosemary, tastes hot and camphorous; has a density of 0.885 at 12° ; turns the plane of polarisation to the left. It begins to boil at 150° , the temperature gradually rising to 200° , where it remains stationary for a short time, and finally rises to 260° . By fractional distillation, the oil may be separated into three portions, boiling from 150° to 180° , from 180° to 210° , and from 210° to 260° .

Fraction boiling between 150° and 180° .—By repeated distillation and rectification over sodium, a liquid is obtained boiling at 157° – 160° , which is laevogyrate. Its vapour-density corresponds with the formula for terpene, $C^{10}H^{16}$. This terpene combines with iodine, and on distilling the product, it decomposes into hydriodic acid and cymene, $C^{10}H^{14}$; by the action of nitric acid, it yields α -toluic acid.

Fraction boiling between 180° and 210° .—By careful distillation, a liquid boiling at 200° – 205° is obtained, which on cooling deposits crystals melting at 176° and boiling at 204° . They exhibit all the properties of laurel camphor. The mother-liquor boils at a lower temperature, and on distillation yields a second crop of crystals and some terebene. Repeated distillation results in the complete separation of these two bodies.

Fraction boiling between 210° and 260° .—On cooling this fraction in a freezing mixture, a large quantity of borneol separates out, which when treated with phosphoric

anhydride, yields a hydrocarbon boiling at 160° , and having the vapour-density 5.23. This, when treated with iodine, yields cymene and hydriodic acid. Amongst the products of the action of nitric acid are borneol, and a crystalline body which melts at the same temperature as camphor. The borneol, distilled with acetic anhydride, yields a product boiling at 230° , which is decomposed by potash, with formation of a hydrocarbon, $C^{10}H^{16}$, and potassium acetate.

Essence of rosemary therefore contains:

A hydrocarbon (lævogyrate), $C^{10}H^{16}$	80 per cent.
A borneol camphor, $C^{10}H^{18}O$	4 to 5 "
A camphor, $C^{10}H^{18}O$	6 to 8 "

When acted on by concentrated sulphuric acid, essence of rosemary yields a mixture of cymene (b. p. 175°), and terpene (b. p. 16°), and on oxidation with chromic mixture, a small quantity of camphor, some formic and acetic acids, and terephthalic acid.

RUBEOSIN. See PHTHALEIN-DYES (p. 1614).

RUBIDIUM AND CÆSIUM. On the preparation of these metals from lepidolite, see H. Peterson (*Dingl. pol. J.* cccxxiii. 111; *Chem. Soc. J.* xxxii. 706). According to Cossa (*Gazz. chim. ital.* 1878, 235), the alum of the island of Vulcano is—with exception of the very rare mineral, pollux—the richest known source of cæsium and rubidium. On the separation of these metals from it, see p. 1331.

Solubility of Rubidium and Cæsium salts.—On comparing the solubility of these salts with the corresponding salts of the other alkali-metals, it is found that nearly all the simple salts of cæsium and rubidium are considerably more soluble than those of the other alkali-metals, and that, on the contrary, the double salts of cæsium and rubidium, as well as those which contain complex acid radicles, are much less soluble than the corresponding salts of the other alkali-metals (Godeffroy, *Ber.* ix. 1363).

The following salts of these metals have been examined by Godeffroy (*Liebig's Annalen*, clxxxii. 176; *Ber.* ix. 1363; *Arch. Pharm.* [3], xii. 47), in addition to those already described (p. 368).

Chlorides. *Cæsioplatinous Chloride*, $2CsCl.PtCl_2$, is formed by heating cæsioplatinic chloride to fusion with oxalic acid, or in a stream of hydrogen, and separates on evaporating the red solution filtered from metallic platinum, in long monoclinic prisms, permanent in the air, dark-red by transmitted, green by reflected light, and exhibiting a fine play of colours. They melt without alteration, but are decomposed at a red heat into cæsium chloride, metallic platinum, and free chlorine. They are moderately soluble in water, insoluble in alcohol. 100 pts. of water dissolve the following quantities of the salt:

at	20°	40°	60°	80°	100°
	3.4	6.73	8.68	10.92	12.10 parts

The yellowish-red solution is not altered by boiling, but is partially decomposed on addition of alcohol, more completely when boiled with glycerol, whereby indeed the whole of the platinum may be precipitated from the solution. The crystals are rhombohedrons with rounded edges. *Cæsiopalladious chloride*, $2Cs.PdCl_2$, crystallises from aqueous solution in tufts of dark red-brown highly lustrous needles. The solution is decomposed by boiling, the whole of the palladium being precipitated as a black powder.

Cæsiouric chloride, $CsCl.AuCl_3$, forms small reddish-yellow needle-shaped crystals, somewhat sparingly soluble in water, alcohol, and ether.

Cæsiomanganous chloride, $CsCl.MnCl_2$, is obtained as a crystalline anhydrous precipitate on mixing the solutions of the two salts in hydrochloric acid, and the mother-liquor, when left to evaporate, yields small reddish monoclinic prisms of the hydrated salt $2(CsCl.MnCl_2) + 5H_2O$.

Rubidium chloride, $RbCl$, crystallises in forms of the regular system, the cube predominating.

Rubidium-antimony chloride, $6RbCl.SbCl_3$, forms hexagonal plates exhibiting the combination 0P.P, with ∞P subordinate. The P-faces are deeply striated in the horizontal direction. The angles of the lateral edges are equal to $129^{\circ} 30'$, whence $a : c = 1 : 1.8336$. *Rubidioferric chloride*, $6RbCl.Fe_2Cl_6$, is obtained by evaporating a solution of the two chlorides with a little hydrochloric acid, in small yellowish-red orthorhombic crystals, permanent in the air, very soluble in water, separated by concentrated hydrochloric acid as a yellowish-red precipitate.

Rubidio-manganous chloride, $2RbCl.MnCl_2 + 3H_2O$, separates, on slow evaporation of the mixed aqueous solutions of the component chlorides, in large pale red crystals easily soluble in water, insoluble in alcohol. From its concentrated solution it is

precipitated by strong hydrochloric acid as an anhydrous crystalline powder. *Rubidio-cadmii chloride*, $2\text{RbCl}, \text{CdCl}_2$, is obtained as a crystalline deposit on mixing the solutions of the two chlorides in hydrochloric acid. If, however, the cadmium chloride is in excess, another double salt, $2(\text{RbCl}, \text{CdCl}_2) + \text{H}_2\text{O}$, separates in long hard needles having a silky lustre; and on evaporating the mother-liquor to dryness, and dissolving the residue in water, the salt $4(\text{RbCl}, \text{CdCl}_2) + \text{H}_2\text{O}$ is obtained in large well-defined prisms. *Rubidio-mercurii chloride*, $2\text{RbCl}, \text{HgCl}_2$, is obtained, on mixing the neutral solutions of the two salts and evaporating, in small anhydrous needle-shaped crystals; and on dissolving these in water, and leaving the solution to evaporate, the hydrated salt, $2\text{RbCl}, \text{HgCl}_2 + 2\text{H}_2\text{O}$, separates in large colourless prisms. The salt $\text{RbCl}, 2\text{HgCl}_2$ is obtained on evaporating the aqueous solution of equal weights of the component chlorides, as a thick crystalline pulp of silky needles. When heated to 50° , it gives off half of the mercuric chloride, and is converted into $\text{RbCl}, \text{HgCl}_2$.

Rubidio-auric chloride, $\text{RbCl}, \text{AuCl}_3$, is obtained on mixing the moderately dilute solutions of the component chlorides, as a golden-yellow precipitate, the aqueous solution of which yields the salt on evaporation in long golden-yellow prismatic crystals resembling those of saltpetre. When heated it first changes into reddish-brown rubidio-aurous chloride, and at a red heat is easily and completely resolved into rubidium chloride and metallic gold (Godeffroy, *Arch. Pharm.* [3], xii. 47).

Silicotungstates. On mixing an aqueous solution of caesium chloride with silicotungstic acid (v. 916), a white crystalline precipitate is formed, which, when washed and dried, has the composition $\text{SiW}^{12}\text{O}_{42}\text{Cs}_8$, or $4\text{Cs}_2\text{O}, \text{SiO}_2, 12\text{WO}_3$. 100 pts. of water dissolve only 0.005 pt. of this salt at 20° , and 0.52 at 100° , or 1 pt. of the salt dissolves in 20,000 pts. of water at 20° , and in 192–200 pts. at 100° . The salt is quite insoluble in alcohol and in water containing hydrochloric acid, but dissolves to a not inconsiderable amount in dilute ammonia.

The corresponding *rubidium salt*, obtained in like manner, is a white precipitate; 100 pts. water dissolve 0.69 pt. of it at 20° , and 5.06 pts. at 100° , or 1 pt. of the salt dissolves in 145–150 pts. of water at 20° , and in 19–20 pts. at 100° . It is insoluble in alcohol, sparingly soluble in water containing hydrochloric acid, but extremely soluble in ammoniacal water (Godeffroy, *Ber.* ix. 1363).

Monorubidium Dioxalate, $\text{RbHC}^2\text{O}^4, \text{C}^2\text{H}^2\text{O}^4$. See OXALATES (p. 1454).

RUBIJERVINE, $\text{C}_{26}\text{H}_{49}\text{NO}_2$. See VERATRUM ALKALOIDS.

RUBY and SAPPHIRE. *Artificial Formation.*—When a mixture of equal parts of alumina and minium is heated to redness in a crucible, a vitreous substance is produced consisting of lead silicate (the silica being derived from the crucible), together with white corundum crystallised in hexagonal prisms. An addition of 2 or 3 per cent. potassium dichromate converts this white corundum into ruby, and a little cobalt oxide with a trace of the dichromate yields sapphires. The crystals scratch quartz and topaz, and have a sp. gr. of 4.0–4.1. The artificial rubies, like the natural gems, are transiently decolorised by ignition. Another mode of operating is to use two crucibles, the lower containing a mixture of equal parts of alumina and barium fluoride, the upper serving as a cover. At the termination of the experiment, rose-red rubies are found in the lower crucible, while the upper contains colourless, long, or sometimes shorter, monoclinic prisms, consisting of 34.32 per cent. SiO_2 , 35.04 BaO, and 30.37 Al_2O_3 . The reaction consists in the formation, in the first instance, of baryta and aluminium fluoride, which latter is resolved into alumina and hydrogen fluoride, but must at the same time serve as a means of transport to the baryta, which, together with a portion of the alumina and silica from the crucible, forms the double silicate (Frémy a. Feil, *Compt. rend.* lxxxv. 1029).

RUFIGALLOL, or *Hexahydroxy-anthraquinone*,

Rufigallic acid.—This view of the constitution of rufigallol, first suggested by Jaffé (*Ber.* iii. 964), is supported by the fact that it is reduced by sodium-amalgam to alizarin (dihydroxyanthraquinone) (Jaffé, *loc. cit.*; O. Widmann, *Ber.* viii. 109), and by heating with zinc-dust to anthracene, $\text{C}^{14}\text{H}^{10}$ (Jaffé, *loc. cit.*; Klobukowski a. Nöling, *ibid.* 819, 831). According to Schiff's view, who regards rufigallol as digallic anhydride (vii. 1062), it should be convertible into gallic acid; this conversion, however, was found by Klobukowski a. Nöling not to be produced either by hydrochloric acid at 250° , or by potash-ley at 200° . Moreover, when heated to 250° with acetic anhydride, it yields a hexacetyl-derivative, $\text{C}^{14}\text{H}^2(\text{C}^2\text{H}_3\text{O})^6\text{O}^8$. Rufigallol, boiled with excess of *monochloroacetyl chloride*, exchanges only 1 at. hydrogen for chloroacetyl, forming the compound $\text{C}^{14}\text{H}^7(\text{C}^2\text{H}_2\text{ClO})\text{O}^8$, which is insoluble in water, alcohol, benzene, and carbon sulphide, and slightly soluble in glacial acetic acid, from which it crystal-

lises in yellow-brown microscopic needles; in strong potash-ley it dissolves with indigo-blue colour, in strong sulphuric acid with blue colour (Klobukowski, *Ber.* x. 880).

Rufigallol is not acted upon by tin and hydrochloric acid, but when heated for an hour or two with excess of hydriodic acid (sp. gr. 1.96) and white phosphorus to the boiling point of the hydriodic acid, it is converted into the compound $C^{14}H^{10}O$, which forms a yellow powder, consisting of microscopic needles insoluble in the ordinary solvents, but dissolving in strong sulphuric acid to a greenish-blue liquid (changing when further heated to blue and then to violet), from which water throws down greenish-yellow flocks. In contact with water and sodium-amalgam, this compound dissolves, forming a red liquid. When distilled with zinc, it yields anthracene. When boiled with *acetic anhydride*, it yields an acetyl-derivative, $C^{14}H^4(C^2H^3O)^6O^2$ [?], which dissolves in glacial acetic acid with splendid blue fluorescence, crystallises from the solution in greenish-yellow needles, and dissolves in sulphuric acid with green colour changing to blue (Klobukowski, *Ber.* ix. 1256).

Methyl- and Ethyl-derivatives. Rufigallol, heated for three or four hours at 120° – 130° with excess of methyl iodide, potash, water, and a small quantity of methyl alcohol, is converted into a red mass, which, when crystallised from acetic ether, yields laminæ having a golden lustre, or lancet-shaped needles consisting of tetramethylrufigallol, $C^{18}H^{16}O^8 = C^{14}H^4(CH^3)^4O^8$. This compound is insoluble in ether, sparingly soluble in boiling alcohol, easily in ethyl acetate and glacial acetic acid. When boiled with a strong alkaline ley it dissolves slowly, forming a red liquid; strong sulphuric acid, on the other hand, dissolves it readily on boiling, forming a crimson solution from which water throws down yellow flocks. It melts at about 220° . Tetrethyl-rufigallol, $C^{14}H^4(C^2H^5)^4O^8$, prepared in like manner with ethyl iodide, is somewhat sparingly soluble in boiling alcohol, and crystallises therefrom in ruby-red needles. It dissolves sparingly in ether, easily in chloroform, benzene, ethyl acetate, and hot glacial acetic acid; reacts with alkalis and strong sulphuric acid like the tetramethyl-compound; melts at a temperature a little above 180° . By further digestion with ethyl iodide and potash, it is converted into hexethyl-rufigallol, $C^{14}H^2(C^2H^5)^6O^8$, which crystallises in orange-yellow needles easily soluble in ether, carbon sulphide, benzene, hot glacial acetic acid, and hot dilute alcohol, and melts at about 140° ; it is insoluble in alcohol, but dissolves with crimson colour in sulphuric acid (Klobukowski, *Ber.* xi. 880).

RUFHYDROELLAGIC ACID, $C^{14}H^8O^6$. See ELLAGIC ACID (p. 730).

RUTHENIUM. According to Deville a. Debray (*Compt. rend.* lxxx. 457), ruthenium tetroxide decomposes at 108° with violent explosion, producing a thick black smoke like that which is given off in the combustion of turpentine-oil, and a strong odour of ozone. On the other hand, this oxide is formed when ruthenium is heated in the oxy-hydrogen blowpipe, ozone being produced in this case. Ruthenium dioxide, heated in a stream of oxygen at a temperature somewhat above that of melting copper, is converted into very finely developed crystals, ruthenic anhydride being perhaps temporarily formed.

RUTILE. See TITANIUM.

RUTILYDENE, syn. with *Nonylacetylene*, $C^{11}H^{20} = C^9H^8C \equiv CH$ (p. 1421).

RYE. *Secale cereale*.—A. Muntz (*Compt. rend.* lxxxvii. 679) has found in unripe rye-grain a peculiar substance called *synanthrose* (as it is also found in several synanthaceous or composite plants), convertible by boiling with dilute sulphuric acid into levulose (see SUGARS). It disappears as the grain ripens, being converted into starch.

To detect ergot in rye-flour, R. Böttger (*Zeitschr. anal. Chem.* 1874, 80) treats a sample of the flour in a test-tube with an equal volume of ether, adds a few crystals of oxalic acid, and heats the whole for a few minutes to boiling. If ergot is present, the solution exhibits a more or less reddish colour.

S.

SABADILLA. On the Alkaloids of Sabadilla seeds, see VERATRUM ALKALOIDS.

SACCHARIC ACID,

Action of *Phosphorus Pentachloride*.—According to Wichelhaus (*Liebigs Annalen*, cxxxv. 252), the action of PCl_5 on cadmium saccharate does not give rise to any organic chloride. C. J. Bell, however (*Ber.* xii. 1271), by substituting the potassium salt for the cadmium salt, has obtained chloromuconic acid, $\text{C}^6\text{H}^4\text{Cl}^2\text{O}^4$, crystallising from alcohol in long silky needles, sparingly soluble in ether and in water, melting at 230° , and agreeing in other respects, and in the properties of its ethylic ether, with the chloromuconic acid obtained from mucic acid (vii. 827).

Ammonium saccharate, slowly distilled at the heat of a paraffin-bath, breaks up almost quantitatively into pyrroline, carbon dioxide, ammonia, and water:

Ethylamine saccharate is also decomposed in a similar manner, yielding ethyl-pyrroline in theoretical amount. No trace of any carboxylated derivative of pyrroline appears to be formed in either case. By these reactions, saccharic acid is distinguished from its isomeride, mucic acid, the amine salts of which, when heated, yield alkyl-derivatives of pyrroline, together with the alkylamides of the mono- and di-carboxylated derivatives of these pyrrolines (see PYRROLINES, p. 1728) (C. A. Bell and E. Lapper, *Ber.* x. 1961).

SACCHARITE. Glocker in 1845 (*J. pr. Chem.* xxxiv. 494) described a mineral which he named saccharite, from its granular, sugar-like appearance. It was originally found on the Gläserndorfer Berg, near Frankenstein in Saxony, in a chrysoprase mine. According to Glocker, saccharite encloses pinchbeck-brown mica-scales, small plates of talc, green fibrous hornblende, long isolated tourmaline crystals, and finely divided disseminated iron pyrites, the surface of the specimens being generally coated with a crust of green pimarite. According to an analysis by C. Schmidt (v. 144), saccharite is a felspar most nearly approaching andesine in composition. A. v. Lasaulx (*Jahrb. f. Min.* 1878, 623) obtained some specimens of a mineral (which appeared to be identical with saccharite in its physical properties) from the five serpentine mounds of the Gumberg, near Frankenstein, and examined them microscopically, together with the original specimen described by Glocker. Glocker's saccharite consists mostly of fine-grained plagioclase, exhibiting a very distinct twin-striation, and optical properties closely resembling those of oligoclase or andesine; next in amount comes orthoclase, then hornblende and tourmaline crystals, whilst in one specimen (in addition to the minerals already mentioned) minute fibres of talc were observed. Some specimens of saccharite from the Wachberg, near Baumgarten, contained a large quantity of round quartz-grains, together with plagioclase, and a few isolated epidote grains. The Gumberg saccharite differs considerably in its microscopical character from that of the other localities, although its outward appearance is almost identical with that of Glocker's saccharite, some specimens being white, with a green coating of pimarite, whilst others have a yellowish, reddish, or deep red colour. Quartz was found to be the predominating constituent of Gumberg saccharite. The yellowish-red specimens were found to be a mixture of predominating quartz, with a small quantity of plagioclase, and a small quantity of colourless, granular garnet, diopside, and epidote. The garnet grains are generally arranged in rows, one behind the other, but they sometimes occur in bands and lenticular forms, in conjunction with granular quartz-aggregates. They seldom enclose other minerals, quartz being the only exception. The brown-red saccharite owes its colour to ferric oxide, which is evenly distributed throughout the mass. The felspar grains did not exhibit any signs of decomposition in any of the specimens, a fact which is at variance with the opinion that 'saccharite is a felspar very much altered, and undergoing decomposition' (*Bism. Min.* 2. Aufl. 310). From microscopical examination of the various varieties of saccharite, v. Lasaulx is of opinion that it cannot any longer be considered as a distinct plagioclase species, but only as a rock-like variable mixture of plagioclase with other minerals, because the plagioclase almost disappears in some cases; and he concludes from its peculiar occurrence in the serpentine rocks, that it is a product of the decomposition of hornblende rocks.

SACCHAROSE. See SUGAR.

SAFRANINE, $C^{21}H^{20}N^4$. This name has been given to a red colouring matter (also called 'aniline-pink'), obtained by Perkin as a product of the oxidation of mauveine; also to a product which Hofmann a. Geyger obtained by treating orthotoluidine, or crude aniline containing it, first with nitrous acid, and then with arsenic acid, or better with chromic acid (vii. 1063). Subsequent researches, however, by Dale a. Schorlemmer (*Chem. Soc. J.* xxxv. 683), and by Perkin (*ibid.* 728), have shown that the products formed in these two processes are not identical but homologous, the body obtained from orthotoluidine having the composition $C^{21}H^{20}N^4$, and being formed as already pointed out (vii. 1063), according to the equations $3C^7H^9N + NO^2H = 2H^2O + C^{21}H^{24}N^4$, and $C^{21}H^{24}N^4 + O^2 = 2H^2O + C^{21}H^{20}N^4$, whereas the colouring matter obtained by oxidation of mauveine has the composition $C^{20}H^{18}O^4$, and is probably formed according to the equation:

The name safranine is now therefore restricted to the higher homologue (C^{21}), while the lower (C^{20}) is called *parasafranine*.

Safranine is also produced in considerable quantity, together with paratolylene-diamine, by heating amidazortholuene with orthotoluidine hydrochloride in alcoholic solution at 150° – 160° :

(O. N. Witt, *Ber.* x. 873).

Safranine is now used extensively in the dyeing of silk, and according to K. Böttger (*N. Rep. Pharm.* xxiii. 181) is easily obtained chemically pure by treating the commercial product with alcohol. It then forms a powder having a greenish surface-shimmer and metallic lustre, and possessing extraordinary tinctorial power. A peculiar and beautiful play of colours may be produced by sprinkling a few particles of the powder in a porcelain capsule with a drop or two of strong sulphuric acid, stirring it at the same time with a glass rod, whereupon a most splendid blue colour is produced which, on addition of a drop or two of water, changes to a brilliant emerald-green, and by alternately dropping in sulphuric acid and water, almost all the colours of the spectrum may be produced in great beauty.

The following process for distinguishing safranine from magenta-fuchsine of similar hue, is recommended in Reinmann's 'Färbezeitung' and *Dingl. pol. J.* cexii. 531. If the dye-stuff is in the solid state, a few grains of it may be placed on a watch-glass and sprinkled with 6 drops of strong sulphuric acid, which will dissolve fuchsine with brown-red colour, whereas with safranine the solution will at first exhibit a green colour, changing to a fine blue. A solution of safranine in alcohol exhibits by transmitted light a clear roseate hue, in reflected light a muddy ponceau to scarlet colour; a solution of fuchsine does not exhibit this dichroism. Dyed stuffs may be boiled with alcohol, which takes up the colouring matter, or they may be treated as follows: Stuffs dyed with fuchsine become lighter in colour when warmed with dilute soap-solution, and are completely decolorised by warming with solution of sodium carbonate, whereas those dyed with safranine are not altered by either mode of treatment. On drenching the dyed stuff with water containing hydrochloric acid, and immersing a plate of zinc in the liquid, fuchsine is decolorised as soon as the evolution of hydrogen begins, whereas safranine remains unaltered for a few minutes and ultimately turns yellow.

Parasafranine, $C^{20}H^{18}N^4$, is obtained, as already observed, by oxidation of mauveine. Perkin prepares the hydrochloride, $C^{20}H^{18}N^4.HCl$, by dissolving mauve dye in water acidulated with hydrochloric acid, keeping the solution at the boiling heat, adding freshly precipitated lead dioxide by small portions till the oxidation has proceeded far enough, then adding sodium hydrate in slight excess, filtering, boiling the red filtrate for a short time with a little powdered zinc and calcium carbonate, again filtering, slightly acidifying with hydrochloric acid, and adding a little sodium chloride to facilitate the precipitation of the colouring matter. The hydrochloride is thus obtained as a red-brown precipitate, dissolving in water and alcohol with a splendid red colour, and giving by analysis 67.96 per cent. carbon, 5.56 hydrogen, and 10.21 chlorine, the formula requiring 68.44 C, 5.42 H, and 10.41 Cl. Similar results have been obtained by Dale a. Schorlemmer. The other salts of parasafranine are prepared by mixing the solution of the hydrochloride in boiling water with a slight excess of caustic alkali, then acidifying with the required acid, and, if necessary, saturating the solution with a soluble salt of the same acid. The *oxalate* thus prepared may be obtained in needles of a dark green metallic aspect by adding oxalic acid and leaving the solution at rest. The *nitrate*, $C^{20}H^{18}N^4.HNO^3$, crystallises beautifully from alcohol in long needles having a dark green metallic reflex, and appearing

of a dark garnet-red colour by transmitted light. It dissolves somewhat sparingly in cold water, with moderate facility in boiling water and in cold alcohol, freely in boiling alcohol.

Safranine salts differ from those of parasafranine in the colour which they impart to silk, yielding shades which are somewhat more scarlet (Perkin).

The following formulæ are suggested by Perkin as probably representing the constitution of safranine and parasafranine:

O. N. Witt, on the other hand, represents safranine by the constitutional formula:

SAFROL. See SASSAFRAS-OIL.

SAFROSIN. A colouring matter belonging to the resorcinol-group, and prepared by dissolving 9 kilos. of tetrabromofluorescein in alkaline water, adding 8 kilos. sodium nitrate, heating the mixture to boiling, and then adding 15 kilos. of sulphuric acid 66° B. The precipitate is filtered off, washed, dissolved in dilute soda-ley, and evaporated. The salt thus obtained dyes wool with a more bluish-red tinge than tetrabromofluorescein (Bindschedler a. Busch, *Chem. News*, xxxviii. 226).

SAGAPENUM. All varieties of this resin when moistened with alcohol and treated with strong sulphuric acid dissolve with dark brown colour, the solution sometimes becoming carmine-red at the edges; on addition of alcohol, the colour changes to light brown-red, violet, and sometimes blue. Hydrochloric acid added to sagapenum moistened with alcohol produces a yellowish-red or sometimes rose-red coloration passing into violet, blue-violet, or even blue. Sagapenum distilled with steam yields 7.5 per cent. of a sulphuretted oil smelling like garlic. Petroleum ether dissolves sagapenum more abundantly than galbanum or gum ammoniacum, the dissolved portion consisting of volatile oil and resin, and containing sulphur (Hirschsohn, *Jahresb. f. Chem.* 1875, 859).

SAGE-OIL. The volatile oil of *Salvia officinalis* has been examined by Muir a. Sigiura (*Phil. Mag.* [5], iv. 336; *Chem. Soc. J.* xxxiii. 292), and further by Muir (*Chem. News*, xli. 223). The composition of the oil varies with its age. When freshly distilled, it contains comparatively small quantities of salviol, $\text{C}^{10}\text{H}^{18}\text{O}$, camphor, and cedrene, but as it ages, these substances increase in quantity, especially the first two. The oil distilled from English sage contains much cedrene boiling at 260°, together with small quantities of terpene, and traces of oxidised compounds. The terpene of sage-oil is identical with that obtained from French turpentine; an isomeride of terpene, boiling at 171°, appears also to be present.

Salviol, $\text{C}^{10}\text{H}^{18}\text{O}$, has a sp. gr. of 0.934 at 15°, and a refractive index for the line D at 20°, equal to 1.4623; hence specific refractive energy = 0.495. A column 100 mm. long rotates the polarised ray 15.13° to the right; hence specific rotatory power = +16.19. Phosphoric anhydride exerts on salviol a very complex action, yielding polymerides of $\text{C}^{10}\text{H}^{16}$, one boiling at 171°, a hydrocarbon of the benzene series boiling below 130°, and a paraffin boiling between 170° and 180°; no cymene is formed, even if the action be continued for some time. Phosphorus pentachloride acts on salviol at high temperatures, producing a chlorinated derivative which is decomposed by distillation, yielding a terpene boiling at 157°, and probably the paraffin above mentioned. Bromine acts energetically on salviol, with liberation of hydrogen and carbon, and formation of a brominated oil, and, under certain conditions, small quantities of a camphor melting at 174°, and boiling at 205°. This camphor separates also from the portions of sage-oil distilling between 205° and 208°; it is partially soluble in salviol, but separates out on cooling the solution to -15°. It is chemically identical with laurel camphor, but is optically inactive.

The compounds present in sage-oil are stable when pure, but decompose when mixed with small quantities of other bodies; and during the ageing and fractionation of the oil, processes of oxidation, deoxidation, and polymerisation probably occur simultaneously.

SAKI. An alcoholic drink prepared in Japan from rice. For the mode of preparation, see O. Korschelt (*Dingl. pol. J.* cccxxx. 76, 172, 229, 330, 421; *Chem. Soc. J.* xxxvi. 413).

SALICYLIC, or **ORTHO-HYDROXYBENZOIC ACID**, $\text{C}^6\text{H}^4.\text{OH}.\text{CO}^2\text{H}.\text{H}^4$. (See pp. 278, 1461).

SALICYLURIC ACID, $C^6H^5NO^4$. This acid has been found, together with salicylic acid, in the urine of fever patients to whom large doses of salicylic acid had been administered. The two acids are best separated by treatment with a mixture of ether and benzene, in which salicylic acid dissolves more readily than salicyluric acid. From the aqueous solution of an impure mixture of the two, the salicyluric acid crystallises out last on cooling (Beck, *Ber.* viii. 817).

SALIRETIN, C^7H^4O , is produced by the action of sodium-amalgam on para-hydroxybenzoic acid; salicylic acid appears to yield an isomeric compound (A. von den Velden, *J. pr. Chem.* [2], xv. 163). The glucoside of saliretin appears to be formed by the action of acetochlorhydrase on sodium-amalgam (A. Michael, *Compt. rend.* lxxxix. 355).

SALITE. This mineral, from the granular limestone of Albrechtsberg in Lower Austria, where it occurs in groups of crystals 12 cm. long, has been analysed by E. v. Bamberger (*Min. Mitth.* 1877, 278). A. analysis; B. values calculated from the formula $MgCaSi^2O^8$:

	SiO^2	Al^2O^3	FeO	CaO	MgO	Sp. gr.
A.	55.60	0.16	0.56	26.77	18.34 =	3.167
B.	55.56	—	—	25.92	18.52 =	100

According to E. Kalkowsky (*Jahrb. f. Min.* 1875, 755), salite is a widely diffused constituent of crystalline slates, also of the chloritic gneiss of Silesia, the dioritic slates of Kupferberg, the mica slate of Waltersdorf near Kupferberg, the hornblende slate of Raspenau in Bohemia, and of the erlan of Schwarzenberg in the Erzgebirge.

SALTS. The specific gravities of a large number of salts have been determined by students working under the direction of F. W. Clarke, and published by him in *Silliman's Journal*, [3], xv. 281. The weighings were made in benzene, but the numbers all refer to water at its maximum density as unity.

$BaIO^6$	5.2179, 5.1853, 5.2855 at 18°.
$AgIO^3$	5.4023 at 16.5°; after recrystallisation from ammonia, 5.6475 at 14.5°.

On the Melting Points of Metallic Salts, see Carnelley (p. 937).

Diffusion of Salts in Solution.—The simultaneous diffusion of salts which do not act chemically on one another—in other words, of such as contain the same base or the same acid—has been investigated by Marignac (*Ann. Chim. Phys.* [5], ii. 546; *Chem. Soc. J.* xxviii. 35; *Jahresb. f. Chem.* 1874, 37) in an elaborate series of experiments, the main result of which is to confirm Graham's observation that in a mixture of two salts, the diffusibility of the less diffusible is diminished, while that of the more diffusible is in some cases slightly increased, in others diminished, but always in a smaller degree than that of the less diffusible salt. This mutual influence becomes less as the solutions are more dilute, but the limit towards which dilution tends to bring the ratio of the coefficients of simultaneous diffusion does not coincide with the ratio of the coefficients of separate diffusion, except in the following cases: The chlorides of potassium, sodium, and ammonium in presence of the corresponding nitrates; sodium chloride and ammonium chloride; potassium nitrate and ammonium nitrate; the sulphates of potassium and ammonium in presence of magnesium sulphate.

Mixtures of two salts which are capable of forming double salts— K_2SO_4 and MgSO_4 , for example—exhibit no tendency to diffuse in equivalent proportions: hence it is probable that double salts are not completely formed in solution, but only at the moment of crystallisation (compare p.). No resolution of a salt into acid and base by diffusion was observed in any of the experiments.

The several acids and bases exhibit the same order of diffusibility in all their compounds, the acid and basic radicles of the salts examined ranging themselves in the two following series, each beginning with the most diffusible; those among which the order has not been determined with certainty are grouped in brackets:

Negative: [Chlorine, bromine, iodine]; nitric acid; [chloric, perchloric, and permanganic acids]; fluorine; chromic acid; sulphuric acid; carbonic acid.

Positive: Hydrogen; [potassium, ammonium]; silver, sodium; [calcium, strontium, barium, lead, mercury]; [manganese, magnesium, zinc]; copper; aluminium.

On the constitution of Salts in Solution as determined by their Thermic relations, see HEAT (pp. 978–987).

Solubility of Saline Mixtures (F. Rudorff, *Ber.* vi. 432, 643).—When water is saturated with two salts which exert no chemical action on one another (the same acid or base being common to both), the solubility of each is found to be diminished. For example, 100 c.c. water at 12° dissolve 29.1 grams of NH_4Cl and 173.8 grams of NH_4NO_3 together, whereas 100 c.c. water at the same temperature can dissolve 37.0 grams NH_4Cl , or 183.0 grams NH_4NO_3 singly. In some cases the proportion of each salt which dissolves is not influenced by the presence of a large excess of either

salt, but in other cases the presence of a large excess of one salt will almost prevent the solution of another. This is well illustrated by the behaviour of a saturated solution of the double salt, $(\text{NH}_4)_2\text{SO}_4 \cdot \text{CuSO}_4$. 10 grams of this solution contain at 16° , 0.855 gram of CuSO_4 and 0.712 of $(\text{NH}_4)_2\text{SO}_4$, but if one-fifth of its weight of CuSO_4 be dissolved in it by the aid of heat, the solution, when cold, contains 1.585 grams of CuSO_4 and only 0.565 of $(\text{NH}_4)_2\text{SO}_4$. If, on the other hand, one-fifth of $(\text{NH}_4)_2\text{SO}_4$ be dissolved by the aid of heat in 10 grams of this solution, and the whole be allowed to cool, the liquor will retain only 0.177 gram of CuSO_4 , but 1.816 of $(\text{NH}_4)_2\text{SO}_4$. If a larger amount of ammonium sulphate be employed, the quantity of copper sulphate remaining in solution may be still further reduced. 100 grams of water at 16.1° dissolve 76.2 grams CuCl_2 or 121.4 grams $\text{CuCl}_2 + 2\text{H}_2\text{O}$.

2. Rudorff has also endeavoured to ascertain whether a saturated solution of salts containing two bases and two acids is the same in whatever manner the bases and acids are combined; for instance, whether a saturated solution made from a mixture of KNO_3 and NH_4Cl is the same as one made from a mixture of KCl and NH_4NO_3 . The results obtained with a mixture of NH_4Cl and KNO_3 indicate that at 14.8° , 100 grams of water dissolve 38.8 grams NH_4Cl and 34.2 of KNO_3 , and, as might be expected, the addition of either of the pulverised salts to the solution causes no change of temperature. With mixtures of KCl and NH_4NO_3 , however, the results are found to vary with the proportions of the two salts in the mixture, and the addition of either of the salts to the solution causes a change of temperature; but the addition of KNO_3 or NH_4Cl produces no such effect. The addition of KCl or NH_4NO_3 to the saturated solution of NH_4Cl and KNO_3 , produces a change of temperature.

The following pairs of salts give a similar result:

But the pairs:

do not give saturated solutions of definite composition.

On the Double Decomposition and Thermic effects accompanying the dissolution of Mixed Salts, see HEAT (p. 979).

Decomposition of Salts by Water.—The action of water on mercuric sulphate, HgSO_4 , bismuth nitrate, $\text{Bi}_2\text{O}_3 \cdot 3\text{N}_2\text{O}_5 + 3\text{H}_2\text{O}$ and $\text{Bi}_2\text{O}_3 \cdot \text{N}_2\text{O}_5 + \text{H}_2\text{O}$, antimonious chloride, SbCl_3 , and potassio-calcic sulphate, $2\text{CaSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 3\text{H}_2\text{O}$, has been examined by A. Ditte (*Compt. rend.* lxxix. 915, 956, 1254). The decomposition of these salts takes place according to the same laws, resulting in the formation of a slightly soluble product, a basic salt, or calcium sulphate, while the water takes up free acid or potassium sulphate.

To each temperature there corresponds a liquid of such composition that any alteration of its concentration in one direction or the other is attended with decomposition, or reproduction of the original salt, and that, whatever may have been its original state, the liquid always returns to this limiting composition. The decomposition appears to be independent of the quantity of undecomposed salt remaining in the liquid, of the quantity of its undissolved constituents, or other acid or saline substances contained in the liquid, provided these bodies exert no chemical action on the salt or its constituents.

Crystallisation of Salts from Supersaturated Solutions.—Gernez showed some years ago that the crystallisation of a salt from a supersaturated solution is most readily induced by the introduction of a crystal of the same salt (v. 350), and J. M. Thomson has lately shown (*Chem. Soc. J.* xxxv. 196) that the same effect is produced by contact with the crystal of a salt isomorphous with that which is contained in the solution. To produce this effect, however, mere identity of form between the introduced crystal or nucleus and the dissolved salt is not sufficient; the two must be truly isomorphous, that is to say, identical in chemical structure as well as in form. Thus, crystallisation is induced in a solution of magnesium sulphate, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, by the introduction of a crystal of the corresponding salts of zinc, nickel, cobalt, or iron, and a supersaturated solution of common alum may be made to crystallise suddenly by dropping into it a crystal of chrome-alum or iron-alum, but not by a cubic crystal of iron pyrites or an octohedral crystal of magnetic iron oxide.

In a mixture of two salts, not isomorphous, the introduction of a crystalline nucleus isomorphous with one of them may produce the following results: 1. Crystallisation may commence suddenly, spreading however gradually through the solution

and causing a deposition only of the salt isomorphous with the nucleus. 2. When sudden crystallisation takes place, causing the deposition of both salts, the salt isomorphous with the nucleus will preponderate. 3. The nucleus may remain growing slowly in the solution, and increasing by a deposition of the salt isomorphous with itself.

In a mixture of two isomorphous salts: 1. Sudden crystallisation may occur, producing a deposition of both salts, apparently in the proportion in which they exist in the solution. 2. When slow crystallisation takes place, the nucleus increases by deposition of the less soluble salt, showing that in mixed supersaturated solutions a gradation of phenomena may occur, passing from those shown in the crystallisation of a true supersaturated solution to those exhibited in the crystallisation of an ordinary saturated solution.

On crystallisation from Supersaturated Solutions, see also Tscherbatschew (*N. Petersb. Acad. Bull.* xix. 42); Violette (*Compt. rend.* lxxvi. 171); Mensbrugghe (*ibid.* lxxvi. 45, 713); de Coppet (*ibid.* 434); Gernez (*ibid.* 566); Tomlinson (*ibid.* lxxvi. 171; lxxviii. 194; lxxix. 167; *Ann. Chim. Phys.* [3], vi. 275); Marignac (*N. Arch. ph. nat.* xlviii. 120); Gernez (*Compt. rend.* lxxvi. 566; lxxix. 219, 1332; lxxx. 44; lxxxiv. 771, 1389); Lecoq de Boisbaudran (*ibid.* lxxx. 321, 393, 888); Grenfell (*Proc. Roy. Soc.* xxv. 124); Tomlinson (*ibid.* xxvi. 523; xxvii. 121). See also *Chem. Soc. J.* xxvi. 468-470; xxxi. 435, 436; xxxii. 696; *Jahresb. f. On the Heat of Formation and Solution of Salts, see pp. 953-958, and 976-994.

SALVIOL. See SAGE-OIL (p. 1771).

SAMATE. See v. 187; also under GEHLENITE (p. 859 of this volume).

SAMARSKITE. Crystals of this mineral from Mitchell County, North Carolina, have been measured by E. S. Dana (*Sill. Am. J.* [3], xi. 201). It occurs, often imbedded in a decomposed felspar, in mica-slates, traversed by granitic veins. It is velvet-black, translucent with brownish colour on the edges, and is accompanied by an octohedrally crystalline mineral (microlite or pyrochlor), columbite and a yellow mica. The observed forms, $\infty P \infty$, $\infty \bar{P} \infty$, P , ∞P , $\infty \bar{P} 2$, $\bar{P} \infty$, $3P_2$, may be referred to the axial ratio

$$a : b : c = 1.1883 : 0.949$$

giving by calculation the prismatic angle $122^\circ 46'$. Analysis (1) by Miss Ellen Swallow (*Sill. Am. J.* [2], xi. 201); (2) by O. D. Allen (*ibid.* [3], xiv. 128); (3) by J. L. Smith (*ibid.* xiii. 359); (4) by Rammelsberg (*Ann. Phys. Chem.* [2], ii. 658; *Jahrb. f. Min.* 1878, 529). Rammelsberg has also analysed samarskite from the Ural. No. 5 is the mean of four analyses:

	1	2	3	4	5

(¹) Loss by ignition.

(²) Insoluble residuo.

(³) With Mn²O³.

Rammelsberg infers from these analyses that samarskite is a heminiobate (tantarate), isomorphously mixed with a uranate; and as $U : (Nb, Ta) = 1.10$ (nearly), the formula of samarskite is $\frac{8R^4Nb^6O^{21}}{R^4U^5O^{21}}$, or

New Metals in Samarskite.—Lecoq de Boisbaudran (*Compt. rend.* lxxxix. 212) observed that the solution of an oxide extracted from samarskite gave a pair of absorption-bands in the blue at 480° and 463.5° , and another pair in the violet at 417° and 400.75° . In both pairs, the most refrangible band is the narrower and more intense of the two. These bands are not identical with those of the decipium, recently described by Delafontaine, or of any other known substances, and indicate the existence of a new metal which Lecoq designates by the name *Samarium*. The bands 417° and 400.75° were observed some time ago by Soret (*Compt. rend.* 1878, lxxvi. 878).

Delafontaine, in examining the earths obtained from samarskite, has observed appearances which lead him to suspect the existence of a new earth different from any yet described (*Ann. Chim. Phys.* [5], xiv. 238). See YTTRIUM-METALS.

SAMBUCUS. An analysis by J. Huber of the ash of elder-tree bark (*Sambucus nigra*) has been published by G. C. Wittstein. The air-dried bark lost at 110° , 11.666 per cent. water, and the bark dried at that temperature yielded 11.717 per cent. of ash having the following composition:

K ² O	Na ² O	CaO	MgO	Al ² O ³	Fe ² O ³	Cl	SO ³	P ² O ⁵	SiO ²	CO ²
13.96	0.97	30.92	10.73	0.25	0.35	0.18	5.82	8.04	5.46	23.27 = 99.95.

SANDAL-WOOD. An amorphous substance, having the composition $C^{17}H^{10}O^4$, is obtained from this wood, and more abundantly from Caliatour wood, by treatment with boiling alcohol and precipitation of the concentrated extract with water; it may be purified by converting the crude product into a lead-salt, washing this salt with hot alcohol, and decomposing it with sulphuric acid. The pure substance melts at 104° – 105° , dissolves in alcohol, acetic acid, alkaline carbonates, and caustic alkalis, and is precipitated from alkaline solutions by hydrochloric acid. When fused with potash, it yields resorcinol, acetic acid, and probably catechol and protocatechuic acid. By oxidation with potassium permanganate, it gives oxalic and acetic acids, together with a substance having the odour of vanillin. Reducing agents appear to have no action on this colouring matter. By the action of hydrochloric acid at 180° , it is decomposed into methyl chloride, a body soluble in hydrochloric acid, which crystallises in colourless needles, and forms a crystalline precipitate (m. p. 81°) with bromine-water; a substance soluble in alcohol, and having the composition $C^8H^{10}O^3$; and a black residue insoluble in alcohol, but soluble in caustic alkalis (Franchimont a. Sicherer, *Ber.* xii. 14).

SANTIDIN. On the variations in the crystallographic elements of this monoclinic felspar, see J. Strüver (*Zeitschr. f. Kryst.* i. 343; *Jahresb. f. Chem.* 1877, 1333).

SANTONIC ACID, $C^{15}H^{20}O^4$. The preparation and properties of this acid have been already described. For further details respecting its crystalline form and optical characters, see J. Strüver (*Gazz. chim. ital.* 1876, 349; *Jahresb. f. Chem.* 1876, 617).

By the action of hydriodic acid, santonin acid is converted into a hydrocarbon, $C^{15}H^{20}$, which is lighter than water, boils between 235° and 245° , and yields an iodine-derivative, $C^{15}H^{25}I$. By boiling for several days with hydriodic acid and amorphous phosphorus, santonin acid is converted into an isomeride of santonin, $C^{15}H^{18}O^3$ (also formed in like manner from santonin), which melts at 160.5° , and distils between 238° and 240° (Cannizzaro a. Amato, *Gazz.* 1874, 446, 462).

Methyl santonate, $C^{15}H^{18}(CH^3)O^4$, is prepared by dissolving 1 mol. santonin acid and 4 mols. KHO in methyl alcohol, evaporating the solution to dryness, and heating the residue with methyl alcohol and excess of methyl iodide under a pressure of two atmospheres; or by the action of methyl iodide on a solution of sodium santionate in methyl alcohol under pressure. The unattacked methyl iodide and part of the alcohol having been distilled off, water is added, the methyl santionate extracted by agitation with ether, and the oily residue left on evaporating the ether is washed with water, and finally purified by crystallisation from ether and from methyl alcohol. Methyl santionate crystallises in colourless needles melting at 86° – 86.5° (Cannizzaro, *Gazz.* 1876, 355).

Ethyl santonate, $C^{15}H^{19}(C^2H^5)O^4$, obtained by heating silver santionate with excess of ethyl iodide, or by passing hydrogen chloride into an alcoholic solution of santonin

acid, crystallises in fine prisms melting at 88°–89°. It is saponified by boiling for eighteen hours with soda-ley of the strength of 4 per cent. It dissolves slowly in cold nitric acid, and after the lapse of an hour or two is precipitated therefrom by water without alteration; but after twenty to thirty hours it is partly decomposed with separation of santonin acid (Sestini, *Gazz.* 1876, 148).

Acetyl-santonin acid, $C^{15}H^{19}(C^2H^3O)O^4$.—When santonin acid is heated for six hours with eight or ten times its weight of acetyl chloride in a flask placed in a water-bath and connected with a vertical condenser, and the product is afterwards distilled, there remains in the flask a dense fuming liquid, which may be freed from undecomposed acetyl chloride by passing a rapid stream of cold air through it for about sixteen hours. There then remains a yellowish-white, confusedly crystalline mass, which is to be well washed with cold water, drained, dried between bibulous paper, and digested three times in succession with a small quantity of ether, which dissolves a certain portion of it, leaving a white crystalline mass nearly insoluble in cold water, soluble in boiling alcohol and ether, slightly soluble in cold ether, very soluble in chloroform, melting at 139°–140°. This substance is acetyl-santonin acid. By spontaneous evaporation of its solution in chloroform it may be obtained in large, hard, pointed prisms. The solution in boiling ether yields it, by cooling and evaporation, in small, very well formed, four and six-sided prisms terminated by pyramids with unequal faces. These crystals, like those of santonin acid itself, act strongly on polarised light. It appears to be the only product of the action of acetyl chloride on santonin acid.

Acetyl-santonin acid heated for two or three hours in boiling water is converted into acetic and santonin acids. If dilute alcohol is used instead of water, an ethylic ether is formed, which melts below 100°. The acid, heated in the dry state to 180°–200°, is resolved into acetic acid and santonin anhydride (santonin), $C^{15}H^9(C^2H^3O)O^4 = C^2H^4O^2 + C^{15}H^9O^3$ (Sestini, *Gazz.* 1875, 121).

Santonin chloride, $C^{15}H^{19}O^3Cl$, is formed by heating santonin acid with phosphorus trichloride, and separates from solution in ether, in crystals which melt at 170°–171°, and are decomposed by water and alcohol, yielding santonin acid and ethyl santonate respectively. The same compound is obtained by the action of acetyl chloride on santonin acid. Santonin bromide and iodide are produced in like manner by treating santonin acid with bromide or iodide of phosphorus. The iodide melts at 136° and the bromide at 145.5° (Cannizzaro a. Valente, *Gazz.* 1878, 309).

Hydrosantonin acid, $C^{15}H^{22}O^4$. The sodium salt of this acid is obtained by treating a solution of sodium santonate with sodium-amalgam of 5 per cent., and the free acid may be precipitated from its solution by hydrochloric acid. The acid separates from ethereal solution in colourless crystals belonging to the orthorhombic system, melts and decomposes at 170°, is less soluble in alcohol and ether than santonin acid, and is optically dextrogyrate. The *sodium salt*, $C^{15}H^{21}NaO^4.3H^2O$, forms orthorhombic crystals, which give off part of their water of crystallisation on exposure to the air. The crystals of the *potassium salt* contain $2H^2O$ (Cannizzaro, *Gazz.* 1876, 341).

Hydrosantonide, $C^{15}H^{20}O^3$, is obtained by boiling a solution of hydrosantonin acid in glacial acetic acid for several hours, or better by heating the acid with glacial acetic acid in closed tubes at about 150° for four hours, and in either case distilling off the acetic acid till the temperature rises to 186°. It is a crystalline substance melting at 155°–156° (Cannizzaro a. Valente, *Gazz.* 1878, 309).

Acetyl-hydrosantonide, $C^{17}H^{22}O^4$, is formed by the action of acetyl chloride in excess on hydrosantonin acid:

It melts at 204°, and sublimes at a higher temperature. It is but slightly soluble in ether, and almost insoluble in water; is not decomposed by hot aqueous potash, but when heated with alcoholic ammonia at 130°, yields a substance having the composition of hydrosantonamide.

Benzoyl-hydrosantonide, $C^{22}H^{24}O^4 = C^{15}H^{19}(C^7H^5O)O^3$, prepared in a similar manner, crystallises in colourless needles melting at 157°. It closely resembles the acetyl-compound, but is decomposed by heating with aqueous potash.

Hydrosantonamide (?), $C^{15}H^{23}NO^3$, is formed by heating acetyl- or benzoylhydrosantonide with alcoholic ammonia at 120°–130°, and may be purified by evaporating the product, washing the residue to remove acetamide and benzamide simultaneously produced, and crystallising from alcohol. It is soluble in alcohol, less soluble in ether, and only slightly soluble in boiling water; melts, with decomposition, at 190°.

ISOMERIDES OF SANTONIN ACID (Cannizzaro, *Gazz.* 1876, 341; Cannizzaro a. Valente, *ibid.* 1878, 309). The addition of the elements of water to santonin, $C^{15}H^{18}O^3$, gives rise to five isomeric acids, $C^{15}H^{20}O^4$, viz. a bibasic acid, *photosantonin*

acid, and four monobasic acids, viz. *santonin* acid, *santoninic* acid (already described, vii. 1076), *metasantonin* acid, and *parasantonin* acid. These four monobasic acids differ not only in their crystalline form, solubility, and other physical characters, but also in their behaviour to reagents; they are therefore metameric, not merely isomeric.

Metasantonin Acid is formed by abstraction of hydrogen from hydrosantonin acid. On adding silver nitrate to a solution of sodium hydrosantonate, a white precipitate of silver hydrosantonate is produced, which dissolves on heating, with precipitation of metallic silver; and on continuing the heat for half an hour, adding soda from time to time to keep the solution nearly neutral, and finally precipitating the silver oxide which remains in solution by adding an excess of alkali, a liquid is obtained which, when acidified with nitric acid, deposits metasantonin acid in the crystalline state; and a further quantity may be obtained from the solution by agitation with ether. Metasantonin acid may, however, be more conveniently prepared by distilling santonin acid under a diminished pressure of 52–43 mm., stopping the distillation as soon as the distillate becomes coloured, and the boiling point rises. Both the distillate and the residue in the retort are dissolved in a solution of sodium carbonate, and after agitation with ether to remove oily matters, the alkaline solution is precipitated with an acid, and the metasantonin acid purified by crystallisation from ether. Metasantonin acid is also formed by the action of alkaline solutions on santonide, $C^{15}H^{18}O^2$. Metasantonin acid, when purified by repeated crystallisation from ether, melts, with decomposition, at 160° – 161° . Its alkali-salts are very soluble. Its specific rotatory power is greater than that of santonin acid.

Metasantonin chloride, $C^{15}H^{18}O^2Cl$, prepared by the action of acetic chloride or of phosphorus trichloride on metasantonin acid, crystallises in slender needles melting at 139° , moderately soluble in ether. *Methyl metasantonate*, prepared by passing hydrochloric acid into a methyl-alcohol solution of metasantonin acid, forms large lustrous crystals melting at 101.5° – 102.5° .

Parasantonin Acid, $C^{15}H^{20}O^4$, is prepared from parasantonide (p. 1779) by boiling it with soda-solution, precipitating with an acid, and purifying by crystallisation from ether or from water. It may also be obtained by decomposing parasantonide with boiling dilute hydrochloric acid. The free acid forms large white crystals, which are moderately soluble in ether and in water. It is a strong acid, easily expelling carbonic acid from its salts. The parasantonates are mostly very soluble in water and in alcohol, but difficult to obtain in the crystalline state. The *barium salt*, $(C^{15}H^{19}O^4)^2Ba$, forms slender needles. Parasantonin acid, when treated with acetic chloride or phosphorus trichloride, does not yield the corresponding chloride, but is converted into parasantonide. *Methyl parasantonate* crystallises in hard prisms melting at 183° – 184° . *Ethyl parasantonate* forms colourless needles melting at 172° , only sparingly soluble in ether.

Photosantonin Acid. Sestini, in 1865 (*Repertorio ital. chim. pharm.* 1865), observed that when an alcoholic solution of santonin was exposed to direct sunlight, it was decomposed, with production of an amorphous resinous substance, a small quantity of formic acid, and a crystalline compound since ascertained to be the diethyl salt of photosantonin acid, $C^{15}H^{18}(C^2H^5)^2O^4$. If the alcohol is anhydrous, nothing but amorphous resinous compounds are obtained, but with aqueous alcohol, ethyl photosantonate is produced with comparatively little resin, 85 grams of santonin in 6 litres of alcohol of 65 per cent. having yielded 28 grams of the ether after being exposed to the summer sun for a month. On substituting methyl for ethyl alcohol, the corresponding methyl compound is produced. The ether is precipitated in the crystalline state on mixing the alcoholic solution with six to eight times its volume of a dilute solution of sodium carbonate, and may be purified by crystallising it first from alcohol, and then from ether-alcohol. Photosantonin acid is also formed when an aqueous solution of sodium santonate, or santonin, suspended in a solution of sodium carbonate, is exposed to sunshine. A similar transformation is effected by the insolation of a solution of santonin in glacial acetic acid of 95 per cent., this being, in fact, the most convenient method of obtaining free photosantonin acid. The free acid may also be obtained from the ether by saponification with a dilute solution of sodium hydrate, or with baryta-water.

Photosantonin acid, $C^{15}H^{20}O^4.H^2O$, crystallises from its alcoholic solution in colourless prisms belonging to the orthorhombic system. It is only slightly soluble in boiling water, but readily in alcohol, ether, and chloroform. It loses its water of crystallisation at 100° , and then melts at 153° .

Photosantonin acid decomposes the alkaline carbonates, with the aid of heat, but does not yield crystalline compounds. *Calcium photosantonate*, $(C^{15}H^{19}O^4)^2Ca + 4H^2O$, crystallises in white silky needles, soluble with difficulty in cold water. On heating

this salt with calcium hydrate, a dicalcic salt is obtained which is readily soluble in water, but may be precipitated in white amorphous flocks by addition of alcohol. *Barium photosantonate*, $C^{18}H^{18}BaO^4 + 2H^2O$, is a white amorphous substance precipitated by alcohol from its aqueous solution. *Silver photosantonate*, $C^{18}H^{18}Ag^2O^4 + 4H^2O$, is obtained as a white precipitate on adding silver nitrate to a solution of barium photosantonate. The *diethyl photosantonate*, obtained in the manner previously mentioned by exposing a solution of santonin in dilute alcohol to direct sunlight, is identical with that prepared synthetically by the action of ethyl iodide on silver photosantonate. It crystallises in large very thin plates, which melt at 67° – 68° . It is noteworthy that both this compound and ethyl santonate become liquid in contact with moderately dilute nitric acid. *Methyl photosantonate*, prepared by the insolation of santonin dissolved in methyl alcohol, crystallises in long prisms, which melt at 56.5° , and are readily soluble in alcohol or ether, and but little soluble in water. The methyl compound prepared synthetically from methyl iodide and silver photosantonate melts at 51° – 52° .

SANTONIN, $C^{18}H^{18}O^4$. *Reactions*.—When santonin is added, even in considerable quantity, to *antimony trichloride*, no coloration is produced till the trichloride is heated to incipient ebullition, when a very characteristic bluish olive-green tint makes its appearance (Watson Smith, *Ber.* xii. 1420).

When santonin is digested with strong *sulphuric acid*, and small quantities of ferric chloride are added, the faint red colour at first produced quickly changes to a very fine purple (D. Lindo, *Chem. News*, xxxvi. 222).

Isomerides. Four compounds are known isomeric with santonin :—

(1 and 2). On boiling santonin with hydriodic acid (b. p. 127°) and amorphous phosphorus, until hydrocarbons cease to be formed, removing these by distillation in a current of steam, concentrating the residue, and neutralising with sodium carbonate, a mixture of two isomerides of santonin is precipitated. This mixture may be purified by crystallisation from water and ether, and the crystals of the two isomerides separated mechanically. One of them, which crystallises in long flexible needles, consists of *metasantonin*, which melts at 160.5° , and boils at 238° – 240° (p. 1776), whilst the other, not previously described, crystallises in large hard prisms melting at 136° . Both these compounds are very stable, and have the same rotatory power; they are not sensibly acted on by acetic anhydride or chloride, or by phosphorus trichloride. They both yield monobrominated derivatives when treated with bromine; *monobromometasantonin* crystallises in silky needles, melting at 212° , whilst the corresponding brominated derivative of the other modification melts at 114° (Cannizzaro a. Carnellatti, *Gazz.* 1878, 318).

(3). *Santonide*. When a solution of santonin acid in glacial acetic acid is boiled for several hours, and the acid is then distilled off until the temperature rises to 180° , a residue is left, which solidifies on cooling to a viscous mass of the colour of amber. This residue is agitated with ether and an aqueous solution of sodium carbonate, the ethereal solution decanted and evaporated, and the santonide thus obtained is purified by repeated crystallisation from ether. *Santonide* melts at 127° – 127.5° . The quantity obtained forms but a small proportion of the product, the greater proportion consisting of unchanged santonin acid, which is dissolved by the alkaline solution.

(4). *Parasantonide* is prepared and purified in a similar manner, but the distillation is continued until the temperature rises to 260° . It melts at 110° – 110.5° . Both santonide and parasantonide are levorotatory, but santonide is the more energetic of the two. *Parasantonide*, boiled with caustic soda-solution, is converted into parasantonin acid (p. 1778) (Cannizzaro a. Valente, *Gazz.* 1878, 809).

SANTONOL. This name is given to two phenolic bodies, $C^{18}H^{18}O^2$, one crystalline, the other liquid, obtained by treating santonin with zinc in a current of hydrogen (vii. 1076).

SAPONIN, $C^{32}H^{54}O^{18}$ (v. 192; vi. 1013). J. Christophsohn (*Arch. Pharm.* [3], vi. 432, 461) infers from comparative experiments that the roots of *Saponaria officinalis* and *Gypsophila Struthium*, the bark of *Quillaja*, and the seeds of *Agrostemma Githago* contain one and the same saponin, the pure preparations obtained from all these sources exhibiting, on elementary analysis, the same composition, and yielding, when decomposed by dilute acids, equal quantities of sapogenin and sugar. The differences hitherto found in the analyses of saponin from various sources must therefore be attributed to impurities in the preparations. Christophsohn also gives the results of quantitative estimations of saponin in various drugs, made either by the preparation of barium-saponin, or by determining the quantity of sapogenin obtained by decomposing saponin with hydrochloric acid. According to these determinations :

Quillaja bark contains	8.51- 8.83 p. c. saponin
Root of <i>Gypsophila Struthium</i>	14.52-14.60 "
Seed of <i>Agrostemma Githago</i>	6.54- 6.80 "
Root of <i>Saponaria rubra</i>	4.29- 5.61 "

Christophsohn also confirms the statement of Bolley and others (v. 194), that saponin and senegin (from senega-root) are identical.

Flückiger, on the other hand, is of opinion that several saponins may exist in different plants, probably forming a homologous series (*Arch. Pharm.* [3], x. 532).

Parillin, or **Sarsaparilla-saponin**, $C^{40}H^{70}O^{18} = C^{32}H^{54}O^{18}$ (saponin) + $8CH^2$ Flückiger (*loc. cit.*; also *Pharm. J. Trans.* [3], viii. 488) prepares this compound by digesting bruised sarsaparilla root several times with warm alcohol of sp. gr. 0.835, distilling the liquid to about one-sixth of the weight of the root employed, and mixing the thick extract with $1\frac{1}{2}$ times its weight of water. The glutinous parillin thereby separated is freed from the liquid by decantation, then suspended in water the liquid is filtered off, and the residue washed.

Parillin is less soluble in weak spirit than in strong alcohol or in water. From boiling alcohol—best from that of sp. gr. 0.970—it crystallises in double-refracting laminae or prisms, but never in measurable crystals. Air-dried parillin contains water of crystallisation which it gives off at 100° . It melts at 210° , is almost insoluble in cold water (1 pt. in 10,000), dissolves at 25° in 25 pts. alcohol of sp. gr. 0.814, much more freely in boiling alcohol. Chloroform dissolves it readily, and leaves it on evaporation in the form of a syrup, which, however, may be crystallised from water. Parillin does not excite sneezing, like saponin, and in the solid state does not taste harsh, but exhibits this taste in aqueous and more decidedly in alcoholic solution; it has a neutral reaction, and is inactive to polarised light. Strong sulphuric acid dissolves parillin with yellow colour, changing, by absorption of water, into a splendid red which lasts for days. Heated with sulphuric acid of 10 per cent., or with phosphoric acid, it assumes a green colour, changing to red and finally to brown, the reaction not being altered by addition of nitric acid or bromine. An aqueous solution of parillin gives with alcoholic, but not with aqueous lead acetate, a precipitate soluble in excess of lead acetate or of alcohol; it is also precipitated by basic lead acetate and by tannic acid. It does not reduce Fehling's solution at ordinary temperatures, and only after several hours when heated; neither does it reduce a cold solution of bismuth nitrate, or a solution of mercuric iodide in sodium bicarbonate. On boiling with dilute acids, however, reduction takes place, a sugar, at least partially crystallisable, being first produced, and a flocculent substance, insoluble in water, called parigenin, being afterwards separated. This sugar reduces all the solutions above mentioned. The reaction is represented by the equation:

This decomposition is accompanied by the production of an extremely sensitive green fluorescence, which is likewise produced when hydrogen chloride is passed into a solution of parillin in chloroform, and in the decomposition of parillin by sulphuric acid; it disappears on addition of water or ammonia.

Parigenin, $C^{28}H^{42}O^4$, is nearly allied to sapogenin, $C^{14}H^{22}O^2$, also to cyclamiretin, $C^{14}H^{24}O^2$, and, like the latter, is but slowly acted on by fused alkalis; it is, however, readily attacked by acetyl chloride (Flückiger).

SAPPHIRE. On the artificial formation of this gem, see RUBY (p. 1767).

SARAWAKITE. A crystallised mineral, probably a chloride of antimony, occurring in cavities of antimony in the state of Sarawak, Borneo. The crystals appear to be quadrate; they are rounded on the edges, and have a diamond lustre (Frenzel, *Min. Mitth.* 1877, 300).

SARCINE. This base has been found, together with carnine, guanine, xanthine, and hypoxanthine, in the extract obtained by boiling yeast with water (Schutzenberger, *Compt. rend.* lxxviii. 493); also, together with guanine, in the spermatie fluid of the salmon (Miescher, *Ber.* vii. 376).

SARCOSINE, or **METHYL-GLYCOCINE**, $CH(CH^3)NH^2.COOH$. See GLYCOCINE (p. 879).

SARCOSINIC ACID, $C^2H^1NO^2 = CH^2(NH^2).CH^2.COOH$. An acid occurring, together with a red colouring matter, in a variety of shellac from Mexico, called 'Arré' by the Indians, and known in commerce as *Soma de Sonora* or *Gummi Sonora*. It crystallises in white silky scales, dissolves easily in cold, still more readily in hot water, but is insoluble in absolute alcohol and in ether; the aqueous solution has an acid reaction. It melts at 195° , does not sublime, gives off ammonia when ignited

with soda-lime, but not when boiled with caustic soda. Treated in aqueous solution with nitrous acid, it gives off nitrogen and is converted into lactic acid. It is a weak monobasic acid; its silver and sodium salts are crystalline; the barium and calcium salts amorphous. It forms crystalline compounds with hydrochloric and nitric acids, and is carbonised by heating with strong sulphuric acid. It is isomeric with alanine, sarcosine, lactamide, and urethane, and agrees in many of its characters with alanine, being like the latter an amido-acid, but differs from it in taste and crystalline form, and in possessing a much less decided acid character. The difference between the two may perhaps be represented by the following formulæ:

SASSAFRAS OIL. Rectified sassafras oil, when cooled to 0° , deposits a considerable quantity of crystals, only a small portion remaining fluid. The oil obtained by heating the crystals to 70° solidifies only after exposure for several weeks to a temperature below 0° ; but if the crystals be allowed to melt at a temperature not exceeding 20° , the liquid mass solidifies easily on cooling. These characters demonstrate the identity of St. Evre's sassafras camphor (v. 199) with the safrol of Grimaux a. Ruotte (vi. 1014). The crystals of safrol belong to the monoclinic system (Arzruni, *N. Rep. Pharm.* xxv. 615).

SAUSSURITE (v. 200). This mineral has been found in thin layers and irregular masses in the nephrite of the Künlin range in Central Asia (p. 1387). An analysis by v. Fellenberg (*Münch. Akad. Ber.* iii. 227) gave:

SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	K ² O	H ² O
48.25	22.60	7.47	1.03	12.70	1.80	6.22	0.55 = 100.62

leading to the formula $(\text{CaO}, \text{K}^2\text{O})3\text{SiO}^2 + 2(\text{Al}^2\text{O}^3, \text{Fe}^2\text{O}^3) \cdot 3\text{SiO}^2$, in which $\text{K}^2\text{O} : \text{CaO} = 1 : 2$ and $\text{Al}^2\text{O}^3 : \text{Fe}^2\text{O}^3 = 5 : 1$.

SAYNITE. The mineral hitherto known by this name, or by that of nickel-bismuth glance (i. 596), is essentially a mixture of polydimite (p. 1660) with bismuth-glance (Laspeyres, *J. pr. Chem.* [2], xiv. 397).

SCAMMONY. For the preparation of pure scammony-resin, E. Perret (*Bull. Soc. Chim.* [2], xxviii. 522) recommends exhausting the crude commercial resin with boiling alcohol, neutralising the alkaline filtrate with dilute sulphuric acid, and separating the resulting precipitate, which contains all the colouring matter, by filtration. The filtrate, freed from alcohol by distillation and dried by prolonged heating at 104° , yields the pure anhydrous resin.

SCANDIUM. A metal of the yttrium group, discovered by F. Nilson in 1879, and further examined by Cleve. It occurs in gadolinite and yttrötitanite, has the atomic weight 44, and forms only one oxide, Sc^2O^3 (see YTTRIUM METALS).

SCAPOLITE. F. D. Adams (*Sill. Am. J.* [3], xvii. 315) finds that many scapolites contain chlorine, fourteen specimens from different localities yielding that element in quantities varying from a mere trace to 2.4 per cent. In some cases the chlorine was not driven off, even at a white heat. It is probable that when the scapolite decomposes, the chlorine is one of the first constituents to disappear.

SCHÉEELITE. See TUNGSTATES.

SCHIZOMYCETES. See FERMENTATION and FERMENTS (pp. 776, 782).

SCHRÖCKINGERITE. A mineral from Joachimsthal, containing uranic oxide, carbonic acid, and water, together with a small quantity of lime, and extremely small traces of sulphuric acid. Loss by ignition = 36.7 per cent. It forms spherical groups of light greenish-yellow six-sided tablets implanted on pitchblende. From its optical characters it appears to belong to the orthorhombic system (A. Schrauf, *Jahrb. f. Min.* 1873, 646).

SCLÉRETHRYTHRIN, SCLEROMUCIN, SCLEROTIC ACID, SCLEROCRYSTALLIN, and SCLEROXANTHIN. Constituents of ergot (p. 737); further, Dragendorff a. Podwisoitzky (*Russ. Zeitschr. Pharm.* xvi. 129, 161; *Jahresb. f. Chem.* 1877, 943).

SCOLECITE. On the variety of scolecite occurring at Poonah in Hindostan, see POONAH-LITE (p. 1663).

SCOPOLIA. *Scopolia japonica* is a solanaceous plant intermediate in character between Solanum and Atropa. Its roots are used in Japan for the same purpose as *Atropa Belladonna* in Europe, but their effect is less powerful. They contain solanine, but no atropine. The plant is highly fluorescent.

SCORODITE. Crystals of this mineral from Dernbach in Nassau have been examined by G. vom Rath (*Jahrb. f. Min.* 1876, 394), who finds the axial ratio to be

$$a : b : c = 0.86730 : 1 : 0.95580$$

and for the angles of the primary pyramid:

Macrodiagonal terminal edge	=	102° 52'
Brachydiagonal	„	= 114° 40'
Lateral edge		= 111° 6'

Brazilian scorodite, measured by N. v. Kokscharow (*ibid.* 1877, 800), gave values agreeing exactly with the above.

W. v. Beck (*ibid.* 162) has analysed a dark liver-coloured or indigo-blue mass of sp. gr. 3.084, occurring on a newly-discovered bed of silver ore in the Troitzker Circle of the Government of Orenburg, and regards it as a mixture of scorodite with brown iron ore and silver chlorobromide. The results are given in the following table.

1-3. Analyses. 4-6. The same, after deduction of silver-compounds and lime:

	AgCl, AgBr (*)	CaO	Fe ² O ³	As ² O ³	H ² O
1. (found)	5.78	2.18	36.80	42.37	13.43 = 100.56
2. „	6.41	2.07	36.73	41.44	13.43 = 100.08
3. „	9.25	1.43	35.40	40.44 (2)	13.43 = 100
4. (corr.)	—	—	39.75	45.75	14.50 = 100
5. „	—	—	40.10	45.24	14.66 = 100
6. „	—	—	39.66	45.30	15.04 = 100

(*) Enclosing small quantities of matrix. (2) Determined by difference.

On so-called *earthy scorodite* from Nertschinsk, see JOGYNITE (p. 1142).

SEBIC, or SEBACIC ACID, C¹⁸H³⁶O⁴ (v. 212). O. N. Witt (*Ber.* vii. 219) prepares this acid by mixing castor-oil with the strongest soda-ley, leaving the mixture for some hours at 40°, separating the resulting hard crust from the small remaining quantity of liquid; then crushes, dries, and heats it, with stirring, in an iron vessel till the smell of octyl alcohol is no longer perceptible and the mass begins to turn brown; and immediately shakes the residue into cold water. From the solution thus obtained, the sebic acid may be precipitated by hydrochloric acid. See also Neison (*Chem. Soc. J.* xxvii. 301).

Metallic Sebrates. Sebic acid is bibasic. Its normal salts appear to be more stable than the acid salts, the latter being, in some instances, decomposed by prolonged boiling of their acid solutions. The acid salts appear to be all more or less soluble in water; the normal salts of the heavy metals and of calcium are insoluble in water; the rest are soluble.

Potassium salts, C¹⁸H³⁶O⁴KH, is prepared by adding a hot alcoholic solution of potassium hydrate to a hot alcoholic solution of sebic acid keeping the latter in excess, and separates at once in minute crystals which are easily purified by washing with alcohol. It forms white anhydrous microscopic needles, not deliquescent, easily soluble in cold, still more readily in hot water, moderately soluble in alcohol, yielding strongly acid solutions. C¹⁸H³⁶O⁴K², obtained by adding a hot alcoholic solution of sebic acid to a large excess of alcoholic potash, and purified by boiling with alcohol, washing with hot alcohol and drying, is a white anhydrous crystalline powder, consisting of minute granules, readily soluble in cold, still more in hot water, sparingly in alcohol, forming solutions which are neutral to litmus.

The *sebrates of sodium* are prepared in the same manner as the potassium salts. C¹⁸H³⁶O⁴NaH is a fine crystalline powder, easily soluble in water, moderately in alcohol, forming solutions which have a marked acid reaction. C¹⁸H³⁶O⁴Na² is obtained in very fine microscopic crystals, non-deliquescent, very soluble in water, slightly soluble in alcohol.

Ammonium sebrates can be obtained in solution in the same manner as the potassium salts, but on attempting to separate them in the solid state, they are invariably decomposed with loss of ammonia.

Silver sebate, C¹⁸H³⁶O⁴Ag², obtained by precipitation, is a white powder rapidly turning pink on exposure to light, and readily soluble in nitric acid.

Barium salts, (C¹⁸H³⁶O⁴)²BaH², prepared by boiling barium carbonate with excess of aqueous sebic acid, is a white confusedly crystallised non-deliquescent salt, easily soluble in water, and crystallising therefrom in needles. C¹⁸H³⁶O⁴Ba, prepared by prolonged boiling of the acid with excess of barium carbonate, separates from concentrated solutions in white anhydrous crystalline crusts, easily soluble in water with neutral reaction. The *strontium salts* were prepared in like manner. The *acid*

salt forms white crystalline crusts; the *normal salt*, a white anhydrous crystalline powder. *Calcium salts*, $(C^{10}H^{16}O^4)^2CaH^2$, prepared by adding a hot solution of acid potassium sebate to a solution of calcium chloride, is a dense white precipitate, slightly soluble with acid reaction in water, partially decomposed by prolonged boiling into sebic acid and the normal salt. $C^{10}H^{16}O^4Ca$, obtained by adding normal sodium sebate to calcium chloride solution, is a dense white amorphous precipitate.

Magnesium salts, $(C^{10}H^{16}O^4)^2MgH^2$, prepared like the acid barium salt, crystallises in groups of white anhydrous needles, easily soluble in water with strong acid reaction, very slightly soluble in alcohol. $C^{10}H^{16}O^4Mg$, prepared like the normal barium salt, forms thin white crystalline crusts readily soluble in water, slightly in alcohol.

Zinc sebate, $C^{10}H^{16}O^4Zn$, is a heavy white pulverulent precipitate, slightly soluble in water and in dilute ammonia. *Nickel sebate*, $C^{10}H^{16}O^4Ni$, obtained by dissolving nickel hydrate in aqueous sebic acid, forms pale-green anhydrous crystalline crusts, slightly soluble in cold, more soluble in hot water, insoluble in alcohol. *Cobalt sebate*, $C^{10}H^{16}O^4Co$, prepared in like manner, forms thin purple-blue anhydrous scales slightly soluble in cold, somewhat more in hot water. Solutions of nickel and cobalt salts are not precipitated by sebic acid or its alkali-salts (Neison). According to O. N. Witt (*loc. cit.*), the rose-coloured solution of cobalt carbonate in boiling aqueous sebic acid, if evaporated after the excess of acid has separated out on cooling, yields crystalline crusts of the hydrated salt $C^{10}H^{16}O^4Co + 2H^2O$; and the same hydrate is obtained, by spontaneous evaporation, partly in rose-red granules made up of microscopic needles, partly in ruby-red prismatic crystals. It gives off the greater part of its water at 120° , assuming a splendid violet colour, the rest with slight decomposition at a higher temperature.

Lead sebate, obtained by precipitation, is a heavy white powder insoluble in water and alcohol, either hot or cold, not changed by boiling with sebic acid.

Cupric sebate, $C^{10}H^{16}O^4Cu$, is a light emerald-green bulky precipitate which shrinks considerably on drying and then forms a green light powder. It dissolves readily in ammonia, forming a dark purple solution, which leaves, on spontaneous evaporation, a bluish-green mass containing ammonia, possibly a cuprammonium sebate.

Mercuric sebate, $C^{10}H^{16}O^4Hg$, obtained by decomposing mercuric chloride either with normal or with acid potassium sebate, is a white insoluble precipitate. Sebic acid in hot aqueous solution does not precipitate mercuric chloride.

Mercurous sebate, $C^{10}H^{16}O^4Hg^2$, obtained by precipitating mercurous nitrate with potassium sebate, is a heavy white amorphous powder, slightly soluble in water, very slightly in alcohol.

Aluminium-hydrogen sebate, $(C^{10}H^{16}O^4)^3AlH^3$, obtained by precipitating a strong solution of alum with acid potassium sebate, or by boiling freshly precipitated alumina with excess of sebic acid, is a white friable powder, slightly soluble in cold, easily in hot water, and separating on cooling in white anhydrous semicrystalline scales (Neison).

Sebic Ethers (Neison, *Chem. Soc. J.* xxix. 314). *Methyl sebate*, $C^{10}H^{16}O^4(CH^3)^2$, is prepared by dissolving 2 pts. by weight of sebic acid in 1 pt. of warm methyl alcohol; gradually adding a double volume of strong sulphuric acid, and heating the mixture for some time on the water-bath, with frequent agitation; adding water after cooling; washing the oily layer thoroughly with water; dissolving it in ether; drying the ethereal solution over calcium chloride and potassium carbonate; distilling; heating the residue for some time at 120° , and leaving it to cool. The crude ether is thus obtained as a white waxy mass, which may be purified by boiling it with a very dilute solution of sodium carbonate, redissolving it in ether, distilling off the latter, and heating the residue at 150° . Methyl sebate thus prepared is a white wax having a strong and rather pleasant odour, and obtainable by spontaneous evaporation of its ethereal solution in small needles or plates having a nacreous lustre. Ether and hot alcohol dissolve it readily; cold alcohol slowly, but in considerable quantity. It is insoluble in cold water, slightly soluble in hot water. It is easily saponified by alkaline hydrates, but not by alkaline carbonates. It melts at 38° ; becomes hard and brittle at -25° to -30° ; and boils, though not without decomposition, at about 288° , yielding a brown distillate, which, however, may be decolorised by boiling its alcoholic solution with animal charcoal.

Ethyl sebate, $C^{10}H^{16}O^4(C^2H^5)^2$, is prepared by passing hydrochloric acid gas into an alcoholic solution of sebic acid, and purified by boiling it first with water, next with dilute sodium carbonate, and again with water; then dissolving it in ether, drying the ethereal solution over calcium chloride and potassium carbonate, distilling

off the ether, and submitting the residue to fractional distillation, collecting apart the portion (about 90 p. c.) which passes over between 306° and 310°.

Pure ethyl sebate is a colourless oily liquid having a density of 0.965 at 16°, and a strong odour like that of melons. It solidifies at -4.6° to a white wax consisting of nodules of minute needles and plates, and becomes hard and friable at -30° to -35°; boils without decomposition at 307°-308°. In its relation to solvents and to alkalis, it resembles the methylic ether.

Ethyl-hydrogen sebate is formed in small quantity in the preparation of the normal ether, but has not yet been obtained pure. It dissolves when boiled with sodium carbonate or shaken up with cold soda-ley, but a considerable portion is at the same time decomposed. On adding an acid to the resulting solution, the acid ether separates, together with small quantities of sebic acid and the normal ether, as an oil which readily crystallises at 10° in delicate snow-white needles.

Amyl sebate, $C^{10}H^{16}O_4(C^2H^{11})^2$, prepared like the ethyl-compound, forms, after purification, a colourless oil having a very strong but pleasant fruity odour, and a density of 0.9510 at 18°. When heated it becomes quite colourless, and when cooled to -5° partly solidifies in thin needles which increase in quantity on further cooling, but the greater portion still remains fluid at -35°. The needles disappear on raising the temperature to +10°, and immediately on addition of a trace of water. This ether boils at a temperature above 360°. It is insoluble in water, but dissolves readily in alcohol either hot or cold, and in unlimited quantity in ether. It is not attacked by boiling solutions of alkaline carbonates or by cold solutions of alkaline hydrates, but is decomposed by alcoholic solutions of the latter, even at ordinary temperatures. When a dilute alcoholic solution of sodium hydrate is allowed to act slowly on an excess of normal amyl sebate, a considerable quantity of the *acid ether* $C^{10}H^{16}O_4(C^2H^5)$ is formed. The resulting solution, when left to evaporate, deposits sodium sebate, then, on addition of water, the undecomposed portion of the normal ether, whilst the sodium salt of the acid ether remains dissolved, and may be obtained by evaporation as a white very deliquescent mass, which may be purified by repeated treatment with alcohol and water. By carefully decomposing this salt with acetic acid, the acid amyl sebate is obtained as a yellowish oil, which solidifies at 10° to a white crystalline mass, easily soluble in alcohol, ether, and hot water; slightly in cold water, and splitting up at 325° into sebic acid and the normal ether.

Aniline-derivatives. Equal weights of sebic acid and aniline, heated together at 150°, produce: (1). *Sebanilide*, a neutral compound soluble in boiling alcohol. (2). *Sebanilic acid*, a monobasic acid, soluble in alcohol and ether (E. Maillot, *Compt. rend.* lxxxvii. 737).

SEEBACHITE. See PHACOLITE (p. 1513).

SELENIUM. *Occurrence and Extraction.*—According to Rössler a. Debray (*Zeitschr. anal. Chem.* 1877, 363), selenium is present in refined silver, being derived from the sulphuric acid (made from pyrites) used in the refining process. If the amount exceeds 1 pt. in 1000, the silver becomes unworkable.

From the seleniferous deposit, or mud, of the lead chambers in sulphuric acid works, the selenium may be advantageously extracted by dissolving it out with potassium cyanide. The washed mud is digested with a moderately strong solution of the cyanide at 80°-100° till the red colour just changes to a pure grey; the residue is lixiviated with boiling water till the liquid no longer shows a reddish opalescence on addition of hydrochloric acid; the solution is then filtered, and the selenium precipitated by hydrochloric acid. By this process, 1 pt. of selenium is obtained for every 2 pts. of potassium cyanide employed. The precipitated selenium contains only small quantities of copper and iron, and perhaps traces of mercury; it may be freed from these impurities by converting it into selenious oxide, subliming this compound, and precipitating the selenium with sulphurous acid (Pettersson, *Ber. vi.* 1466; Nilson, *ibid.* vii. 1719).

On the occurrence of Selenium in Tellurium ores, see TELLURIUM.

Atomic Weight.—Pettersson a. Ekman, by reducing a known weight of selenious oxide, SeO_3 , with sulphurous acid, and weighing the reduced selenium, have found, as a mean of five experiments, that the atomic weight of selenium is 79.08 (*Bull. Soc. Chim.* [2], xxvii. 205).

Allotropic Modifications.—Observations on the allotropic modifications of selenium, especially the amorphous vitreous variety, and the granular or so-called metallic selenium, produced therefrom by fusion and slow cooling, have been made by Draper a. Moss (*Chem. News*, xxxiii. 1). Vitreous selenium has no definite melting point, but becomes softer at 60° and upwards, and perfectly fluid at 250°; it is restored to

its original state by rapid cooling, and then remains unaltered at ordinary temperatures for years. Carbon bisulphide dissolves only traces of this modification. Thin splinters of it transmit light of ruby-red colour. When heated for some time between 94° and 200° , and then slowly cooled, it acquires a metallic aspect and granular fracture, and becomes perfectly opaque even in the thinnest layers. It melts at 217° , without previous softening, is perfectly fluid at 250° , and is reconverted into the vitreous modification by rapid cooling.

On the Electric Conductivity of the several Modifications of Selenium, see ELECTRICITY (p. 721).

Selenium enclosed in the vacuum of a Sprengel mercury-pump, or dipped into mercury, condenses the vapour of that metal, and becomes coated with a layer of substance which conducts electricity, and though merely superficial, cannot be removed either by mechanical or by chemical means, and therefore does not appear to consist of metallic mercury (R. J. Moss, *Chem. News*, xxxiii. 203).

Selenium imparts a greyish-blue colour to the flame of hydrogen (Fresenius, *Zeitschr. anal. Chem.* 1876, 295).

When selenium is dissolved in strong sulphuric acid, it is partly oxidised, and on boiling the green solution, it immediately becomes colourless, gives off large quantities of sulphur dioxide, and no longer yields a precipitate of selenium when mixed with water, but deposits red selenium on addition of stannous chloride. A highly concentrated solution of selenium in sulphuric acid, which has a blackish-green colour, does not readily give off sulphur dioxide, but this gas is immediately evolved on addition of fresh quantities of strong sulphuric acid (A. Hilger, *Ber.* vii. 26).

Selenious Oxide, Acid, and Salts. Selenious oxide absorbs dry *hydrogen chloride* rapidly and with considerable rise of temperature. The product first formed is an amber-yellow liquid composed of equal numbers of molecules of the two constituents ($\text{SeO}_2 \cdot \text{HCl}$). This liquid, when heated, begins to give off hydrogen chloride at 26° . Its dissociation-tension in millimeters at various temperatures is as follows:

Temperature . . .	30°	40°	55°	75°	100°	106°	118°
Tension . . .	15	48	142	313	664	760	1012

At low temperatures the liquid continues to absorb hydrogen chloride, and ultimately becomes converted into a transparent yellow crystalline solid, containing 2 mols. of hydrogen chloride to 1 of selenious anhydride ($\text{SeO}_2 \cdot 2\text{HCl}$). This substance is resolved by heat (its dissociation-tension being considerable even at the ordinary temperature) into hydrogen chloride and the compound $\text{SeO}_2 \cdot \text{HCl}$, which latter is permanent below 26° . The following tensions in millimeters were observed:

Temperature . . .	-20°	0°	12°	15°	22.5°	30°	33°
Tension . . .	60	219	418	483	672	760	993

Dry hydrogen bromide is rapidly absorbed by selenious anhydride, forming in the first place the compound $\text{SeO}_2 \cdot 2\text{HBr}$, which crystallises in brilliant steel-grey spangles. This compound is stable below 55° , but is resolved at higher temperatures into selenium, bromine, and water. Its solution in a very small quantity of water is nearly black; a large quantity decomposes it, forming hydrobromic and selenious acids. The compound $\text{SeO}_2 \cdot 2\text{HBr}$ energetically absorbs hydrobromic acid gas, with evolution of heat, giving rise to a crystalline compound corresponding with the formula $2\text{SeO}_2 \cdot 5\text{HBr}$. This compound is decomposed at 65° with formation of water and disengagement of bromine, but at lower temperatures it is transformed into $\text{SeO}_2 \cdot 2\text{HBr}$ and hydrobromic acid. The following are the values of the dissociation-tension of the compound $2\text{SeO}_2 \cdot 5\text{HBr}$ at various temperatures:

At -25° . . .	0 mm.	At 30° . . .	287 mm.
" -6° . . .	108 "	" 41° . . .	335 "
" 0° . . .	135 "	" 54° . . .	404 } Traces of bromine
" $+11^{\circ}$. . .	191 "	" 62° . . .	404 } vapour.
" 14° . . .	209 "	" 70° . . .	Decomposition with
			abundant evolu-
			tion of bromine.

Hydriodic acid reacts with selenious oxide even at -10° , the products being water, iodine, and selenium. Selenious oxide also combines with anhydrous *hydrocyanic* and *hydrofluoric acids*. Selenious oxide and *hydrogen selenide* in presence of water decompose each other, with separation of selenium. This result is always the same, whether the solutions be concentrated or dilute, hot or cold; and no compound corresponding with pentathionic acid has been obtained. The reaction affords a convenient

means of obtaining selenium soluble in sulphide of carbon (A. Ditte, *Compt. rend.* lxxxiii. 56, 223).

Selenious acid in presence of ammonium chloride is completely precipitated, by a *magnesium salt and ammonia*, after long standing or on brisk agitation, the precipitate of ammonium-magnesium selenite being crystalline, and exhibiting under the microscope a very close resemblance to that of ammonium-magnesium phosphate. This reaction affords the means of separating selenious acid from selenic, sulphurous, sulphuric, and telluric acids (Hilger a. v. Gerichten, *Zeitschr. anal. Chem.* 1874, 132).

Selenites.—An elaborate investigation of these salts has been made by L. F. Nilson (*Researches on the Salts of Selenious acid*, Nova acta reg. Soc. Scient. Upsal. Ser. iii. 1875; *Bull. Soc. Chim.* [2], xxi. 258; xxiii. 260, 353, 494). The following is a summary of the results:

$\text{SeO}^3\text{K}^2 + x\text{H}^2\text{O}$	Very deliquescent prisms.
SeO^3KH	Very hygroscopic prisms.
$\text{SeO}^3\text{KH} + \text{SeO}^3\text{H}^2$	Shining prisms, permanent in the air.
$\text{SeO}^3\text{Na}^2 + 5\text{H}^2\text{O}$	Small needles, or large four-sided prisms.
SeO^3Na^2	Tetragonal prisms, formed by slow evaporation at 60°.
SeO^3NaH	Radiate prisms, permanent in the air.
$\text{SeO}^3\text{NaH} + \text{SeO}^3\text{H}^2$	Large prisms, permanent in the air.
$\text{SeO}^3\text{Li}^2 + \text{H}^2\text{O}$	Needles having a silky lustre.
SeO^3LiH	Prisms resembling arragonite.
$\text{SeO}^3\text{LiH} + \text{SeO}^3\text{H}^2$	Long prisms permanent in the air.
$\text{SeO}^3(\text{NH}^4)^2 + \text{H}^2\text{O}$	Formed by saturating an alcoholic solution of SeO^3H^2 with NH^3 . Small prisms, giving off 18 per cent. NH^3 on exposure to the air.
$2\text{SeO}^3(\text{NH}^4)^2 + \text{SeO}^3\text{H}^2$	By saturating an aqueous solution of SeO^3H^2 with NH^3 . Long deliquescent prisms.
$\text{SeO}^3\text{Ba} + \text{H}^2\text{O}$	Microscopic prisms.
$\text{SeO}^3\text{Ba} + \text{SeO}^2$	Sparingly soluble prisms, separating from a solution of BaCO^3 in SeO^3H^2 , on evaporation at 60°.
$\text{SeO}^3\text{Sr} + 3\text{H}^2\text{O}$	Crystalline powder.
$\text{SeO}^3\text{Sr} + \text{SeO}^3\text{H}^2$	Large shining prisms.
$\text{SeO}^3\text{Ca} + 2\text{H}^2\text{O}$	Small crystals having a satiny lustre; efflorescing in the air.
$\text{SeO}^3\text{Ca} + \text{SeO}^2$	Large crystals, forming on evaporation at 60°.
$\text{SeO}^3\text{Ca} + \text{SeO}^3\text{H}^2 + \text{H}^2\text{O}$	Shining prisms, obtained by evaporation at ordinary temperatures.
$\text{SeO}^3\text{Mg} + 6\text{H}^2\text{O}$	Hexagonal plates or short prisms, giving off $5\text{H}^2\text{O}$ at 100°.
$\text{SeO}^3\text{Mg} + \text{SeO}^3\text{H}^2 + 3\text{H}^2\text{O}$	Crystalline mass.
$\text{SeO}^3\text{Mn} + 2\text{H}^2\text{O}$	Amorphous precipitate, gradually becoming crystalline.
$\text{SeO}^3\text{Ni} + 2\text{H}^2\text{O}$	Crystalline powder.
$\text{SeO}^3\text{Ni} + \text{SO}^3\text{H}^2 + 2\text{H}^2\text{O}$	Four-sided prisms.
$\text{SeO}^3\text{Ni} + \text{SO}^3\text{H}^2 + \text{SeO}^2$	Small plates.
$\text{SeO}^3\text{Co} + 2\text{H}^2\text{O}$	Amorphous bluish-red precipitate.
$\text{SeO}^3\text{Co} + \text{SeO}^2$	Small red prisms.
SeO^3Cd	Small insoluble prisms.
$\text{SeO}^3\text{Cu} + 2\text{H}^2\text{O}$	Small bluish prisms.
$\text{SeO}^3\text{Cu} + \text{SeO}^3\text{H}^2 + 2\text{H}^2\text{O}$	Bluish-green powder.
$5\text{BeO}.2\text{SeO}^2 + 10\text{H}^2\text{O}$	
$\text{BeO}. \text{SeO}^2 + 2\text{H}^2\text{O}$	
$\text{BeO}. \text{SeO}^2 + \text{SeO}^3\text{H}^2$	
$\text{BeO}. \text{SeO}^2 + 2\text{SeO}^3\text{H}^2$	

The gadolinite and cerite metals form selenites analogous in composition to those of aluminium, iron, indium, and chromium. The following selenites of these metals have been obtained:

1. From dilute solution of a normal salt and normal sodium selenite:

2. From basic salts with a quantity of acid exactly sufficient for the formation of a normal salt:

3. From basic or neutral salts with a quantity of acid sufficient for the formation of a diselenite:

4. From a basic salt with a quantity of acid sufficient for the formation of a diselenite or of a tetraseselenite:

5. From a basic salt with a quantity of acid exactly sufficient for the formation of a tetraseselenite:

Nilson has also obtained two selenites of bismuth and antimony, which exhibit a certain analogy between these trivalent metals and the preceding:

Among the rare earth-metals, thorium exhibits no analogy to the rest, not even with tin or zirconium, but stands alone with respect to its selenites, as in many other respects; thus:

Selenic Acid, SeO_4H^2 . v. Gerichten (*Liebig's Annalen*, clxviii. 214) prepares this acid from selenium containing sulphur by oxidising the selenium with nitric acid, adding potash, passing chlorine into the solution till it no longer gives a red precipitate with stannous chloride, then precipitating the selenic acid as barium selenate, and decomposing this salt with a slight excess of potassium carbonate. Any barium sulphate that may have been precipitated with it then remains undecomposed. This mode of separation is not exact enough for quantitative analysis, but sufficiently so for the purpose in hand. Any small quantity of barium selenate that may be dissolved may be recovered by slight concentration of the filtrate.

Selenic acid may be estimated by boiling it with hydrochloric acid, and determining the quantity of evolved chlorine by titration with iodine and sulphurous acid (Petersson, *Zeitschr. anal. Chem.* 1873, 287).

Selenic Oxide or **Anhydride**, SeO_3 .—By passing dry oxygen over dry selenium heated in a glass tube, and then passing the resulting selenious oxide, together with oxygen, over red-hot platinum sponge, a white deposit was once obtained which resembled sulphuric anhydride, and dissolved in water with a hissing noise, yielding a solution containing selenic as well as selenious acid; but a second experiment made in the same manner yielded nothing but selenious acid (v. Gerichten, *loc. cit.*)

METALLIC SELENATES. On the Optical properties of these Salts. see LIGHT (p. 1190).

Ammonium selenate, $(\text{NH}_4)^2\text{SeO}_4$, when heated, first gives off ammonia, and is converted into the acid selenate, $(\text{NH}_4)\text{HSeO}_4$, and the latter, when further heated, is resolved into selenium, selenious oxide, water, and nitrogen (Cameron & Davy, *Chem. News*, xxxviii. 133).

Seleniosulphates (v. Gerichten, *loc. cit.*)—Double salts of the form $K^2SeO^4.M'SO^4 + 6H^2O$ [$M = Ni, Co, Fe, Zn, Mn, Cd, Cu, Mg$], are prepared by mixing concentrated solutions of the corresponding sulphates with potassium selenate. They crystallise well, and are isomorphous with the corresponding double sulphates and double selenates. In a similar manner are prepared the corresponding salts $M'SeO^4.K^2SO^4 + 6H^2O$. The *copper salt* crystallises in fine well-formed light blue monoclinic combinations, sometimes tabular, but more frequently prismatic, with great elongation of the basal pinacoid. All these salts are isomorphous with the corresponding double selenates.

Seleniosulphuric Alums.—The salt $K^2SeO^4.Al^2(SO^4)^3 + 24H^2O$ is obtained in limpid octohedrons by mixing the solutions of potassium selenate and aluminium sulphate, and the corresponding chromic, ferric, and manganic alums are obtained in like manner. The salt $K^2SO^4.Al^2(SeO^4)^3 + 24H^2O$ is likewise obtained in transparent octohedrons by mixing the solutions of potassium sulphate and aluminium selenate; so also the corresponding chromic and ferric alums.

Seleniocyanates.—The *potassio-platinic salt*, $K^2Pt(CSeN)^6$, is formed on mixing the alcoholic solutions of potassium seleniocyanate and platinum chloride, and separates from the boiling and filtered liquid in crystals which may be purified from an admixed reddish salt by recrystallisation from alcohol. They are hexagonal plates, generally small, almost black by reflected, dark garnet-red by transmitted light. Sp. gr. = 3.377 at 10° (weighed in benzene). The *gold salt*, $KAu(CSeN)^2$, was obtained in a similar manner in dark red very easily decomposable prisms (J. W. Clarke, *Ber.* xi. 1325).

SELENIUM-BISMUTH-GLANCE, or *Frenzelite*. This mineral, from Guanajuato in Mexico, crystallises in the orthorhombic system, is isomorphous with antimony-glance, and exhibits the faces $\infty P \infty$, $\infty P \infty$, ∞P , together with several unmeasurable faces, ∞Pn . Sp. gr. 6.25 at 21° . An analysis by Frenzel (*Jahrb. f. Min.* 1874, 679) gave 67.38 per cent. Bi, 24.13 Se, and 6.60 S, agreeing approximately with the formula $2Bi^2Se^3 + Bi^2S^3$, which requires 68.35 Bi, 26.07 Se, and 5.28 S.

SELENIUM-COMPOUNDS, ORGANIC. *Ethyl selenide* or *Selenethyl*, $(C^2H^5)^2Se$, is produced by the action of phosphorus pentaselenide on potassium ethylsulphate. For this purpose, equivalent quantities of these two compounds and potassium hydroxide are digested with a small quantity of water at 50° , and the product is subjected to fractional distillation. The distillate consists for the most part of ethyl monoselenide, contaminated, however, with traces of diselenide, which are removed by digesting the distillate with more potassium ethylsulphate, potash, and water, with addition of a little phosphorus, and distilling afresh.

Pure ethyl monoselenide, thus obtained, is a clear, colourless, mobile, highly refractive liquid, smelling like the light hydrocarbons and boiling at 108° . It mixes with alcohol and ether in all proportions.

Triethyl-selenonium Iodide, $Se(C^2H^5)^3I$.—Ethyl monoselenide and ethyl iodide, when mixed in molecular proportions, combine slowly at ordinary temperatures to form white crystals of this compound. It is stable in the air, not hygroscopic, but very easily soluble in water and alcohol, and sparingly in ether. It sublimes completely between 80° and 126° without melting, and is at the same time resolved into ethyl monoselenide and ethyl iodide, which collect in the receiver and recombine in the course of twelve hours to form triethyl-selenonium iodide.

Triethyl-selenonium Hydroxide, $Se(C^2H^5)^3OH$, is formed by the action of silver oxide on triethyl-selenonium iodide. It is a powerful base, forming a syrupy solution which absorbs carbon dioxide and water with avidity. Its salts are all crystalline: they have the odour of leeks and a burning bitter taste. With the exception of the tartrate, they all deliquesce rapidly in the air, and hence cannot well be analysed.

The *tartrate*, $Se(C^2H^5)^3C^4H^5O^6 + 2H^2O$, crystallises in delicate needles of a pale rose-red colour; it dissolves very easily in water, forming an acid solution.

The *platinochloride*, $[Se(C^2H^5)^3Cl]^+PtCl_4^-$, crystallises in highly refractive red rhombohedrons.

These results point to the conclusion that selenium is an element of variable atomicity, being bivalent in the compound $(C^2H^5)^2Se$, and quadrivalent in the compounds $(C^2H^5)^3SeC^2H^5I$ and $(C^2H^5)^3SeC^2H^5(OH)$ (L. v. Pieverling, *Liebig's Annalen*, cxxxv. 331).

SERPIOLITE. See MEERSCHAUM (p. 1269).

SERANIM. An explosive mixture formed of potassium chlorate and nitroglycerin (Nobel, *Monit. scient.* [3], vi. 248).

SERICITE-ROCKS. See *Jahrb. f. Min.* 1878, 264, 296, 383; *Chem. Soc. J.* xxxvi. 23, 25, 207.

SERPENTINE. The following are recent analyses of this mineral: 1. Noble serpentine from Snarum (J. R. Müller, *Min. Mitth.* 1877, 25). 2 and 3. Light and dark-coloured pebbles of transparent serpentine from the shores of the islands Iona and Tiree, Scotland (Stanford, *Chem. Soc. J.* xxvi. 19). 4-6. From the bed of magnetic iron ore in the Tilley-Foster mine, Putnam County, New York. 4. White, cauliflower to fibrous; sometimes in small granules imbedded in the ore or filling small clefts. 5. Green in thin layers, of lighter or darker colour, sometimes cauliflower in small clefts (Breidenbaugh, *Sill. Am. J.* [3], vi. 209). 6. Grey-green in radio-fibrous granules. Sp. gr. 2.4. 7. Light-green translucent serpentine from New Jersey, incrustated with a yellowish mass traversed by bands of chrysotil. Sp. gr. = 2.51 (Berwerth, *Min. Mitth.* 1875, 110):

The serpentines of Upper Alsace have been examined by B. Weigand (*Min. Mitth.* 1875, 183). They may be divided into a northern group (Bluttenberg or Bressoir) and a southern group (Amarinertal). The northern group includes three kinds of serpentine, all imbedded in gneiss, but showing by the difference of their chemical and microscopical characters that they have originated from different rocks, the serpentine of Bonhomme (No. 1) being derived from olivine-rock, that of Starkenbach from a bronzite rock poor in olivine, that from the Rauenthal (No. 2) from a hornblende rock. In the south, the serpentine (No. 3) is associated with gabbro, consisting—together with felspar, quartz, and diallage—of a fine-fibred hornblende impregnated with quartz, which is sometimes almost wholly predominant, and has probably formed the material for the conversion of the rock into serpentine.

1. Bonhomme; *a* and *b*. Blackish-green serpentine; *c*. Noble serpentine from the clefts.

2. Rauenthal; *a*. Solution obtained by the action of dilute hydrochloric acid continued for several days on the pulverised serpentine; *c*. Total analysis; *d*. Hornblende-rock, probably the matrix of the serpentine, into which it gradually passes.

3. Amarinertal.

In 1a also traces of MnO, NiO, and Cr²O³; in 2a and 2b, traces of NiO.

An elaborate memoir on the serpentines of Zöblitz, Greifendorf, and Waldheim in Saxony, containing numerous analyses, has been published by J. Lemberg (*Zeitschr. geol. Ges.* xxvii. 531; *Jahresb. f. Chem.* 1875, 1262). The chemical examination shows that the matrix of the Zöblitz and Greifendorf serpentines consisted of olivine, garnet, and hornblende, the olivine having been converted into serpentine, the garnet

for the most part into chlorite, whilst the hornblende has opposed the greatest resistance to alteration. Veins containing felspar are in many places separated from the serpentine by contact-zones, mostly formed of hornblende. These veins, in the neighbourhood of the serpentine, and sometimes throughout their entire thickness, are converted into masses resembling serpentine and steatite. No undecomposed olivine has yet been found in the serpentine of Waldheim.

On the Serpentine and other rocks in which the Pyropes of Meronitz in Bohemia are imbedded, see Doelter (*Min. Mitth.* 1873, 13; *Jahresb. f. Chem.* 1873, 1217).

SESAME OIL. On the detection of this oil, see OILS (p. 1428).

SESQUIPHENOLCINCHONIDINE, $3C^{20}H^{20}N^2O \cdot 2C^8H^6O$. See CINCHONABASES (p. 486).

SHEA-BUTTER, or GHEA-BUTTER. The fat of *Bassia Parkii*. See v. 238, and further, C. Deite (*Dingl. pol. J.* cccxxi. 168; *Chem. Soc. J.* xxxvi. 568).

SIEGBURGITE (A. v. Lasaulx, *Jahrb. f. Min.* 1875, 128). A fossil-resin occurring in considerable quantity in the lignite-sand and sandstone overlying the beds of lignite in the neighbourhood of Troesdorf and Siegburg, on the northern border of the Siebengebirge. The sand, which consists of fine, white, often limpid quartz-granules, contains small quantities of silver-white mica, and blackish or brownish grains of coaly substance, together with greyish-white, kidney-shaped, or nodular concretions, the particles of which are cemented together by an easily inflammable resin. On breaking the lumps, which are moderately hard and compact, the resin appears in small golden-yellow to brown-red and hyacinth-red granules, for the most part somewhat uniformly distributed between the sand-grains. The proportion between resin and sand varies considerably; in some of the concretions, the resinous cement is so finely distributed as to be scarcely visible, even under a magnifier, although sufficiently abundant to take fire when the lump is held in a flame; in others it is very abundant, sometimes amounting to more than 60 per cent., and appears in the interior of the lump, in easily separable pieces, larger than peas, and having a conchoidal fracture. Its hardness is 2 to 2.5, therefore the same as that of amber, and it cannot be scratched with the nail. After it has burnt away, the lumps fall to pieces.

The resin melts easily, and burns with a yellow, very smoky flame, emitting a pleasant aromatic odour, totally different from the stinking bituminous odour given off by retinite. It is burned for incense in the churches of the district. When distilled it gives off a light, greenish-yellow oil, smelling somewhat like petroleum; this distillate does not deposit succinic acid. The resin is but partly soluble in ether, to which it imparts a faint yellow colour; the ether, when evaporated, leaves a yellow oil, but no crystalline deposit. The resin is likewise only partly soluble in alcohol, and almost insoluble in oil of turpentine.

An analysis of a single specimen gave 85.139 per cent. carbon, 7.904 hydrogen, and 6.957 oxygen; a mixture of the resins from several lumps gave 81.37 per cent. C., 5.26 H., and 13.37 O. The former analysis may be represented by the formula $C^{85}H^{7.9}O^6$; the latter by C^8H^8O . These results show that the composition of the resin is variable, and that the difference of composition in different specimens is due to more or less advanced oxidation.

Only four other fossil resins are known, containing a proportion of carbon approaching to that of Siegburgite, viz.: (a). *Rosthornite*, from the coal beds of the Sonnberg in Carinthia (*Chem. Soc. J.* [2], ix. 1174). (b). *Girona*, or *Buccaramanga resin*. (c). *Copaline*, or *Highgate resin*, from the blue clay of Highgate-hill. (d). *Krantzite*, from the lignite of Lattorf, near Nieburg:

	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>
C	84.42	82.7	85.73	79.25
H	11.01	10.8	11.50	10.41
O	4.59	6.5	2.77	10.34

All these resins are distinguished from Sieburgite by their physical properties as well as by their composition. Rosthornite is soft, and may be scratched with the nail; it differs also from Sieburgite in its relations to solvents. Girona resin is more like Sieburgite, but contains less oxygen. Highgate resin contains about the same amount of carbon, but a larger proportion of hydrogen, and much less oxygen; it differs also from Sieburgite in emitting an aromatic odour when broken, whereas Sieburgite does not emit such an odour, even when rubbed. Krantzite is a soft, flexible resin, differing from Sieburgite both in composition and in physical properties.

A variety of retinite is found in the lignite beds of Friesdorf, and another in those of Roisdorf, in the same locality.

SIKERANINE. An alkaloid occurring, according to Buchheim (*N. Rep. Pharm.* xxv. 344), in the mother-liquors of the extract of henbane seeds, from which hyoscyamine has been separated.

SILICA, SiO_2 . On the occurrence and formation of crystallised silica, see QUARTZ (p. 1374).

Hydrate.—Transparent hydrated silica, having the properties of hydrophane, may be obtained by pouring a layer of dilute oxalic acid on a solution of an alkaline silicate in a vessel inclined at an angle of 45° , and leaving the liquid at rest for several months. A layer of transparent silica then forms at the surface of contact of the two liquids, and below this are formed layers of gelatinous silica which gradually fill the vessel.

The hydrated transparent silica thus produced scratches glass, contains much hygrometric water, which it loses at a low temperature (30° – 35°), becoming at the same time milky like opal, and of the same hardness; in this state it also retains 9–13 per cent. of water. Its density varies from 2.03–2.07, and it is singly refractive. Portions which have become opaque by exposure to air or by heating, become translucent when treated with water, thus resembling hydrophane. After exposure to a red heat, this hydrated silica has a mother-of-pearl lustre, is very brittle, exhibits cleavage in its longitudinal direction, and dissolves in a boiling concentrated solution of potash. The gelatinous silica formed at the same time becomes, in the course of a few months, transparent and very hard, and exhibits the properties of hydrophane (E. Monier, *Compt. rend.* lxxvi. 1318).

Ullik (*Ber.* xi. 2124) finds that the gelatinous silica which separates after some time on pouring a somewhat dilute solution of sodium silicate (water-glass) into hydrochloric acid, may be completely washed by repeated treatment with water, without the slightest loss of coherence. In this manner, perfectly pure silica is obtained as a translucent gelatinous mass of quite unaltered shape, which dries up in the air to a transparent substance resembling hyalite, and splitting up into larger or smaller pieces; it has the density of opal, and approximately the composition Si^3H^2 . The lumps, when quickly heated to redness, crumble to a shining sand, but by raising the temperature gradually, larger unbroken pieces may be obtained, perfectly vitreous and transparent, and still to a certain extent hygroscopic. The specific gravity, determined immediately after ignition, is 2.323, which is that of tridymite. The gelatinous silica, obtained as above, possesses in a high degree the properties of a membrane, and being a substance of known composition, should be well adapted for the study of the laws relating to dialysis.

When a solution of a silicate is mixed with an alkaline solution of alumina, a precipitate is formed, consisting of silica or alumina, accordingly as one or the other of these substances is in excess. The dialysis of such a solution has been studied by H. Le Chatelier (*Compt. rend.* lxxviii. 1046). The solution employed contained 0.20 gram SiO_2 , 0.30 Al_2O_3 , and 3.80 Na_2O . On dialysis there remained on the membrane a white pulverulent precipitate containing 0.120 g. SiO_2 and 0.115 alumina; the whole of the alkali had passed through the membrane, and contained in solution 0.105 Al_2O_3 and 0.010 SiO_2 . H. Sainte Claire Deville remarks (*ibid.* 1048) that such a decomposition by dialysis may afford an explanation of certain natural phenomena, in which clay or even chalk may be supposed to play the part of the membrane, and thus the presence of flints in chalk may be accounted for.

Action on Carbonates.—When silica is heated with sodium carbonate in a platinum crucible, the quantity of carbon dioxide evolved tends to a fixed limit, which cannot be exceeded at any particular temperature, but rises steadily with increase of temperature. If y denote the loss of carbon dioxide and x the time, the relation may be expressed by the equation:

$$y = \frac{ax}{b + x}.$$

An acid silicate is first formed, and then resolved into a normal silicate and free silica, which again acts on the silicate, and so on till an equilibrium has been established between these opposite actions. The evolution of carbon dioxide is accelerated by passing a stream of dry air into the crucible; but the decomposition is then never complete. Titanic acid acts on carbonates in a similar manner, and so, according to Hiortdahl, does zirconia (v. 1084).

SILICATES. *Behaviour at high temperatures.*—Silicates which do not contain any volatile constituents suffer no chemical change when fused, and some of them even reassume their crystalline form on solidification, but the greater number form a glass which has a lower specific gravity than the original mineral, and is easily decomposed by acids. There is, however, a very important class of silicates, including topaz, mica, tourmaline, &c., which undergo chemical change on fusion, owing to the volatilisation of some of their constituents, as hydrogen and fluorine.

Experiments made with various kinds of topaz and mica show that only the former lose the whole of their fluorine at the temperature of a porcelain-furnace, and that too only under favourable circumstances. One part of the fluorine is evolved as hydrofluoric acid, and the rest as the silicofluoride contained in the original mineral, whilst the metals K, Li, Mg, Fe, Al, and Si, existing as fluorides, remain behind as oxides. This shows that the fluorine in these silicates is combined in a manner similar to the oxygen. In the topazes, not only the silicon of the aluminium silicofluoride, but also a portion of the silicon from the oxysilicates, is converted by the hydrofluoric acid into silicon fluoride, and evolved as such (Rammelsberg, *Ann. Phys. Chem.* [2], vii. 146).

Analysis.—To estimate the silica in silicates, Maskelyne & Flight (*Ber.* vi. 1414) heat the mineral with *hydrofluoric acid* in a platinum retort through which a stream of hydrogen is passed, and receive the gaseous silicon fluoride thereby evolved in aqueous ammonia of sp. gr. 0.88. The retort is first heated in a water-bath for two hours, whereby the mineral is decomposed, but only a trace of silicon fluoride is evolved, afterwards in a paraffin-bath at 132°, whereupon the silicon fluoride passes over, the operation being completed in five to ten minutes. The process is then repeated with fresh hydrofluoric acid and ammonia-solution to ensure that the decomposition is complete. The ammoniacal solutions are then evaporated in a platinum dish, whereby the silica is dissolved; the cooled solution of ammonium silicofluoride is precipitated with potassium chloride and absolute alcohol; and the silicon is estimated as potassium silicofluoride. One advantage of this method is that the potassium silicofluoride weighs four times as much as the corresponding silica, an important consideration in the case of minerals poor in silica. For the success of the operation, the digestion for two hours in the water-bath is indispensable. Addition of sulphuric acid is to be avoided, as it serves only to retard the distillation of the silicon fluoride.

The decomposition of silicates by hydrofluoric acid is recommended by A. R. Leeds (*Zeitschr. anal. Chem.* 1877, 323), when it is desired to estimate the iron as ferrous oxide. The reaction must be conducted in an apparatus in which the solution is protected from contact with the air.

For the decomposition of silicates and estimation of the alkalis therein contained, A. Terreil (*Compt. rend.* lxxxi. 1268) recommends the use of *barium hydrate*, as it melts easily and at a comparatively low temperature, and nevertheless effects a complete decomposition of the silicate. The finely pulverised substance is fused with 7 or 8 times its weight of fused barium hydrate at the lowest possible temperature (below dull redness) in a silver or platinum crucible, which under these circumstances is not sensibly attacked, especially if the air be excluded; the mass after cooling is boiled several times with water; the excess of baryta and lime, if present, is removed by carbonic acid; and the alkalis are determined in the filtrate by known methods.

G. Bong (*Bull. Soc. Chim.* [2], xxix. 50) effects the decomposition by fusing the finely pounded mineral in a platinum crucible with about three times its weight of pure *red lead*; the fused mass is then digested with nitric acid; the solution evaporated to dryness; the residue treated with water; the solution filtered from the insoluble silica is freed from lead by hydrogen sulphide; and the analysis is completed in the ordinary way. This method also has the advantage of effecting the decomposition at a much lower temperature and in a shorter time than that of fusion with sodium carbonate, and, moreover, greatly facilitates the estimation of the alkalis.

For the estimation of water in silicates, the following method is described by L. Sipőcz (*Wien. Akad. Ber.* [2 Abth.], lxxvi. 51). The silicate mixed with four times its weight of a mixture of potassium and sodium carbonate is placed in a platinum-boat provided with an overlapping cover, which is thrust into the middle of a platinum tube 40 cm. long and 17 mm. internal diameter. This tube is dried by heating it to 130° and passing a stream of dry air through it for about an hour after

which it is laid in a combustion-furnace, and the mixture is thoroughly ignited, while a stream of dry air is continuously passed through the tube. The water which passes over is condensed in an absorption-tube containing fragments of glass moistened with strong sulphuric acid.

SILICON, or SILICIUM. On the Specific Heat of Silicon, see **HEAT** (pp. 926-927).

On the Estimation of Silicon in Pig-iron, see p. 1108.

Organic Compounds of Silicon:

Ethylc Orthosilicoacetate, $\text{Si}(\text{CH}_3)(\text{OC}^2\text{H}^5)^2$, homologous with ethylic orthosilicopropionate (vii. 1082), is formed, together with zincmethylethoxyl, $\text{Zn}(\text{CH}_3)(\text{OC}^2\text{H}^5)$, by the action of zinc-methyl on ethyl silicate, and may be separated from the product by fractional distillation, as a liquid boiling between 145° and 151° . It resembles the corresponding propionic ether, has a density of 0.9283 at 0° , is soluble in alcohol, insoluble in water, but slowly decomposed thereby. Hydriodic acid converts it into silico-acetic acid, CH_3SiOOH , which is an amorphous powder insoluble in water and in ether, and burns when strongly heated, producing silica, carbon dioxide, and water (Ladenburg, *Ber.* vi. 1029).

Methylc Orthosilicopropionate, $\text{Si}(\text{C}^2\text{H}^5)(\text{OCH}^3)^2$, is obtained by gradually adding sodium (12 grams) to a warmed mixture of methyl silicate (40 g.), and zinc-ethyl (12 g.), then distilling and fractionating the product:

This is a liquid closely resembling the corresponding ethylic ether in odour and appearance, but less stable. Sp. gr. 0.9747 at 0° . Boiling point 125° – 130° . It is insoluble in water, but decomposes in contact therewith, especially on addition of ammonia, yielding silicopropionic acid; readily acted upon also by aqueous hydriodic acid (Ladenburg, *Ber.* v. 1081).

Silicic Phenyltrichloride, or **Silico-benzenyl Trichloride**, $\text{SiC}^6\text{H}^5\text{Cl}_3$, is formed, together with mercuric phenylchloride, by heating mercury-diphenyl with silicon tetrachloride in sealed tubes at 300° . When separated from the product by repeated fractionation, it is a colourless fuming liquid, having a faint odour like that of silicic chloride, and boiling at 197° . It sinks in water and decomposes slowly; quickly, on the other hand, when heated, or on addition of ammonia, yielding silico-benzoic acid, $\text{SiC}^6\text{H}^5(\text{OH})^2$. It is likewise decomposed by absolute alcohol, with formation of ethyl silicobenzoate, $\text{SiC}^6\text{H}^5(\text{OC}^2\text{H}^5)^2$, which is a colourless liquid having an ethereal and at the same time pungent odour (probably due to impurity), boiling at 237° , and having a sp. gr. of 1.0133 at 0° , 1.0055 at 10° . By contact with the air, or more quickly by the action of water, it is converted into a polyorthobenzoic ether. With hydriodic acid it yields, together with ethyl iodide, a hard mass mostly coloured by free iodine, which, after purification by addition of ammonia, repeated evaporation with water, and washing of the residue with water, consists of silico-benzoic acid, the identity of which with that prepared from the chloride has, however, not yet been established. Both these acids dissolve in ether, in aqueous and alcoholic potash, and sparingly in alcohol, but are nearly insoluble in water, and both are converted into silicobenzoic anhydride, $(\text{SiC}^6\text{H}^5\text{O})_2\text{O}$, by precipitating their solution in absolute alcoholic potash with carbon dioxide, filtering, evaporating the filtrate, and drying the residue at 100° . This anhydride dissolves with moderate facility in ether, and remains on evaporation in transparent brittle spherical masses resembling Prince Rupert's drops. It is slightly soluble in alcohol; water takes up only traces of it. It dissolves readily in warm aqueous potash, and is not precipitated from the solution by dilute hydrochloric acid, but on adding ammonia in excess, nearly the whole is precipitated as silicobenzoic acid. When the potash-solution is evaporated to dryness and the residue further heated, water distils over together with benzene. Silicobenzoic anhydride, when heated in contact with the air, is converted into a somewhat fluid, scarcely coloured mass, and this when further heated gives off combustible vapours, and leaves a black tumefied mass which does not burn away completely even at a white heat. Silicobenzoic acid is intermediate in its chemical relations between silicic and benzoic acids (Ladenburg, *Ber.* vi. 379).

Silicic Phenyltriethide, $\text{SiC}^6\text{H}^5(\text{C}^2\text{H}^5)^3$, is produced, together with zinc chloride, by heating about equal quantities of silicic phenyltrichloride and zinc-ethyl in sealed tubes at 150° for some hours, then, after opening the tubes, continuing the heating for an equal time at 180° , and, after a further evolution of gas, at 165° till no more gases are given off on further heating. The contents of the tubes are then to be

cautiously dropped into water, the zinc oxide thereby separated dissolved in hydrochloric acid, and the oily layer, after addition of ether, evaporated, washed, dried, and fractionated.

Silicic phenyltriethide is a colourless liquid boiling at 230° , and giving off a vapour which has an odour like that of oil of cloves but fainter. Sp. gr. = 0.9042 at 0° . It is insoluble in water, but soluble in ether; burns with a bright but very smoky flame. When treated with very strong nitric acid, it turns black and gives off the odour of nitrobenzene. Dilute nitric acid does not act upon it at ordinary temperatures, but decomposes it when heated, likewise with separation of the phenyl-group. Silicic phenyltriethide, heated with strong sulphuric acid, is decomposed, apparently with formation of triethylsilicic acid (vii. 1083):

Silicic phenyltriethide, heated with *bromine* in a reflux apparatus, is converted, with evolution of hydrogen bromide, into a bromo-derivative boiling at 270° – 280° . On slowly passing *chlorine* into silicic phenyltriethide, the liquid being cooled from time to time, again treating the portion which boils below 250° with chlorine, washing the product with a small quantity of water, and fractionating it after drying with calcium chloride, a small quantity of a thick liquid is obtained, having the composition $\text{SiC}^2\text{H}^5\text{Cl}$. It has an aromatic odour, a density of 1.0185 at 0° , boils at 260° – 265° , burns with a smoky, green-edged flame, is insoluble in water, and is not decomposed thereby; does not yield acetic ether when boiled with alcohol and potassium acetate.

The action of zinc-ethyl on silicic phenyltrichloride yields, in addition to silicic phenyltriethide, two other bodies, one of which appears to be silicic ethide, $\text{Si}(\text{C}^2\text{H}^5)^4$, boiling at 147° – 152° (vii. 1084), the other silicic diphenyldiethide, $\text{Si}(\text{C}^6\text{H}^5)^2(\text{C}^2\text{H}^5)^2$, boiling at about 310° (Ladenburg, *Liebig's Annalen*, clxxiii. 151; *Ber.* vii. 387).

Silicopropyl-compounds (Cahours, *Compt. rend.* lxxvi. 1383). *Silicopropyl ether*, $\text{Si}(\text{C}^3\text{H}^7\text{O})^4$, is formed on adding anhydrous propyl alcohol by small portions to silicic chloride, and is obtained by rectifying the product, as a colourless liquid of sp. gr. 0.915 at 18° , and boiling at 225° – 227° . It is readily decomposed by boiling water, with separation of silica.

Silicopropyl monochloride, $\text{Si}(\text{C}^3\text{H}^7\text{O})^3\text{Cl}$, is formed by heating silicon chloride with silicopropyl ether in closed vessels at 160° :

It has a sp. gr. of 0.980 , and boils at 208° – 210° . *Silicopropyl dichloride*, $\text{Si}(\text{C}^3\text{H}^7\text{O})^2\text{Cl}^2$, is formed by the action of silicon chloride on the monochloride at 160° – 165° , or on silicopropyl ether in the requisite proportion:

The dichloride is a colourless liquid of sp. gr. 1.028 , and boiling between 185° and 188° .

Silicic Tolytrichloride, $\text{SiC}^7\text{H}^7\text{Cl}^3$, is prepared by heating mercury-tolydide (m. p. 238°) with silicon chloride at 300° – 320° , and fractionally distilling the product. It is a strongly refracting, fuming, viscid liquid, smelling like silicon chloride, heavier than water, and decomposed thereby. On dropping it into ammonia, a body separates which is insoluble in water, may be conveniently dissolved out by ether, and remains on evaporation of the ether as an oil which gradually changes to a viscid mass, and finally to a white, translucent, hard, amorphous body, this change taking place more quickly at the heat of the water-bath. This body, after drying at 100° , gave numbers intermediate between those required by the formula of silicotoluic acid, $\text{C}^7\text{H}^7\text{SiOOH}$, and those required by its anhydride, $(\text{SiC}^7\text{H}^7\text{O})^2\text{O}$. Silicotoluic acid melts at about 150° , and is completely converted into the anhydride at 200° (Ladenburg, *Liebig's Annalen*, clxxiii. 165; *Ber.* vii. 389).

SILICO-TUNGSTATES OF CESIUM AND RUBIDIUM. See RUBIDIUM (p. 1767).

SILK. An analysis of silk-cocoons, by A. Renouard, gave the following results:

	In the entire cocoon	In the inner layer	In the outer layer
Gummy substance . . .	29.30	31.47	27.72
Sericin or Fibroin . . .	70.70	68.33	73.28

The gummy substance was obtained by boiling the cocoon with a strong solution of soap, then washing with boiling acetic acid; the insoluble residue was calculated

as fibroïn. Mulder's analysis of silk is regarded by Renouard as incorrect; he stated that silk contained 19–21 per cent. glutinous substance, and 24–25 per cent. albumin (*Biedermann's Centralblatt, für Agriculturchemie*, 1879, 72).

Air-dried silk contains 9.91 per cent. water (Benard, *Dingl. pol. J.* cccxxvi. 216).

According to E. Pfeiffer (*Arch. Pharm.* [3], i. 424), the yellow colouring matter of raw silk consists of chlorophyll more or less altered and deprived of its blue constituent; and from the greenish cocoon, or from greenish raw silk, unaltered chlorophyll may be extracted, separable by ether containing hydrochloric acid into its blue and yellow constituents.

In the manufacture of raw silk, the cocoons are immersed in water, with the object of softening but not of dissolving the natural gum by which the threads are held together. Now raw silk owes its colour, strength, and beautiful appearance to the presence of its soluble constituents; and when soft water is used in winding it, the silk is inferior in strength, colour, and general appearance to that obtained when hard water is employed, because the soluble constituents of the silk are more rapidly dissolved by the soft than by the hard water. Soft water may be improved for spinning purposes by the addition of gypsum, magnesium sulphate, or sodium carbonate (Gabbia a. Fextor, *Ber.* xii. 17).

Raw silk boiled with baryta-water yields the same products as fibroïn (Schützenberger a. Bourgeois, p. 785). Champion, by treating silk with concentrated baryta-water, obtained an acid, called *sericic acid*, to which he assigns the formula $C^{20}H^{60}N^8O^{14}$ (vii. 1080).

According to J. Löwe (*Dingl. pol. J.* cccxxii. 274), silk dissolves in an alkaline glycerin-copper solution, and is precipitated therefrom by hydrochloric acid in the form of a white jelly. The copper-solution is prepared by dissolving 16 grams of pure crystallised cupric sulphate in 140–160 g. water, then adding 8–10 g. pure glycerin of sp. gr. 1.24, and dropping in soda-ley till the copper precipitate is redissolved.

The presence of cotton in silk-tissues may be detected by means of chromic acid, which unites with the silk-fibre, and dyes it, whilst the cotton-fibre remains uncoloured (Jacquemin, *Compt. rend.* lxxix. 523).

On the Bleaching and Dyeing of Silk, see *Dingl. pol. J.* ccxxiv. 99; *Jahresb. f. Chem.* 1877, 1225.

SILVER. Two specimens of native silver from Allemont in Dauphiné, analysed by A. H. Church (*Jahrb. f. Min.* 1874, 715), were found to contain:

	Ag	Hg	Sb		Sp. gr.
A.	71.69	26.15	12.16	= 110	11.10
B.	73.39	18.34	8.27	= 100	10.05

There is probably some error in analysis A. Nies (*Jahresb. f. Chem.* 1874, 1230) suggests that the percentage of antimony is probably 2.16.

Elaborate investigations on ancient specimens of native silver have been published by E. v. Bibra (*Ueber alte Eisen- und Silberfunde. Archäologisch-chemische Skizze*, Nürnberg und Leipzig, 1873).

M. M. P. Muir (*Chem. News*, xxxv. 6) found in one specimen of arborescent silver from the Thames Gold-field in New Zealand, 97.05 per cent. silver, 0.98 mercury, and 1.98 silica and matrix (= 99.26), together with 0.00005 copper and 0.00109 iron.

An analysis by F. Field (*Chem. News*, xxvii. 175) of native brittle silver from Bolivia, gave 78.12 per cent. Ag, 12.01 AgCl, 9.34 Fe^2O^3 , and 0.40 Co.

Extraction and Purification.—The amalgamation of silver ores in Chili is now preceded by treatment with cuprous chloride, which acts on silver sulphide as represented by the equation:

The cuprous chloride is prepared by saturating a solution of cupric sulphate with common salt, and boiling the solution with copper turnings. The crushed ores are first treated with the copper solution alone; mercury is then added (20 to 25 pts. to 1 pt. silver); the mixture is agitated in barrels; and the amalgam is subsequently purified by washing with water, any cupric oxide that may be present being removed by ammonium carbonate. If the ore contains chloride or bromide of silver, a quantity of lead is added equal to 25 per cent. of the amount of silver, whereby chloride of lead is formed, and the loss of mercury by conversion into chloride is avoided (Fonseca, *Dingl. pol. J.* cccviii. 396; also Prime, *Amer. Chemist*, iv. 87; *Jahresb. f. Chem.* 1873, 990; and Krönke, *Dingler*. cccxvi. 401; *Jahresb.* 1877, 1122).

The method of Amalgamation practised in Colorado is described by T. Egleston (*Dingl. pol. J.* ccxxvi. 517; *Jahresb.* 1877, 1123).

Extraction with Calcium Thiosulphate.—The following process, practised at the Stewart smelting works, Georgetown, North America, is described by W. Brunton (*Dingl. cccxii. 177*). The ores, after being subjected to a chlorinating process, are introduced into round wooden tubs 1·2 m. high and 2·7 m. in diameter. Each tub holds about 2 tons of ore, and is furnished with an agitator and a closely-fitting cover with two ventilators for the conveyance of steam and sulphurous acid. The tubs are filled with the ore, and the latter treated with Hunt and Douglas's liquid (consisting of sodium chloride and ferrous chloride). The mixture is then agitated, and at the same time sulphurous acid and steam are introduced. The whole of the cupric oxide present in the ore is thus dissolved by the ferrous chloride. The reason for the addition of sulphurous acid is that the ferrous chloride would otherwise be converted into ferric chloride by the oxidising ingredients present in the ore, and the copper would then be precipitated. The cupric chloride in presence of sodium chloride converts the whole of the silver sulphide present in the ore into chloride. After the mixture has been agitated in these tubs for five hours, the solution is allowed to settle, then drawn off, and the tubs are again filled with water, steamed and agitated. After two hours' washing with hot water, the apparatus is again stopped and the clear water drawn off. Calcium thiosulphate is now added from a reservoir placed above the tubs, and after agitation for four hours at 38°, the mixture is left to settle and the clear silver solution drawn off. In the case of ores very rich in precious metals it is advisable to repeat this operation before washing with warm water at 40°. Finally the tubs are emptied.

The solution containing the sodium chloride and ferrous chloride is passed through a filter in order to separate mechanical impurities, and then run into tanks filled with iron filings, where the copper is precipitated and the solution brought back to its former condition. The washings are evaporated to 15° B., and submitted to a similar treatment. The silver solution is placed in large precipitating vessels, treated with calcium sulphide, agitated for a few minutes, and left to deposit. The liquid is then run into the regenerating vessels and treated with sulphurous acid, which converts the whole of the excess of calcium sulphide used into thiosulphate. The washings from the treatment with calcium thiosulphate are worked up in a similar manner. When the precipitate in the precipitating vessels is from 125–150 mm. high, it is washed with hot water, dried, and roasted in a small reverberatory furnace at a low temperature, until all the sulphur has been driven off. Fluxes are added if necessary, and the temperature is raised until the whole mass is in a state of perfect fusion. The slags are then removed, and the pure metal skimmed off and poured into moulds. If the slags contain more than 20 ounces of silver per ton, they are worked up again with the ore.

From the Fahl-ores of Baranna, in Mexico.—The ore, containing zinc-blende, galena, iron and copper pyrites, quartz, silver, and a trace of gold, is crushed and roasted with 5 to 7 per cent. of salt. The copper and zinc are then extracted by treatment with cold water, and the copper is precipitated from the solution by iron. From the insoluble residue the silver with a little lead is extracted by solution of sodium thiosulphate, and the silver precipitated by calcium sulphide. This precipitate when roasted gives a metal of 650–700 thousandths fineness, which is purified by cupellation with lead (*Chem. Centr.* 1878, p. 830).

From Silicious Ores.—Round the great Salt Lake in Utah, enormous deposits of spongy silica are found, which have evidently been deposited from hot springs. These deposits contain lead oxide, cupric oxide, ferric hydrate, ferric oxide, and silver chloride in varying proportions. The quantity of the latter is from 1–10 kilograms per ton, but as an average 2·3–2·5 kilograms. The great amount of silica, seldom less than 90 per cent., makes it impossible to extract the silver by smelting, and it has also been found very difficult to extract the silver chloride by alkaline chlorides or thiosulphates. But the following method gives very good results, not more than 100 grams of silver per ton of ore being lost.

One part of the ore is boiled with 3·5 pts. of salt and 3·5 pts. of strong hydrochloric acid until the mass is disintegrated, then the same quantity of hydrochloric acid is added, and 1 pt. of manganese oxide is gradually introduced. When the evolution of chlorine ceases, the liquid is decanted, the residue washed with water, and the silver is precipitated from the solution by iron. To remove lead and a little copper, it must be refined by cupellation. On working on a large scale, the above proportion will be found sufficient for 2–3 pts. of ore. As manganese oxide, pyrites, salt, and coal are plentiful in Utah, this process can be carried out without difficulty (A. Guyard, *Bull. Soc. Chim.* [2], xxv. 99).

From burnt Cupreous Pyrites.—The residues of cupreous iron pyrites which have been burnt in the sulphuric acid manufacture contain small proportions of copper and

silver, amounting to about 3·6 per cent. of the former, and from 15 to 28 dwts. per ton of the latter. Two methods are employed for the recovery of the silver. The first, known as Claudet's, depends on the almost complete insolubility of silver iodide in cold solutions of metallic and alkaline chlorides. It is conducted by lixiviating the burnt residues after calcination with sodium chloride; the first three washings, which contain nearly all the silver, are, after settling, run into precipitating tanks; a sample from each tank is then assayed for silver; and an amount of potassium iodide, calculated as equivalent to the total silver present, is added in solution to the copper liquors, which are, at the same time, diluted with $\frac{1}{10}$ water, and mixed with milk of lime, the whole being thoroughly stirred. The precipitate, consisting of silver iodide, lead sulphate, calcium sulphate, and oxychloride and subchloride of copper, is allowed to settle. The accumulated precipitate is withdrawn and washed with hydrochloric acid to remove copper salts, and then treated with metallic zinc, whereby zinc iodide is formed, with separation of metallic silver and gold if present. The zinc iodide is then dissolved out, standardised, and used instead of potassium iodide, for operating upon a new quantity of copper liquor. It is essential to the success of the process that only very little or no cuprous chloride should be present in the copper liquors, because it separates out on dilution, and, moreover, interferes with the precipitation of the silver iodide.

The second process consists in blowing through the copper-liquors sulphuretted hydrogen diluted with air. Its first effect is to precipitate a far larger proportion of silver than of copper. The hydrogen sulphide is obtained by acting upon 'tank waste' with hydrochloric acid, in large covered tanks. Before blowing, the copper in the solution is estimated by standard potassium cyanide solution, and the blowing is allowed to proceed until the quantity of copper is diminished by 6 per cent. The precipitate, which still contains a little chloride, is washed and filtered, then calcined at a low temperature, whereby chlorides of copper and silver, and oxide and sulphate of copper are produced. This is then ground to rough powder, lixiviated with water to remove copper sulphate, then with hot solution of sodium chloride, which dissolves the silver chloride. The solution, however, contains also copper and some lead sulphate; it is mixed with milk of lime, well washed, to remove calcium chloride, then digested with dilute sulphuric acid to remove oxide of copper, and again washed. After drying, the precipitate has the composition—

Ag	PbO	CuO	Fe ² O ³	CaO	SO ²	Cl	H ² O	Insol. residue	Total
8·77	28·66	3·75	2·61	13·67	31·73	4·70	4·20	1·40	99·49

The value of the silver recovered is about 2s. 6d. per ton of ore worked, the cost by either plan being about 10d. The quantity of these ores treated annually amounts to about 350,000 tons (T. Gibb, *Chem. News*, xxxi. 165).

On the Separation of Silver from Argentiferous Lead, see LEAD (p. 1166).

On the Recovery of Silver from Cast-iron Crucibles in which that metal or its alloys have been fused, see Javorsky a. Priwoznik (*Dingl. pol. J.* ccxvii. 214; *Chem. Soc. J.* xxix. 453).

For the recovery of Silver from solutions of the Cyanide (photographic baths, &c.), E. v. Bibra (*J. pr. Chem.* [2], xiv. 185) recommends, as most expeditious and least costly, the method of precipitating the silver cyanide with sulphuric acid, igniting the precipitate, and dissolving it in nitric acid. On adding hydrochloric acid to the resulting solution, the whole of the silver is precipitated as pure chloride, which may be most advantageously reduced from its ammoniacal solution by metallic zinc.

Physical Properties.—According to Kirmis (*Pogg. Ann.* clviii. 121), the forms of electrolytically precipitated silver vary with the intensity of the current, the concentration of the solution, and the density of the current at particular points. Thread-like masses of silver, called 'moss-silver,' are produced by heating silver sulphide in a current of steam and hydrogen gas (W. M. Hutchings, *Chem. News*, xxxv. 117, 186).

Pseudomorphs of native silver after Stephanite or Brittle Silver-ore, occur at Przibram in Bohemia (G. vom Rath, *Pogg. Ann.* cxi. 266; V. v. Zepharovich, *Wien. Akad. Ber.* [1 Abth.] lxi. 33).

The specific gravity of pure silver was found by W. Chandler Roberts (*Proc. Roy. Soc.* xxiii. 494) to be 10·57 in the solid, and 9·4612 in the fluid state; that of an alloy of 718·33 pts. silver and 281·07 copper was found by experiment to be 9·9045; by calculation 9·998. Mean coefficient of cubical expansion through 1050 degrees = 0·00011164; therefore coeff. of linear expansion = 0·00003721.

The melting point of pure silver is given by various authorities at 999° to 1034° (v. 277); according to Becquerel it is 1040°; according to J. Violle (*Compt. rend.* lxxv. 543) pure silver melts at 954°.

Absorption of Oxygen by Silver.—Dumas (*Ann. Chim. Phys.* [5], xiv. 289) found

that when pure silver prepared in the ordinary way was heated in a porcelain flask, it began to give off pure oxygen at 400° – 500° , the evolution of gas going on for six hours, then ceasing, and not being renewed even when the metal was heated to fusion. The silver when cold formed a finely crystallised metallic mass, having a density of 10.512, which is somewhat higher than that usually given for pure silver. The quantity of oxygen thus evolved from a kilogram of silver amounted to 57 cc. at 0° and 760 mm. or by weight to 82 mg., so that the kilogram of metal employed contained only 999.918 grams of pure silver. In a second experiment in which the influence of the atmosphere on the fused silver was greater, 1 kilo. yielded 155 cc. or 226 mg. oxygen, so that the amount of real silver in the kilogram was only 999.774 grams. In a third experiment, performed in a glass tube, the quantity of oxygen obtained was 174 c.c. = 249 mg., showing that the kilogram of metal contained 999.751 grams of pure silver.

This occlusion of oxygen by silver is of great importance with regard to the use of that metal as the basis of determinations of atomic weights, inasmuch as different values must be obtained according to the quantity of oxygen occluded in the particular sample of silver employed in the experiments. Thus, in the experiments of Marignac a. Stas on the atomic weights of silver and chlorine (i. 905), the introduction of the correction required for the occluded oxygen would give the ratio $\text{Ag} : \text{Cl} = 108 : 35.5$ rather than $108 : 35.45$.

The whole of the oxygen occluded in silver may, as already observed, be drawn off by heating the metal in a vacuum at 600° . If, on the other hand, the temperature be raised to the melting point, and oxygen be brought in contact with the silver, the gas is rapidly absorbed, and partly given up again, with spitting, as the metal solidifies, the remaining portion being however retained.

Reactions.—On the reaction between silver and nickel in the melted stato, see NICKEL (p. 1390).

On the Action of Light on Haloid Silver salts, see LIGHT (p. 1231).

The reduction of silver from its salts by pure hydrogen, observed by Russell and others (vi. 718; vii. 660; viii. 1070), was confirmed in the first instance by the experiments of B. Renault (*Compt. rend.* lxxiv. 984); but subsequent observations by the same chemist (*ibid.* lxxvi. 384) seem to show that the reduction is not effected by pure hydrogen, but only when the gas contains traces of arsenetted or siliciuretted hydrogen. On the whole, however, the balance of evidence appears to be in favour of the reduction of silver salts by pure hydrogen.

Estimation.—Soluble thiocyanates precipitate silver completely from its solutions as thiocyanate, CSNAg , and the precipitate is not acted upon by mineral acids. On adding a solution of potassium or ammonium thiocyanate to an acid solution of a silver salt containing a small quantity of ferric sulphate, the whole of the silver is precipitated, while the excess of the thiocyanate solution gives a blood-red colour with the ferric salt, so that the end of the reaction may be very sharply determined.

As ammonium thiocyanate is very hygroscopic, it is advisable, instead of weighing out a definite quantity of this salt, to titrate a solution of it against a solution which contains 10.8 grams of pure silver dissolved in nitric acid, the liquid being made up to 1000 c.c. 10 c.c. of this solution are put into a beaker, together with 5 c.c. of a solution of ferric sulphate (50 grams to one litre of water), 150–200 c.c. of water are added, and the ammonium thiocyanate solution is then allowed to flow in drop by drop until a pale red tint is obtained. This method is applicable in presence of tolerably large quantities of copper. Chlorine, bromine, or iodine may be estimated by precipitation with an excess of a silver solution containing a known amount of silver, and subsequent titration with thiocyanate solution in order to determine the excess of silver added (*J. Volhard, J. pr. Chem.* [2], ix. 217; more fully, *Liebig's Annalen*, xc. 1–51; *Chem. Soc. J.* xxxiv. 743–5).

On the application of this method to the estimation of Silver and Gold in Cupelled Silver, see Lindemann (*Dingl. pol. J.* cexxvi. 66; *Chem. Soc. J.* xxxiv. 530).

G. Sire (*Ann. Chim. Phys.* [5], ii. 151) points out that, in taking samples from silver objects for the estimation of the silver, it is necessary first to remove the superficial layer, which is richer in silver than the interior, by boiling with nitric acid, or other manipulations. His experiments show that differences of 3 to 4 per cent. may occur, accordingly as the surface-layer, or the metal remaining after this layer has been scraped off, is taken for analysis.

A modification of the Apparatus used in Gay-Lussac's Method of Silver Assaying is described by Sire (*Ann. Chim. Phys.* [4], xxviii. 108; *Jahresb. f. Chem.* 1873, 946).

Compounds of Silver.

On Alloys of Silver with Copper, see COPPER (p. 561).

On Silver-amalgam, see MERCURY (p. 1270).

Silver arsenide, AgAs , is obtained in the form of a white, brittle, very hard, crystalline metallic button, sp. gr. 8.51, when silver arsenate is gently fused with potassium cyanide. It loses arsenic on heating, forming a new compound having the sp. gr. 9.01; fused under a layer of boric acid at a higher temperature, it is converted into Ag^3As , sp. gr. 9.51 (A. Descamps, *Compt. rend.* lxxxvi. 1022).

Reaction of Silver Arsenite with Ammonia.—The light yellow precipitate of silver arsenite is usually said to be soluble in aqueous ammonia. J. R. Santos (*Chem. News*, xxxviii. 94) has however observed that, if the precipitate formed on mixing solutions of silver nitrate and sodium arsenite be washed several times by decantation, it no longer dissolves (at all events not completely) in aqueous ammonia, but assumes a well-marked crystalline character and a deeper yellow colour. In fact, tribasic silver arsenite, Ag^3AsO_3 , is not by itself soluble in ammonia, but dissolves readily therein in presence of alkaline nitrates. By the continued action of ammonia, it is slowly and imperfectly decomposed, being perhaps converted into a salt of argent-ammonium. A silver arsenite containing in combination or admixture a proportion of arsenic larger than that of the tribasic salt, dissolves at once in ammonia without the presence of alkaline nitrates. The solubility of silver arsenite in acetic acid is governed by the same conditions as its solubility in ammonia.

Chlorides. According to v. Bibra (*Ber.* viii. 741), pure argentous chloride can be obtained by the action of hydrochloric acid on argentous citrate (produced by treating argentic citrate with washed and dried hydrogen at 100°). Argentous chloride is a black powder, the greater part of which dissolves in ammonia, the rest in nitric acid. The residue left by nitric acid is also soluble in ammonia. Potassium cyanide also dissolves the body; sulphuric acid dissolves about 2 per cent. of it; acetic acid and potash do not act upon it. Its analysis leads to the empirical formula Ag^2Cl^3 , but its reactions with nitric acid and ammonia seem to show that it is a mixture, not a definite compound. The blackened chloride produced by the action of light on argentic chloride cannot, according to v. Bibra, be regarded as argentous chloride.

According to Carey-Lea (*Sill. Am. J.* [3], xv. 189), the substance produced by the action of light on silver chloride is of a much more permanent character than that formed in the case of the other silver haloids, inasmuch as nitric acid decomposes the bodies so produced from silver bromide and iodide (with separation of silver, and formation of ordinary silver bromide and iodide), but is without action on the substance formed from silver chloride. After five days' action of strong sunshine on moist silver chloride, exposed in a thin layer and frequently stirred up, about 1, per cent. of the chloride is acted upon. The darkened chloride is not acted on by nitric acid of sp. gr. 1.28 in the cold, so that it does not contain reduced silver; but as it is quickly whitened by *aqua regia*, it is probable that the darkening is due to the formation of a subchloride or oxychloride. By digesting the darkened chloride (precipitated in presence of hydrochloric acid) with nitric acid of sp. gr. 1.28, for 18 hours on the sand-bath, a perceptible amount of silver was dissolved.

Darkened silver bromide is readily acted on by the same nitric acid, complete decomposition taking place after heating for some hours.

Silver Chloroplatinite, AgCl.PtCl_2 , produced by the action of silver nitrate on a solution of potassium chloroplatinite, is an amorphous flesh-coloured precipitate insoluble in water, decomposed by hydrochloric acid (Nilson, *J. pr. Chem.* [2], xv. 269).

On *Silver Ferrocyanide*, see CYANIDES (p. 612).

Effects of Heat on Chloride, Bromide, and Iodide of Silver. G. F. Rodwell* (*Proc. Roy. Soc.* xxv. 280) has described various experiments made for the purpose of determining the coefficients of expansion and contraction of the iodide of silver, and the coefficients of expansion of the chloride and bromide. The results are given in the following table. It will be seen that the coefficients of the chloride and bromide are a little higher than those of the most expansible metals (lead and zinc), and that the coefficient of the bromide is higher than that of the iodide. The iodide of silver, on the other hand, has long been known to exhibit certain anomalies, contracting through a given range of temperature on heating. The following facts have been established in regard to these anomalies. If a mass of the molten iodide be allowed to cool, the following effects may be observed: (a). At the moment of solidification a considerable contraction takes place. (b). The solid on further cooling undergoes slight and regular contraction after the manner of solids in general,

* Communicated by the author.

until it reaches a temperature of 142° , when it undergoes sudden and violent expansion, passing from the amorphous to the crystalline condition. (γ). After undergoing this expansion, the mass, on further cooling, undergoes slight expansion. According to Fizeau, the point of maximum volume is at -60° and the coefficient of contraction augments with the temperature. The iodide exists in two allotropic conditions. Above 142° it is a yellow flexible transparent solid, while at 142° it changes to a pale-green, crystalline, opaque, brittle substance.

EFFECTS OF HEAT ON THE CHLORIDE, BROMIDE, AND IODIDE OF SILVER.

Chlorobromiodides. Rodwell (*Proc. Roy. Soc.* xxv. 292) has also determined the coefficients of expansion, and other properties, of five compounds of silver with chlorine, bromine, and iodine. Chlorobromides of silver have been found in the mines of Chañarcillo in Chili, also, according to Dana, an iodobromide. The compounds described were formed by fusing together in a porcelain crucible the chloride, iodide, and bromide of silver in such proportions as furnished bodies of the composition shown in the annexed table. The coefficients of expansion having been determined by a method described by Rodwell, the volumes given in the table were calculated therefrom. The melting points were determined by Carnelley, by his new method (p. 937). The following facts will be observed by reference to the table:

1. The chlorobromiodides contract on being heated from 124° – 133° . Hence they possess two points of similar density.

2. While the iodide of silver commences its contraction when the temperature rises to 142° , and ends it at 145.5° , the chlorobromiodides begin to contract 18° lower, and cease to contract at 12° lower.

3. The specific gravity is in all cases above the mean of that of the constituents.

4. The melting points are in all cases lower than those of the constituents. Thus No. 3 melts at 326° , viz. 201° lower than iodide of silver, which constitutes 58 per cent. of its weight.

5. The melting points diminish from No. 1 to No. 3, and increase again from No. 3 to No. 5.

6. The contraction undergone by some of the chlorobromiodides is greater than that of the iodide of silver itself, although it is associated with two such expansible bodies as the chloride and bromide of silver; while, on the other hand, No. 1 has, during certain ranges of temperature, a higher coefficient than any of the substances composing it.

7. These anomalies are, no doubt, due to the way in which the iodide changes from

the crystalline to the amorphous condition within the surrounding mass of chloride and bromide. Let us, for instance, consider one case, No. 3, the composition of which is $\text{Ag}^2\text{I}^2, \text{AgBr}, \text{AgCl}$. 'In every 100 mols. between the temperature of 124° and 133° we have 58 mols. undergoing somewhat rapid contraction, while 42 are undergoing expansion. At the same time, other events are taking place within the mass; heat is disappearing as internal work, and is changing the crystalline into the amorphous iodide; that is, converting an opaque, brittle, highly crystalline body (the iodide alone is here spoken of, not the chlorobromiodide) into a transparent, plastic, denser body. What the precise function of the molecular motion which disappears can be, it is difficult to assume, since in this case it not only changes the state of the body, but likewise approximates its molecules.'

Peroxide. When electrolytically prepared silver peroxide is brought in contact with aqueous ammonia, a violent evolution of nitrogen takes place, and Berthollet's fulminating silver (v. 300) is formed, but remains dissolved in the excess of ammonia. On evaporating a small quantity of this solution in an iron spoon, a dangerous explosion takes place. When the dry and finely pulverised peroxide is moistened with a few drops of oil of cloves, the oil takes fire, and silver having the metallic lustre is separated (Böttger, *Ber.* vi. 1396).

Silver Silicofluoride, Ag^2SiF_6 , is formed on bringing silver nitrate in contact with silicofluoric acid, as a greyish-white precipitate, which is decomposed even by a weak solution of ammonia (S. Kern, *Chem. News*, xxxiii. 35).

SILVER-ULTRAMARINE. See ULTRAMARINE.

SINISTRIN, $\text{C}_6\text{H}^{10}\text{O}^3$. This name is given by O. Schmiedeberg (*Ber.* xii. 704) to a carbohydrate occurring abundantly in the squill (*Urginea Scilla*). In external appearance it closely resembles achroo-dextrin, but it is lævogyrate, and is almost wholly converted into lævulose by the action of warm dilute acids. It may be obtained by adding lead acetate to powdered squill made into a thin paste with water, as long as a precipitate is formed, mixing the filtrate, after removal of lead, with excess of calcium hydrate, which precipitates the sinistrin, and decomposing the precipitate with carbonic anhydride, any lime remaining in the liquid being removed by careful addition of oxalic acid. The filtrate is then decolorised by animal charcoal, gently evaporated at 40° – 50° , and the sinistrin precipitated by alcohol. Pure sinistrin, $\text{C}_6\text{H}^{10}\text{O}^3$, is colourless and amorphous: it dissolves in water in all proportions, and in presence of an alkali holds copper oxide in solution without reducing it. Its specific rotatory power is $[\alpha]_D = -41.4^\circ$. Saliva and diastase have no action on sinistrin, but warm dilute sulphuric acid completely converts it into sugar, consisting of a mixture of lævulose with an optically inert variety, both of which are capable of fermentation, and reduce copper oxide in alkaline solution.

The name *sinistrin* is also applied by G. Kühneman (*Ber.* viii. 387) to a lævogyrate substance resembling dextrin, contained in ungerminated barley.

SIPYLITE. A niobate, occurring in Amherst County, Virginia, associated with albanite and magnetite, and occasionally with a few large crystals of hydrous zircon. It appears in small irregularly shaped masses, very brittle, exhibiting small, but distinct conchoidal, and also uneven fracture. Colour, brownish-black, in thin splinters red-brown; streak, light cinnamon-brown; lustre, resinous and pseudo-metallic; translucent in thin splinters; hardness = 6, nearly; sp. gr. 4.80. When heated before the blowpipe the mineral decrepitates and glows brilliantly, becoming pale greenish-yellow and opaque. Its analysis gave:

$\text{Nb}^2\text{O}^3, \text{Ta}^2\text{O}^3$ (?)		WO^3	SnO^2	ZrO^2	$\text{Eb}^2\text{O}^3, \text{Y}^2\text{O}^3$ (?)	Ce^2O^3

(?) Ta^2O^3 = about 2 per cent.

(?) Y^2O^3 = about 1 per cent.

Grouping together the acid oxides of Nb, Ta, W, Sn, and Zr, reducing all the basic oxides present to the equivalent amounts of dyad oxides, and leaving out the water, these numbers may be represented by the formula $\text{R}^{\text{V}}\text{M}^{\text{V}}\text{O}^8.4\text{R}^{\text{V}}\text{M}^{\text{V}}\text{O}^7$ (J. W. Mallet, *Sill. Am. J.* [3], xv. 397).

SIUM. The root of *Sium latifolium* contains sugar, gum, albumin, pectin, a colourless fragrant volatile oil, and a resin, which appears to be the poisonous constituent (A. R. Porter, *Pharm. J. Trans.* [3], vii. 174). N. Rogers (*ibid.* 433) found

in the root two acid resins and an indifferent resin, from which a body was obtained which crystallised in colourless needles and volatilised without decomposition; also volatile oil, starch, sugar, gum, albumin, salts of potassium, sodium, calcium, and magnesium, and lastly a volatile alkaloïd which he regards as *pastinacine*.

SKATOLE, C^6H^7N (Brieger, *Ber.* x. 1027; xii. 1985; Nencki, *ibid.* x. 1032). A crystallisable substance, closely resembling indole, found, together with acetic, butyric, and isobutyric acids, and small quantities of phenol and indole, in human excrements (*σκαρος*). It is also a product of the fermentation of albuminoids, and is best prepared by the fermentation of blood-albumin with a little pancreas and water, indole being formed at the same time. Skatole crystallises in irregularly dentate, shining plates, resembling indole, which, by frequent recrystallisation from hot water, can be obtained snow-white. The crystals, which have a highly disagreeable faecal odour, melt at 94° – 95° . Skatole is rather less soluble in water than indole, and can be easily distinguished from the latter by not being coloured by chlorine-water, and by the fact that an aqueous solution of skatole, treated with a drop of fuming nitric acid, gives not a red precipitate, but a white cloudiness. It is soluble in warm dilute nitric acid, but separates unchanged on cooling. It is decomposed when boiled for some time with nitric acid, giving off vapours which have the odour of nitro-phenol.

Skatole forms the chief constituent of the volatile aromatic portion of human faeces. The faeces of dogs (whether fed on bread or on meat diet) contain no skatole, but only indole and a volatile yellow oil (not yet analysed), having a revolting and peculiarly irritating odour. The same oil is obtained by distillation from various pathological fluids of the human organism.

Skatole, when administered in small doses, appears to exert no deleterious action on the animal organism, but in larger quantities it produces tetanus, and gives rise to an increase of the proportion of ethylsulphates to sulphates in the urine.

Nencki (*J. pr. Chem.* [2], xx. 466) regards skatole as methyl-indole, $C^6H^6(CH^3)N$, and Ossikovsky (*Ber.* xiii. 332) represents it by the constitutional formula :

An isomeride of skatole, $C^6H^4\langle\begin{smallmatrix} \text{CH}^2 \\ \text{N} \end{smallmatrix}\rangle C(CH^3)$, called *Methyl-ketole*, and regarded as the methyl-derivative of an hypothetical body, *ketole*, $C^6H^4\langle\begin{smallmatrix} \text{CH}^2 \\ \text{N} \end{smallmatrix}\rangle CH$, is formed

by treating orthonitrophenyl-acetone, $C^6H^4\langle\begin{smallmatrix} \text{CH}^2 \cdot \text{CO} \cdot \text{CH}^3 \\ \text{NO}^2 \end{smallmatrix}\rangle$, with ammonia and zinc-dust at a temperature just below the boiling point of the mixture. The nitro-compound is then converted into the corresponding amido-compound, $C^6H^4(NH^2) \cdot CH^2 \cdot CO \cdot OH^2$, and the latter, by loss of H^2O , into methyl-ketole. On distilling the product in a current of steam, the methyl-ketole crystallises from the distillate in colourless plates or needles having a strong odour like that of indole. It melts at 59° , and distils without decomposition at a higher temperature. It dissolves in hot water and in hydrochloric acid, and the acid solution yields with platinic chloride a crystalline double salt, and with picric acid a deposit of yellowish-red needles. With nitrous acid it gives a yellowish, and with bleaching powder a fugitive blue coloration (A. Baeyer a. O. R. Jackson, *Ber.* xiii. 137).

SLATE. Analyses of twenty varieties of Thuringian slates from the neighbourhood of Lehesten, near Gräfenenthal, have been published by H. Mäder (*Arch. Pharm.* [3], iii. 197, 289; *Jahresb. f. Chem.* 1873, 1224). These slates contain no magnesia.

The following analyses of 'green slate' from Reichenau in Lower Austria, traversed by veins of epidote and calcspar, are given by Zellner a. Breck (*Min. Mitth.* 1873, 130):

SiO ²	Al ² O ³	Fe ² O ³	FeO	MgO	CaO	Na ² O	K ² O	H ² O	CO ²

SMILACIN, syn. with *Parillin*, the Saponin of Sarsaparilla. See **SAPONIN** (p. 1780).

SODA. Elaborate reports on the progress of the soda-manufacture by Le Blanc's process have been published by G. Lunge (*Dingl. pol. J.* ccxxiv. 195, 318; *Jahresb. f. Chem.* 1877, 1145; further, *Dingl.* ccxxxi. 266, 377, 443; *Chem. Soc. J.* xxxvi. 677, 751).

Experiments by J. Mactear (*Chem. Soc. J.* xxxiii. 475) on the decomposition of sodium sulphate by carbon in various proportions and at different temperatures have led to the following results:

1. When sodium sulphate is mixed with a quantity of carbon in excess of two equivalents, and exposed to a temperature considerably above red heat out of contact with air, the sulphate is ultimately converted into monosulphide of sodium, while the oxygen is evolved as carbon monoxide:

2. When sodium sulphate and carbon, finely divided and intimately mixed, are exposed to a temperature of dull redness (say from 1150°–1300° F.), out of contact with the air, a certain quantity of sodium carbonate is formed, together with an equivalent proportion of sodium bisulphide, as well as monosulphide, while the carbon combines with the oxygen of the sodium sulphate to form carbon monoxide and carbon dioxide. The amounts of carbonate and bisulphide formed vary inversely as the temperature, while the amount of sulphate decomposed varies directly as the temperature. The reaction which is most in accordance with these experiments is:

Any excess of carbon acts apparently in the first instance on the CO₂, reducing it to CO, and finally on the Na₂CO₃ + Na₂S₂, producing Na₂S + CO.

The decomposition of potassium sulphate by carbon takes place at lower temperature, but the decomposition is of the same character as in the case of sodium sulphate, the products consisting of carbonate and bisulphide of potassium.

The following process for the manufacture of carbonate and other salts of sodium is described by Weldon (*Chem. Centr.* 1878, 109). Sodium sulphate is melted in a Siemens' regeneration furnace, and poured on to the requisite amount of red-hot coal contained in a revolving furnace, the inside of which is protected from the action of the molten sodium sulphide by a thick layer of compressed magnesia, coke, or graphite. The carbon dioxide set free during the process is collected in gasometers, and used in the manufacture of sodium bicarbonate. The sodium sulphide is converted into caustic soda by the action of superheated steam. Silicate and phosphate of soda are made by heating a mixture of the sulphide with silica, or with aluminium phosphate, in a current of superheated steam.

Sodium bicarbonate separates out when carbonic acid is passed into a cold solution containing 12.20 per cent. of sodium sulphide. The monocarbonate is obtained by calcining the bicarbonate.

On the recovery of Sulphur from Soda-waste, see Kraushaer (*Dingl. pol. J.* ccxxvi. 412; *Jahresb. f. Chem.* 1877, 1148; *Chem. Soc. J.* xxxiv. 171).

On the action of Manganous Chloride at high temperatures on Soda-waste, see Watson Smith (*Chem. News*, xxxvi. 113).

F. Fischer (*Ber.* ix. 1558) has examined the gases given off from the furnaces in Leblanc's soda-process, and finds them to contain, on the average, 16 per cent. carbon dioxide, 6–10 oxygen, and 77–79 nitrogen, but no carbon monoxide. The temperature of the melted mass, taken with a Siemens' pyrometer, was found to vary from 713°–792°.

Ammonia-soda Process. This process consists in decomposing a solution of sodium chloride with ammonium bicarbonate, whereby sodium carbonate and ammonium chloride are produced. The sodium bicarbonate is obtained as a precipitate which is dried and converted by heat into monocarbonate, and the ammonium chloride is heated with caustic lime, the ammonia thereby set free being mixed with the carbon

dioxide produced by heating the sodium bicarbonate, and thereby reconverted into ammonium bicarbonate, to be used for the decomposition of fresh quantities of sodium chloride. The advantages of this process are: the direct transformation of sodium chloride into carbonate; the non-precipitation of other metals from the mother-liquors; the absolute freedom of the product from sulphur-compounds; the simplicity of the plant; the small amount of fuel and labour required; and the absence of noxious gases (R. Wagner, *Dingl. pol. J.* ccix. 282). Nevertheless, the process, when tried on the manufacturing scale, presented so many difficulties, that its prospect of success appeared but small till certain valuable improvements were introduced by E. Solway. The chief difficulties consisted in the loss of ammonia in consequence of imperfect absorption, and the production of large quantities of useless calcium chloride in the decomposition of the ammonium chloride by lime. The loss of ammonia has been prevented to a great extent by passing the mixture of carbon dioxide and ammonia-gas through a vertical cylinder from 35–60 ft. high, provided with a number of false bottoms, through which the solution of sodium chloride trickles downwards, and is thus brought well in contact with the upward-moving gases. The sodium bicarbonate separates in the form of a powder which remains on the false bottoms, and is from time to time collected, dried, and converted into monocarbonate as above mentioned. To avoid the production of calcium chloride, for which there is scarcely any use, the decomposition of the ammonium chloride is effected with magnesia, the resulting solution of magnesium chloride being evaporated, and the residue ignited, whereby hydrochloric acid is evolved, which may be condensed in towers, and magnesia is obtained, which may be used again in the process (Weldon, *Ber.* viii. 782).

Another difficulty experienced in the process arises from a reverse action, by which, under certain circumstances, sodium bicarbonate and ammonium chloride reproduce ammonium bicarbonate and sodium chloride. This, however, may be obviated by due attention to the temperature and concentration of the solutions. According to Grünberg (*Ber.* vii. 644), the proportions of common salt, ammonia, and water should be so regulated that, after the precipitation of the sodium bicarbonate, there should remain a saturated solution of ammonium chloride, containing only a very small quantity of sodium bicarbonate. 100 pts. of a solution of sal-ammoniac saturated at 17° (25·89 p. c.) can dissolve, at ordinary pressure and temperature, 5·742 pts. sodium bicarbonate. According to Honigmann (*Dingl. pol. J.* ccxii. 507), when carbon dioxide is passed into a saturated solution of equivalent quantities of common salt and ammonium carbonate, a mixture of 94 per cent. sodium bicarbonate and 6 per cent. ammonium bicarbonate is precipitated, whilst the liquid contains 12 per cent. sodium chloride and 4 per cent. ammonium bicarbonate, together with 20 per cent. sal-ammoniac. The smaller the quantity of common salt in solution, the greater is the quantity of ammonium bicarbonate precipitated. For these reasons Honigmann suggests the use of an excess of common salt, viz. 1·5 mol. NaCl to 1 mol. ammonium carbonate.

On the Utilisation of Gas-liquors in the Ammonia-soda process, see Gerlach (*Dingl. pol. J.* ccxxiii. 82; *Chem. Soc. J.* xxxii. 236).

The following direct methods of preparing sodium carbonate from the chloride have also been proposed.

C. Bohlig (*Dingl. pol. J.* ccxxiv. 621) heats magnesium oxalate with equivalent quantities of hydrochloric acid and common salt, whereby acid sodium oxalate is precipitated and magnesium chloride dissolved. The acid sodium oxalate, after washing with water, is mixed by agitation in an air-tight barrel with an equivalent quantity of magnesium carbonate and water, whereupon, after the pressure has risen for a time to 2 atmospheres, a concentrated solution of sodium bicarbonate is produced, together with a precipitate of magnesium oxalate. On separating this precipitate and boiling the solution of sodium bicarbonate with magnesia (obtained from the solution of magnesium chloride above mentioned), sodium monocarbonate is produced, together with magnesium carbonate, which may be used over again. The acid solution of magnesium chloride obtained by the first process is evaporated down, the residue heated to redness in a reverberatory furnace, the magnesia thereby produced is employed in the second process, and the undecomposed magnesium chloride is extracted with water, and converted into carbonate by means of the fire-gases from a coke furnace. The oxalic acid required for the process is obtained by the action of boiling potash-ley of 36° B. on deal shavings.

A similar process may be employed for the preparation of potassium carbonate from potassium chloride.

Grüneberg a. Foster (*Dingl. pol. J.* ccxi. 93) suggest the preparation of sodium carbonate from common salt by means of *alumina*. The salt is mixed with alumina and water to a pulp, and the mass is dried, broken into small pieces, and subjected to the action of overheated steam. Hydrochloric acid then escapes, and sodium aluminate

remains, which may be purified by lixiviation, and decomposed either with carbonic acid for the preparation of sodium carbonate, or with lime for the preparation of caustic soda. The alumina may be replaced by ferric oxide or other metallic oxides. The process is said to be applicable also to the preparation of potassium carbonate and hydrate from potassium chloride.

On the preparation of sodium carbonate from the *nitrate* (Chili saltpetre), see Siebel (*Ber.* vii. 1786; *Chem. Soc. J.* xxviii. 670), and Lieber (*Ber.* viii. 49; *Chem. Soc. J.* xxviii. 671).

SODALITE. An analysis by Fleischer of this mineral from the sodalite-syenite (ditroite) of the Ditro range, is published by G. vom Rath (*Jahrb. f. Min.* 1876, 774):

Cl	SiO ²	Al ² O ³	CaO	K ² O	Na ² O	Na	H ² O
6.08	38.66	32.81	0.95	1.04	13.28	3.93	2.36 = 99.11

SODIUM. *Occurrence in Plants.*—An examination by Contejean (*Compt. rend.* lxxvi. 1151) of about 600 species of plants by means of the gas blowpipe, has led to the following conclusions. More than three-fourths of terrestrial (non-maritime) plants contain sodium. The sodium is contained in largest quantity in the underground parts of the plants, and the quantity decreases in the higher parts, so that the flowers, the upper part of the stem, and upper leaves contain little or none, whilst the base of the stem, the lower leaves, and the root contain a notable quantity. Aquatic plants contain sodium in all their submerged parts in nearly equal proportion, whilst the parts above the surface of the water follow the same law as in land plants. Plants growing in wet places and in marshes, &c., are richer in sodium than plants growing on dry land, especially in their subterranean parts.

From experiments by Déhérain (*Chem. Centr.* 1878, 783), it appears that beans grown in water containing sodium chloride alone in solution assimilate the salt in small quantities, but that if other salts are present in the water, sodium chloride is taken up only when its proportion is large compared with that of the other salts. The other salts employed were calcium and potassium nitrates. Beans grown in water containing 1 gram of each of the three salts showed no trace of sodium in their ashes; if, however, the proportion of sodium chloride was raised to 4 grams, a small quantity was assimilated. In such a solution the plants lived several days, whereas in one which contained 4 grams of sodium chloride only, the assimilation of that salt was rapid, but the plants very soon died. Soda is taken up from the ground by beans, only when its proportion to the other salts is large, and hence the absence of soda in the ash of the plant does not necessarily prove that the soil in which it was grown was free from soda, but may arise from the soda being mixed with sufficient quantities of other salts.

The laws of diffusion offer no explanation of the fact that sodium chloride is more readily assimilated in the absence of other salts. When beans which had begun to germinate were placed in salt water, they frequently removed more salt than water; Böhm had shown that distilled water cannot support their growth, but that water containing calcium salts readily does so: hence it may be inferred that the germinating beans assimilate by preference calcium and potassium salts, and take up sodium chloride only when the calcium and potassium salts are absent, or are deficient in quantity relatively to the sodium chloride.

All the above facts support the opinion that soda is useless, if not hurtful to most plants. The roots of land plants and the submerged parts of aquatic plants absorb soda without selection, and it is but partially transferred to the upper parts. The proportion of soda in all aquatic plants is also found to be practically the same. In maritime plants, even though soda is present in large quantity in most parts, the flower is never found to contain the smallest trace of this substance.

Preservation of Sodium with bright Metallic Surface.—For this purpose, R. Böttger (*Ber.* vii. 1536) places the metal in a basin containing alcohol till it acquires a perfectly bright surface, then quickly transfers it to a second basin containing chemically pure petroleum-ether, and finally to a third containing a saturated solution of chemically pure naphthalene in petroleum-ether. In this last solution the sodium remains unaltered.

Chloride. This compound separates on cooling from solution in hot hydrochloric acid in needle-shaped hydrated crystals, which contain 94.5 per cent. NaCl, and 5.48 H²O, and appear to change after some time into the ordinary crystals of the anhydrous salt (*E. Bevan, Chem. News*, xxxv. 17).

According to S. Cabot (*Amer. Chemist*, v. 443), heated sodium chloride is decomposed by the action of air and water-vapour, as shown by the equation $\text{H}^2\text{O} + 2\text{NaCl} = 2\text{HCl} + \text{Na}^2\text{O}$.

E. Chevreul (*Compt. rend.* lxxv. 493) finds that a solution of the chlorides of

sodium and ammonium containing not more than 1 mol. NH_4Cl to 1 mol. NaCl , yields on evaporation crystals of a double chloride, but that a mixed solution containing any larger proportion of ammonium chloride yields crystals of the latter only. A solution of the chlorides of potassium and ammonium, on the other hand, yields crystals of a double salt, whichever of the two salts may be in excess.

Peroxide, Na_2O_2 . This compound is easily obtained by adding to a solution of sodium hydroxide of about 20 per cent. a solution of 5 per cent. hydrogen dioxide, and then a moderate excess of 80 per cent. alcohol. A crystalline precipitate is then rapidly deposited, consisting of hydrated sodium peroxide, which must be quickly separated from the liquid. The crystals, which are transparent flexible plates like mica, having a fine nacreous lustre and often of considerable size, have the composition $\text{Na}_2\text{O}_2 + 8\text{H}_2\text{O}$, and are identical with those which Harcourt obtained (v. 340) by spontaneous evaporation of an aqueous solution of sodium dioxide. When heated they give off 7 mols. H_2O and 1 at. O, and are converted into sodium hydroxide. In preparing them, care must be taken to keep the sodium hydroxide in excess, since an excess of hydrogen dioxide often completely prevents their formation (T. Fairley, *Chem. Soc. J.* xxxi. 125).

Sodium Monosulphide, Na_2S , is produced when a rapid stream of hydrogen sulphide is passed over fused sodium chloride: $2\text{NaCl} + \text{H}_2\text{S} = \text{Na}_2\text{S} + 2\text{HCl}$ (Kingzett, *Chem. News*, xxvii. 25).

On the Thermochemistry of the Sulphides of Sodium, see Sabatier (*Compt. rend.* lxxxix. 43; *Chem. Soc. J.* xxxvi. 865).

SOLANINE. This base has been represented by various formulæ. Zwenger a. Kind's analyses lead to the formula $\text{C}^{48}\text{H}^{71}\text{NO}^{18}$ (v. 346); according to Kletzensky (vi. 1030) it is $\text{C}^{21}\text{H}^{33}\text{NO}^7$. A. Hilger (*Liebigs Annalen*, cxv. 317) from recent analyses assigns to it the formula $\text{C}^{42}\text{H}^{67}\text{NO}^{15}$, and to solanidine, obtained from it by boiling with dilute acids, the formula $\text{C}^{26}\text{H}^{41}\text{NO}^2$, but it is not easy to see how a compound of this latter formula can be formed, together with glucose, from solanine containing 42 atoms of carbon. Hilger finds that solanine, when thus decomposed, yields 35.7 to 36 per cent. glucose, whereas Zwenger a. Kind's equation (v. 347) requires 64 per cent. The subject evidently requires further examination. Both solanine and solanidine yield monoacetyl-derivatives (Hilger).

SONOMATE. A sulphate of aluminium and magnesium from the Geyser-springs of Sonoma County, California. It is colourless, with a silky lustre, and has a density of 1.604. The following analyses have been made of it, leading to the formula $2\text{MgSO}_4, \text{Al}_2(\text{SO}_4)_3, 33\text{H}_2\text{O}$:

SO^3	Al^2O^3	FeO	MgO	H^2O
38.78	7.66	2.01	7.14	44.41 = 100
38.30	8.36	1.56	7.51	44.27 = 100

(E. Goldsmith, *Zeitschr. Kryst.* i. 380).

SOPHORINE. An alkaloïd obtained from the pods of *Sophora speciosa*. It is liquid, and forms a stable chloride, which crystallises readily, and gives a deep red colour with ferric chloride. The base appears to be poisonous (H. C. Wood, *Pharm. J. Trans.* [3], viii. 1047).

SORBIC ACID, $\text{C}^6\text{H}^6\text{O}^2$. The *tetrabromide* of this acid, $\text{C}^6\text{H}^2\text{Br}^4\text{O}^2$, obtained by Barringer a. Fittig (vii. 1091), has been further examined by Kachel a. Fittig (*Liebigs Annalen*, clxviii. 276), who prepare it by mixing sorbic acid with about ten times its weight of carbon sulphide, and gradually adding the calculated quantity of bromine. Traces only of hydrobromic acid are then evolved, and the liquid, on standing for a day or two, deposits the tetrabromide in large well-formed crystals exhibiting the properties already described, or sometimes in geodes of opaque needles.

Sorbic tetrabromide, or tetrabromocaproic acid, forms well-defined salts. The *sodium salt*, $\text{C}^6\text{H}^2\text{Br}^4\text{O}^2\text{Na}, 2\text{H}_2\text{O}$, forms magnificent silvery scales, easily soluble in water and in alcohol, but quite insoluble in a concentrated solution of sodium carbonate. The *potassium salt* is very soluble and difficult to obtain pure. It is not precipitated by the addition of potassium carbonate to its solution. The *ammonium salt* separates in fine needles from the solution of the tetrabromide in excess of ammonia. The *barium salt*, $(\text{C}^6\text{H}^2\text{Br}^4\text{O}^2)_2\text{Ba}, 1\frac{1}{2}\text{H}_2\text{O}$, may be formed by mixing barium chloride and the sodium salt. The *calcium salt*, $(\text{C}^6\text{H}^2\text{Br}^4\text{O}^2)_2\text{Ca}, 7\text{H}_2\text{O}$, obtained in a similar manner, crystallises with great facility in fine large silvery scales. It is much less soluble in cold water than the barium salt, and makes its appearance even in somewhat dilute solutions. The *zinc salt* is similar in appearance to the barium salt.

These salts are decomposed by boiling with water, reproducing the tetrabromide, which separates in the form of a liquid afterwards becoming crystalline. A portion of the salt, however, undergoes further decomposition, and the hydrobromic acid liberated assists the separation of the tetrabromide, forming at the same time a corresponding quantity of sodium bromide.

When sodium hydrate or carbonate is added for the purpose of neutralising this hydrobromic acid as fast as it is generated, resinous products only are obtained; but, on substituting barium carbonate for the alkaline salt, a volatile highly irritating compound, probably acrolein, is produced, giving with ammoniacal nitrate of silver a reddish precipitate which deposits metallic silver on application of heat. The residue contains a small quantity of brown resinous matter, but no organic acid.

Sorbic Dibromide or *Dibromhydrosorbic acid*, $C^6H^8Br^2O^2$, is prepared like the tetrabromide, using however only one instead of two molecules of bromine, and remains, after the carbon sulphide has been removed by distillation, as a thick yellow oil, which gradually solidifies in a crystalline mass, to be purified by pressure and recrystallisation from petroleum-benzin. The dibromide thus prepared forms small shining crystalline laminae melting at 90° – 95° , easily soluble in alcohol, ether, and petroleum-benzin, less soluble in boiling water. It forms easily decomposable salts. Its alcoholic solution, mixed with alcoholic potash, yields a precipitate of potassium bromide.

Hydrosorbic acid, $C^6H^{10}O^2 = CH^3.CH^2.CH^2.CH=CH.CO^2OH$, metameric with ethyl-crotonic and pyroterebic acids, is formed by the action of water and sodium-amalgam on sorbic acid and on the tetrabromide (vii. 1091). When fused with potash, it is resolved, with evolution of hydrogen, into acetic and normal butyric acid, whereby it is distinguished from pyroterebic acid, which when similarly treated yields acetic and isobutyric acids. From ethyl-crotonic acid, which likewise yields normal butyric acid, it is distinguished by its physical properties, being liquid at ordinary temperatures, and not solidifying at -18° , whereas ethyl-crotonic acid is solid at ordinary temperatures, and melts at 41.5° . The formulæ of the three isomeric acids, and their modes of decomposition by melting alkalis, are represented by the following equations:

Action of Hydrobromic Acid on Sorbic and Hydrosorbic Acids (C. Stahl, Ber. ix. 120). Pulverised sorbic acid agitated with fuming hydrobromic acid dissolves completely, forming a clear liquid, and after a few hours there rises to the surface an oil which, after several days' standing and frequent agitation, sinks to the bottom and solidifies. The solution then yields well-defined nearly colourless crystals of dibromhexoic or dibromocaproic acid, $C^6H^{10}Br^2O^2$, which dissolves very easily in carbon sulphide, and by recrystallisation therefrom may be obtained pure and in colourless crystals. It melts at 68° , dissolves but very slightly in water, even at the boiling heat, and separates on cooling from a hot saturated solution as an oil which solidifies on addition of a trace of the solid acid. The acid is decomposed by prolonged boiling with water.

Hydrosorbic acid dissolves immediately in fuming hydrobromic acid, forming a clear solution, and after a short time an oily layer collects on the surface, its separation being complete in about three hours. This oil, after washing with water and drying over sulphuric acid, is nearly colourless, and consists of pure monobromocaproic acid, $C^6H^{11}BrO^2$. This acid does not solidify at -18° . It dissolves readily in dilute soda-ley, and the solution, if immediately treated with an acid, yields the bromocaproic acid unaltered; but after some hours acids separate nothing from it, and the acidified liquid yields on distillation, not bromocaproic, but hydrosorbic acid. From this cause also it yields, when treated with sodium-amalgam, not caproic but hydrosorbic acid (Stahl).

Pyroterebic acid, which is isomeric with hydrosorbic acid, does not unite with hydrobromic acid either at ordinary temperatures or when heated with it in sealed tubes (Fittig, Ber. ix. 1198).

SORDIDIN, $C^{18}H^{18}O^7$. A neutral crystallisable substance occurring, together with usnic acid and zeorin, $C^{13}H^{22}O$, in the lichen *Zeora sordida* (see ЗЕОРА).

SPECTRAL ANALYSIS. I. EMISSION SPECTRA. a. Spectra of Metalloids. Nitrogen.—In the last Supplement to this Dictionary some experiments of Schuster were mentioned, which tended to prove that the baric-spectrum of nitrogen was due to an oxide. This idea was controverted by Salet (*Compt. rend.* lxxxii. 665), who showed that nitrogen can be heated in contact with sodium or potassium, and yet give the spectrum in question. There is no reason now to doubt that the spectrum is really due to pure nitrogen.

Oxygen.—The spectrum of this element has recently been examined by Schuster (*Phil. Trans.* clxx. 1879, 37). Four spectra are distinguished.

1. The *Elementary Line-spectrum*.—This is the spectrum which appears at the highest temperature to which we can subject oxygen; that is, whenever the jar and air-break are introduced into the electric circuit. It consists of a great number of lines, especially in the more refrangible part of the spectrum. It has been called elementary line-spectrum to distinguish it from the other line-spectrum, because, according to one hypothesis which has been suggested to explain the variability of spectra, the molecule which gives this spectrum is in a simpler or more elementary state than that which gives the other so-called compound line-spectrum. We may, however, adopt the nomenclature independently of any hypothesis that may have suggested it.

2. The *Compound Line-spectrum*.—This spectrum appears at lower temperatures than the first. It consist of four lines: one in the red, two in the green, and one in the blue. With the exception of the blue line, all the lines in this spectrum widen very easily, and with an increase of pressure, more easily even than the hydrogen lines. They do not widen out equally on both sides, but more towards the red than towards the violet. This fact is especially noticeable in the more refrangible of the two green lines. The blue line always remains sharp.

3. The *Continuous Spectrum of Oxygen*.—This spectrum appears at the lowest temperature at which oxygen is luminous. The wide part of a Plücker tube, filled with pure oxygen, generally shines with a faint yellow light, which gives a continuous spectrum. Even at atmospheric pressure this continuous spectrum can be obtained by putting the contact-breaker of the induction-coil out of adjustment, so that the spark is weakened. According to Becquerel, an excess of oxygen in the oxygen-hydrogen flame produces a yellow colour, which is very likely due to this continuous spectrum. The continuous background which often accompanies the elementary line-spectrum must not be confounded with this spectrum.

The *Spectrum of the Negative Glow*.—This spectrum, which was first accurately described by Willner, is always seen in the glow surrounding the negative electrode in oxygen. It consists of five bands: three in the red, and two in the green. The least refrangible of the red bands is so weak that it easily escapes observation; the two other red bands are rather near together, and may be taken for one single band, if the dispersion applied is small. The two green bands, which appear of the same brightness throughout, with pretty sharply defined edges, are resolved into a series of lines, when looked at with high optical powers.

The following description of the appearance of a vacuum-tube filled with pure oxygen, as it undergoes gradual exhaustion, will give an idea of the way in which the spectra of oxygen gradually diffuse into each other:

At first the spark has a yellow colour, and the spectrum is perfectly continuous. Almost immediately, however, four lines are seen in the capillary part above the continuous spectrum. One of these lines is in the red, two are in the green, and one is in the blue. The discharge still passes as a narrow spark throughout the length of the tube. In the wide part the spectrum remains continuous, and it extends more towards the red and blue than in the capillary part. It seems as if the four lines had taken away part of the energy of the continuous spectrum. As the pressure diminishes, these lines increase considerably in strength, the spark spreads out in the wide part of the tube, and the intensity of the continuous spectrum is therefore considerably diminished, while it still forms a prominent part in the spectrum of the capillary part. When the pressure is small, the continuous spectrum decreases in intensity. At the same time, the negative glow, with its own characteristic spectrum, gradually extends through the negative half of the tube into the capillary part. The continuous spectrum has now entirely disappeared, and the bands of the negative pole and the four lines stand out on a perfectly black background. It is under these conditions that the change from the compound line-spectrum to the elementary line-spectrum is best studied. The mere insertion of the Leyden jar makes hardly any difference; the jar does not seem to be charged at all. If, in addition to the jar, we insert a movable air-break, which can be opened or closed at will, while we look through the spectroscopic, we shall be able to see alternately two perfectly distinct spectra. If

the air-break is closed, the four lines of the compound-spectra only are seen; if the air-break is opened, these four lines will disappear entirely, and the elementary line-spectrum will come out. We have here as complete a transformation as we have from the band to the line-spectrum of nitrogen, taking place under exactly the same circumstances (*Phil. Trans.* clxx. 51).

Carbon.—The spectrum which is seen at the base of every candle-flame has lately given rise to a good deal of discussion. Attfeld, Morren, Dibbits, Wüllner, W. M. Watts, and others had come to the conclusion that the spectrum was due to carbon and not to any hydrocarbon. Dibbits had furnished an answer to the theoretical difficulty that the spectrum of carbon should appear at so low a temperature. Before combustion, the carbon is combined with hydrogen; after combustion, it is combined with oxygen. It must therefore have existed during a certain stage of transition in the form of simple carbon uncombined. During this stage of transition it gives us the carbon-spectrum. In the year 1875, after Angström's death, Thalén published a paper in which he describes some experiments jointly made with Angström (*Nov. Act. Ups.* ix.) In consequence of these experiments, the authors expressed the opinion that the candle-spectrum was due to a hydrocarbon. The experiments which they gave in support of their view were made by taking the spark of carbon-electrodes in various gases, and examining the spectra of the 'auréole' or 'glory' as it might be called. If the spark is taken in oxygen, the undoubted spectrum of carbonic oxide appears; in hydrogen the candle-spectrum is seen; and in nitrogen some blue and violet bands are added to the candle-spectrum, which appear to be due to a compound of carbon and nitrogen. As it is known that acetylene is formed when the spark is taken in hydrogen, Angström and Thalén conclude that the spectrum seen in the 'glory' is due to acetylene.

Recently Liveing and Dewar have supported Angström's view (*Proc. Roy. Soc.* xxx. 152). They sum up that part of their work which relates to the candle-spectrum as follows:

In the next place, the green and blue bands, characteristic of the hydrocarbon flame, are well seen when the arc is taken in hydrogen; but, though less strong when the arc is taken in nitrogen or in chlorine, they seem to be always present in the arc whatever the atmosphere. This is what we should expect, if they be due, as Angström and Thalén suppose, to acetylene; for we have found that the carbon-electrodes always contain, even when they have been long treated in chlorine, a notable quantity of hydrogen. In the flames of carbon-compounds they by no means always appear; indeed, it is only in those of hydrocarbons or their derivatives that they are well seen. Carbonic oxide and carbon disulphide, even when mixed with hydrogen, do not show them; and if seen in the flames of cyanogen, hydrocyanic acid, and carbon tetrachloride mixed with hydrogen, they are faint, and do not form a principal or prominent part of the spectrum. This is all consistent with the supposition of Angström and Thalén.

Lockyer (*Proc. Roy. Soc.* xxx. 335) describes an experiment in which the bands in question were seen when the spark was taken in carbon tetrachloride, although no lines of hydrogen were visible. Those who believe the spectrum to be due to the element carbon rely chiefly on the brilliancy with which its bands are developed when cyanogen is burnt in oxygen; also when the spark is taken in cyanogen, carbon tetrachloride, and carbonic oxide at high pressure, all the gases being dried with the greatest care. Those who oppose this view, and who hold that the spectrum is due to a hydrocarbon, refer to the impossibility of excluding all traces of moisture, and to the fact that this spectrum is well developed under circumstances where we know hydrocarbons to be present.

Compounds of Carbon and Nitrogen.—A cyanogen flame shows, besides its own characteristic red and yellow bands, a series of flutings in the blue, violet, and ultra-violet. These bands have until recently been ascribed to carbon, as they were observed in carbon compounds not containing nitrogen, but according to experiments of Liveing and Dewar (*Proc. Roy. Soc.* xxx. 494), they can in those cases always be traced to impurities containing nitrogen. Thus, according to Watts, the bands are seen when a spark is taken in carbonic oxide at the atmospheric pressure. According to Liveing and Dewar this is true, if the carbonic oxide has been prepared from ferrocyanide of potassium. When, however, the gas was made by the action of sulphuric acid on dried formate of sodium, a faint trace of one of the bands only could be detected. When the gas was prepared by heating a mixture of quicklime with pure and dry potassium oxalate, no trace whatever of the bands in question appeared. Similarly, Watts and Lockyer had observed the bands in a tube containing carbon tetrachloride, but, according to Liveing and Dewar, these bands do not appear when the tetrachloride has been well purified, and when all traces of air have been expelled from the tube.

Chlorine, Bromine, Iodine.—Giamician (*Wien. Ber.* [2], lxxviii. 872) has given an account of the successive changes which the spectra of these bodies undergo when the pressure is either greatly reduced or increased. Lines which are visible at one pressure disappear altogether, and are replaced by others when the pressure is changed.

b. Spectra of Metals. A most important contribution to our knowledge of the spectra of metals has appeared in Lecoq de Boisbaudran's 'Spectres lumineux' (Gauthier Villars, 1874). Lecoq de Boisbaudran has mapped the spectra of most metals as they appear when a spark is taken from a solution of the metallic salts. Not only is this method of great convenience to the chemist, who can generally obtain without difficulty a solution of the substance he wishes to examine, but it enables us also to observe metallic spectra at much lower temperatures than when the solid metal is used as pole; for a spark which is not sufficient to volatilise the metal will give a spectrum when taken from a metallic solution. We may also mention Rand Capron's 'Photographed Spectra,' a series of photographs of metallic, gaseous and other spectra, taken generally for each metal both with the arc and spark.

Bunsen (*Pogg. Ann.* clv. 366-384) has described the methods employed by him to detect erbium, yttrium, cerium, lanthanum, and didymium by means of their spectra. His paper is accompanied by plates giving the spectra obtained when a spark is taken from the chlorides of these elements.

Thalén (*K. Vetensk. Akad. Handl.* xii. No. 4) has also examined the spectra obtained from the chlorides of yttrium, erbium, lanthanum, and didymium, and given a list of their lines in wave-lengths.

During the year 1879, Nilson announced the discovery of a new metal, 'scandium.' Thalén has examined the spectrum of this metal, and found that it contained many characteristic lines. His final measurements will be found in the *Comptes rendus* (xci. 1880, 45). See YTTRIUM METALS.

It was explained in the last Supplement how Lockyer could, by means of his method of long and short lines, eliminate for each metal all lines due to impurities. An element present as an impurity made itself apparent by its longest lines, and hence it was assumed that, whenever the long lines of an element were present, they were due to an impurity. In his subsequent investigations, Lockyer (*Proc. Roy. Soc.* xxviii. 1878, 159) found that after the impurities had been eliminated by this method, there was still a large number of coincidences left between the lines of different metals. It was argued that the hypothesis that identical lines in different spectra are due to impurities is no longer sufficient to account for the fact, that therefore an additional hypothesis is needed, and that once we accept this additional hypothesis, even some of the long-line coincidences would find a better explanation by the new hypothesis. The new hypothesis Lockyer bases on the assumption that the elements are not simple bodies. Evidence is adduced that in the hottest stars hydrogen alone is present; that magnesium, sodium, calcium come in during the next stage; and that only when the temperature of the star has reached that of our sun, iron and the heavier metals are observed. If we assume the reason for these facts to be that part of the lighter elements enter into combination together to form the heavier metals, we should explain the short-line coincidences. Lockyer supports his views by the behaviour of some metals when exposed to different temperatures. Thus calcium (*Proc. Roy. Soc.* xxiii. 1876, 352) in the flame or in a very weak spark shows only the blue line. In the arc the two violet lines (H and K) make their appearance. As the power of the arc or spark is increased, the violet lines gain relatively in strength, and finally the blue line disappears altogether. The spectrum of iron behaves in a remarkable way; the relative intensity of the lines varying much according to circumstances. In solar storms weak iron lines are often seen, while some of the strong ones appear much more seldom. In two subsequent papers, Lockyer (*ibid.* 1878; xxix. 1879, 247) follows out the solar evidence, discussing the lines seen by Young in the solar chromosphere. Maps are given, showing for each line the frequency with which it has been seen by Young and the intensity as given by Thalén. The two quantities, as it appears, are by no means identical. The question is discussed whether the lines most often seen in solar storms and in spots are those which are common to two or more metals, and Lockyer concludes that they are.

Some remarkable phenomena are mentioned by Lockyer in a further communication to the Royal Society (*Proc. Roy. Soc.* xxix. 1879, 266). A spark is passed through a vacuum tube; below one electrode a piece of sodium is gradually heated. At first a yellow glow is seen between the electrode and the metal, the glow giving the yellow sodium line. As a greater quantity of sodium-vapour is volatilised, the yellow glow rises, and a brilliant leaf-green glow now adjoins the metal. The leaf-green glow

gives the red and green lines of sodium without the yellow lines. In a similar way, the yellow-green lines of potassium could be seen without the red.

c. Spectra of Compound Bodies. An important communication on the spectrum of the flame of hydrogen was sent on June 16, 1880, to the Royal Society by Mr. Huggins (*Proc. Roy. Soc.* xxx. 1880, 576). Photographs of the spectrum given by a non-luminous flame of hydrogen showed a strong series of bands in the ultra-violet lying between wave-lengths 3062 and 3276. This spectrum is in all probability a spectrum of water. The spectrum was also found to be present in the blue cone of an ordinary blowpipe flame. Liveing and Dewar (*ibid.* xxx. 1880, 580) independently discovered the same spectrum, and found it to be present when a spark was taken in moist gases.

In the year 1878, Liveing and Dewar (*ibid.* xxviii. 368, 474) mentioned that a spark taken between magnesium poles in hydrogen showed some lines which were not present when the spark was taken in an atmosphere of nitrogen or carbonic oxide; they ascribe the spectrum to a combination of hydrogen and magnesium. Their first communication left it rather doubtful whether the line was not simply due to the lower temperature of the spark in hydrogen, but the more detailed account of their experiments (*ibid.* xxx. 1880, 93) leaves no reasonable doubt that the presence of hydrogen is necessary to the formation of this spectrum.

Liveing and Dewar (*ibid.* xxviii. 1879, 352) discovered a band 5700 to 5175 which seems to be due to a compound of potassium and carbonic oxide.

The *Proceedings of the Cambridge Philosophical Society* (iii. 96) contains a drawing of the spectrum of calcium fluoride obtained when a fluor moistened with hydrochloric acid is heated in the flame of a Bunsen burner. The drawing differs somewhat from that given of the same spectrum by Mitscherlich (*Phil. Trans.* clxvii. 1876, 207).

As regards some theoretical questions, especially with regard to the formation of double spectra, we must refer to two papers by E. Wiedemann (*Wied. Ann.* v. 500; viii. 202), who has described in the latter paper some experiments made for the purpose of deciding whether heat is absorbed or given out the moment a gas changes its spectrum. In the case of hydrogen it was indeed found that an absorption of heat took place when the band-spectrum changed into the line-spectrum, and that the amount is independent of the cross-section of the vacuum-tube containing the hydrogen, and also of the pressure. Unfortunately the band-spectrum of hydrogen is one of doubtful origin, many spectroscopists ascribing it to an impurity of hydrocarbons. Wiedemann will, however, no doubt extend his observations to other gases which possess undoubted double spectra.

II. ABSORPTION-SPECTRA

a. Absorption-spectra of Vapours. We have had in the last few years three maps of the absorption-spectrum of bromine. One by Roscoe and Thorpe (*Phil. Trans.* clxvii. 1876, 207), one by Moser (*Pogg. Ann.* clx. 1877, 177), and apparently the best and most accurate one by Hasselberg (*Mém. de St. Pé.* xxvi. 1878, 4). Roscoe and Thorpe's map extends, however, further into the red than the other two. Moser investigated the changes seen in the spectrum when the vapour is heated. Some of the bands seem to disappear and to be replaced by others. Hasselberg, in the same paper, gives us a very accurate set of measurements of the absorption-spectrum seen when white light is sent through the vapour of nitrogen tetroxide. Moser also investigated the changes in this spectrum, and finds that three bands near C disappear at a high temperature. It seems likely that these bands are due to the more complex molecule N_2O_4 which we know to be broken up when the temperature is raised.

The absorption-spectra of metallic vapours were examined by Liveing and Dewar, and the results were communicated in a series of papers to the Royal Society (*Proc. Roy. Soc.* xxvii. 132, 350, 494; xxviii. 352, 367, 471; xxix. 402). At first the substances were heated up in an iron tube, and the continuous spectrum sent out by the tube was used as background against which the reversals were observed. In order to obtain higher temperatures, the iron tube was replaced in the later experiments by crucibles of lime or carbon, and the substances were heated either in a jet of the oxyhydrogen flame or later by means of the voltaic arc derived from a dynamo-electric machine. The following is a short summary of the results which were obtained:

Sodium.—In the iron tube the channelled spaces described by Roscoe and Schuster were seen, but it was pointed out that the green line (5510) was not coincident as assumed by them with the double green sodium line. In the later experiments with higher temperatures, all the lines except one pair given by Thalén as belonging to

sodium were seen reversed, and the order in which they appeared was as follows: The double yellow line, the pair at 5687, the pair at 4983, the pair at 4670, and finally the double red line at 6160. It is curious that the pair at 5154 has not been seen reversed. The pair at 4670 is not given by Thalén at all, but by Lecoq de Boisbaudran. A mixture of magnesium and sodium gave a band at 5300, which was seen only in this mixture.

Potassium.—In the iron tube the channelled spaces appeared in the green; but those in the red observed by Roscoe a. Schuster were not seen. There can be little doubt however that they do exist and really belong to potassium. The dark line at 5730, Liveing a. Dewar proved not to be identical with the potassium line near it, as assumed by Roscoe a. Schuster. No line of potassium was reversed in the iron tube; but a mixture of potassium and magnesium gave two dark lines in the red (6580, 6475) which could not be traced either to potassium or to magnesium, but appear only when the two metals are present together. At higher temperatures the lines of potassium make their appearance.

Lithium.—Lithium gave no results in the iron tube, but when the chloride was introduced together with metallic sodium and potassium, the red line was seen reversed. At higher temperature the green line was seen reversed.

Rubidium.—Rubidium chloride heated in a glass tube with sodium shows the reversal of the two violet lines. At higher temperature the less refrangible of the two red rays is also reversed.

Cesium.—Cesium chloride heated in a glass tube showed the two blue lines.

Magnesium showed in the iron tube in an atmosphere of hydrogen the reversal of 6, and the spectrum which has been already mentioned was traced to a compound of magnesium and hydrogen. At higher temperatures the other metallic lines appear, with the exception of 4481, which was not seen, but on the other hand a new line at 4354 was seen reversed.

In a similar way the absorption-spectra of the vapours of barium, calcium, strontium, silver, gallium, lead, zinc, cadmium, bismuth, copper, iron, and manganese are described.

Absorption-spectra of Liquids. The study of the absorption-spectra of liquids is daily gaining more importance. As, however, the absorption-spectrum of a salt often varies with the solvent, and even with the presence of other bodies, great care is necessary when the spectroscopie is used in qualitative analysis. In some cases, however, the instrument may give much information. H. W. Vogel (*Ber. d. Chem. Ges.* 1876, ix. 1641), for instance, shows how small traces of alumina or magnesia may be traced in solutions. For this purpose Vogel makes use of the action of purpurin on these bodies. An alcoholic solution of purpurin shows an absorption over F and one between 6 and E. If the solution is alkaline, a band appears between E and D; this is to be avoided, which can be done by adding a small quantity of lime-water to the solution. If to this solution a liquid containing small quantities of an aluminium salt is added, two very characteristic bands appear, one between E and D and one between F and 6. Salts of magnesia show bands in nearly the same position, but magnesia bands disappear on addition of a drop of acetic acid, while the bands which are due to alumina remain. Vogel (*ibid.* 1875, 1533) also shows how manganese, chromium, cobalt, uranium, and iron can under certain circumstances be recognised by means of the spectroscopie.

Chromium compounds. Erhard has subjected some of the salts of chromium to a careful investigation. He describes the absorption-spectrum of crystals of chromium-potassium sulphate, and finds it to be identical with that of chromium ammonium sulphate. It is characterised by some absorption-bands in the red more refrangible than C. The remainder of the spectrum is the same as that of the solutions of the salt, exhibiting strong continuous absorption in the blue, but partial transmission of the violet. Chromic chloride differs from the other salts by transmitting light between E and G. The red oxalate of potassium and chromium transmitted only the red. The blue oxalate gave an absorption band in the red, and transmitted some of the blue and violet.

The absorption-spectra of the solutions of the alums, of chromium sulphate, and of the chloride and nitrate resemble each other, and transmit more light than a solution of the oxalates, tartrate, and acetate. Professor Soret has paid some attention to the absorption-spectra of the chromates (*Archives sc. phys. Nat.* 1878, lxi. 322), and has traced them into the ultra-violet by means of his spectroscopie with fluorescent eyepiece. He finds the spectra of the chromates of potassium, sodium, and ammonium, of the diluted bichromates of potassium and ammonium, to be identical. Chromic acid showed the same spectrum less distinctly.

Discovery of new elements. The spectroscope has played an important part in the discovery of some new earths from the minerals gadolinite and samarskite. Marignac had been led to the discovery of a new element which he called *ytterbium*. He gave some of his preparations to Soret, who after examination came to the conclusion that at least one other element was present besides (*Compt. rend.* 1878, lxxxvi. 1062). This element gave some very characteristic bands, especially in the ultra-violet. The bands were not due either to any previously known elements, or to the newly-discovered ytterbium, which gives no characteristic absorption-bands (its emission-spectrum was mapped by Lecoq de Boisbaudran; *Compt. rend.* 1879, lxxxviii. 1342). This new element Soret only called X, as he considers it to be identical with one the discovery of which had been announced by Delafontaine, to whom he consequently left the choice of a name. Subsequent researches have confirmed this supposition, and the element was named by its discoverer *philippium*. Clève independently discovered its existence by means of the spectroscopic evidence, and called it *holmium*, but afterwards acknowledged Soret's priority.

Soret, and after him Clève, also found some remarkable variations in the intensity of a red absorption-band ($\lambda = 684$), and suggested the possibility of the existence of a distinct element, for which the name of *thulium* was suggested by Clève; Soret, however, who has the priority of the discovery, did not consider the evidence sufficiently strong as yet to justify his giving any name to this element, the existence of which though probable is not proved.

Delafontaine (*Compt. rend.* 1878, lxxxvii. 632) also thinks he has obtained conclusive evidence of the existence of another earth, *decipium*, which is characterised by two bands ($\lambda = 416$ and $\lambda = 478$), and Lecoq de Boisbaudran (*ibid.* 1879, lxxxix. 212) has obtained an absorption-spectrum which he considers to be due to an element different again from decipium, which he calls *samarium*. It seems certain that the products examined by Delafontaine and Lecoq de Boisbaudran contain a new substance, but also that they contain something in common. Whether samarium is identical with decipium, or whether they are mixtures in unequal quantities of a new body with a known one, or of two new bodies, it is as yet impossible to say.

Relationship between different spectra. We have to note some important investigations on the question whether an element preserves its absorbing properties when combined with another, and whether substances having a similar chemical constitution present analogies in their spectra. Gladstone and Miller had previously given their attention to this question, and found that acids and bases preserved their absorbing powers when combined together. This result has been confirmed by Soret (*Arch. sc. phys. Nat.* 1878, lxi. 322), who finds that, if acids transparent to the ultra-violet rays combine with transparent bases, the compound is also transparent; but an acid which absorbs certain parts of the spectrum will also absorb it when combined with a transparent base. A very curious confirmation of this law is derived from a study of nitric acid and the metallic nitrates, which all begin to absorb the ultra-violet rays at the same limit, and have a maximum of absorption for a wave-length of about 3000 tenth metres. More recently Soret has examined, jointly with Rilliet (*Compt. rend.* 1879, lxxxix. 747), the absorption-spectra of the alcoholic nitrates and nitrites, and finds that, although the place where the general absorption begins is much the same as in the metallic salts, nevertheless some of the characteristic properties disappear. Hence Soret and Rilliet conclude that the alcoholic nitrates have a chemical constitution different from that of the metallic salts.

Hartley and Huntington (*Phil. Trans.* 1879, clxx. 257), in a long and careful work, have examined the question of relationship of spectra in similarly constituted bodies. They have arrived at the following conclusions:

(1). The normal alcohols of the series $C^nH^{2n+1}OH$, are remarkable for transparency to the ultra-violet rays of the spectrum, pure methylic alcohol being nearly as much so as water.

(2). The normal fatty acids exhibit a greater absorption of the more refrangible rays of the ultra-violet spectrum than the normal alcohols containing the same number of carbon-atoms.

(3). There is an increased absorption of the more refrangible rays corresponding to each increment of CH_2 in the molecule of the alcohols and the acids.

(4). Like the alcohols and acids, the ethereal salts derived from them are highly transparent to the ultra-violet rays, and do not exhibit absorption-bands.

They have also examined substances containing the benzene-nucleus, and obtained the following results:

(1). Benzene, and the hydrocarbons, alcohols, acids, and amines derived therefrom are remarkable—first, for their powerful absorption of the more refrangible rays; secondly, for the absorption-bands made visible by dissolving them in water or

alcohol; and thirdly, for the extraordinary intensity of these absorption-bands—that is to say, their power of resisting dilution.

(2). Isomeric bodies containing the benzene-nucleus exhibit widely different spectra, inasmuch as their absorption-bands vary in position and in intensity.

(3). The photographic absorption-spectra can be employed as a means of identifying organic substances, and as a most delicate test of their purity. The curves obtained by co-ordinating the extent of dilution, or, in other words, the quantity of a substance, with the position of the rays of the spectrum transmitted by the solution, form a strongly-marked and highly characteristic feature of very many substances.

Hartley has since extended his experiments, and seems to have come to the conclusion that no carbon-compound will give distinct absorption-bands unless it contains three pairs of carbon-atoms doubly linked together.

Influence of the Solvent on the Position of Absorption-bands.—Kundt discovered that, if a body showing characteristic absorption-bands is dissolved in different liquids, the bands are sometimes slightly shifted towards one or the other end of the spectrum. In his latest and most complete investigation (*Wied. Ann.* 1878, iv. 34) he examined chlorophyll, aniline green, cyanine, fuchsine, quinizarin, and the yolk of egg, dissolving these bodies in the following substances: methylic alcohol, water, ether, acetone, ethyl alcohol, amyl alcohol, chloroform, benzene, toluene, oil of cassia, and bisulphide of carbon. The general result was that if two solvents have diffusive powers which differ much, the one with the greater dispersion will show the absorption-band displaced towards the red. If the liquids have approximately equal dispersive powers, the results are not the same for all bodies, and no general rule can be given. A paper by Clees (*ibid.* 1878, iii. 389) will also give some useful experimental facts, but his discussion is vitiated by a serious error in the theoretical part.

III. APPLICATION OF SPECTRUM ANALYSIS TO ASTRONOMY.

Owing to the calm state of the solar surroundings in the last few years, solar physics has not advanced so rapidly as it otherwise would have done. Considerable progress has however been made in some of its branches. We have had several new maps of the solar spectrum. In the visible part, Dr. H. C. Vogel, of the Potsdam Observatory, has in the first publication of that institution given a map on a larger scale than Angström's, reaching from the green into the violet. Prof. Piazzi Smyth (*Trans. Roy. Soc. Ed.* xxix. 285) has also carefully remeasured the visible part of the solar spectrum from A to H. He does not give a map, but gives symbolical representations of the appearance of each line, together with its measurement, which is reduced to wave-numbers in British inches; that is, the number of waves contained in a British inch. Cornu (*Ann. Ec. Norm.* iii. 421, ix. 21) has taken comparisons of the ultra-violet regions of the solar spectrum with the metallic lines, and he has carefully drawn up a map of Angström's scale of wave-lengths. Most of the ultra-violet lines which have been identified by him belong to iron and nickel, but some also to manganese, magnesium, and sodium. Abney (*Proc. Roy. Soc.* xxx. 67) has succeeded in preparing silver bromide which absorbs the red and ultra-red rays, and is sensitive to these rays. In the Bakerian Lecture for 1879, Abney has explained his methods (the full paper will appear in the forthcoming volume of the *Philosophical Transactions*) and the apparatus by means of which he has been able to obtain photographs of the spectrum as far as $\lambda = 10750$ tenth metres, thus extending our knowledge of the solar radiation through nearly a whole octave.

Two total eclipses of the sun, one in 1875 and one in 1878, fell into a time where sun-spots were very rare and the solar corona in a very quiet state. The first-mentioned eclipse was observed in Siam (*Trans. Roy. Soc.* 1878, Part I.). Photographs were obtained of the corona, which was symmetrical, round an axis nearly, if not entirely, coinciding with the solar axis. Photographs were also taken with a camera having a prism placed in front of the object-glass. The image of the corona was drawn out into a band showing that nearly the whole of its light gave a continuous spectrum. The prominences, on the other hand, gave distinct images corresponding to the hydrogen line F and near G. The strongest image, however, was in the extreme violet, near H. This image was very likely due to a hydrogen line, which has since been discovered to coincide with H. The eclipse of 1878 was observed by many astronomers in America. Photographs of the corona were taken by the Washington observers, which will most likely prove to be more perfect than any we have hitherto possessed. The corona much resembled that of 1875. Its spectrum was chiefly continuous, the bright green line not being very conspicuous. Draper's party observed the dark Fraunhofer lines in the spectrum of the corona.

Considerable interest was aroused by Draper's (*Amer. Phil. Soc.* 1877) announce-

ment that he had discovered, by means of photography, bright lines in the violet part of the spectrum, which corresponded with the bright lines of the oxygen. Copies of his photograph accompanied the paper. Just those observers, however, who were accustomed to work with instruments of greater power than those generally in use, felt rather doubtful as to Draper's conclusions. The existence of bright lines in the solar spectrum has often been mentioned. But when such an apparently bright line is examined with instruments of high power, it is generally found to be due to an effect of contrast. Dark lines closely ruled together, which could not be resolved with the lower dispersion, now appear on either side. These dark lines fuse together if the dispersion is insufficient, and make the interval between them appear brighter than the general background. It was and still is held by several observers (Christie, *Monthly Notices, R. A. S.*) that Draper's bright lines are due to this cause. It must however be urged, on behalf of Draper, that, granting the existence of these bright lines, it is quite possible that they should come out better with smaller dispersive powers; for the lines of oxygen we know would not be sharp, and high powers might easily draw them out into bands of such width and decreased intensity that we might not fail to detect them. Draper (H. C. Vogel, *Observations at the Potsdam Observatory*, vol. I.) has since his first publication repeated his experiments with more powerful apparatus, and his photographs obtained have convinced many observers, whose opinion is entitled to much weight, of the justness of his conclusions. But the question will most likely not be settled to the general satisfaction of spectroscopists until photometric measurements have shown that these bands are really brighter than the other parts of the spectrum.

An important step has been made by Huggins, who has succeeded in obtaining admirable photographs of the spectra of some of the stars. The following quotation (*Proc. Roy. Soc.* xxx. 21) will show the extent and some of the results of the work.

'Photographs have been obtained of the stars Sirius, Vega, α -Cygni, α -Virginis, η -Ursæ Majoris, α -Aquilæ, Arcturus, β -Pegasi, Betelgeux, Capella, α -Herculis, and α -Pegasi; also of the planets Jupiter, Venus, and Mars, and of the different parts of the moon.

'The spectra of Sirius, Vega, α -Cygni, α -Virginis, η -Ursæ Majoris, α -Aquilæ, and Arcturus, are laid down in a map on the scale of Cornu's map of the ultra-violet part of the solar spectrum.

'The stellar spectra extend from about G to O in the ultra-violet. The stars of the white class are arranged so as to exhibit, first, the remarkable spectrum typical of this class, and then some of the modifications it appears to undergo.

'The typical spectrum of this region of this class consists of twelve strong lines winged at the edges. The continuous-spectrum extends in the photographs beyond S, but no lines are seen more refrangible than the twelfth line 3690. Two of these lines agree in position with the hydrogen line (γ) 4340, and the other line at λ . The third line agrees with H_1 . The remaining nine form a group, in which the distance between any two adjacent lines is less as the refrangibility increases, suggesting that they are connected with each other and represent probably one substance.

'A very suggestive modification presents itself in the difference of the character of the line H_2 . In these stars this line is either absent or very thin as compared with its appearance in the solar spectrum. In the spectrum of Arcturus, which belongs to the solar type, this line exceeds in breadth and intensity its condition in the solar spectrum. The white stars may, therefore, be arranged in a series in which the line H_2 passes through different stages of thickness, at the same time that the typical lines become narrower and more defined, and other finer lines present themselves in increasing numbers. Arcturus seems to present a spectrum on the other side of that of the sun in the order of change from the white-star group.'

H. W. Vogel (*Nature*) has taken photographs of the spectrum of hydrogen, and has been able to identify several of the lines which appear on Huggins' photographs of the spectra of white stars with hydrogen lines, especially the line which is apparently coincident with H_1 .

A. S.

SPERGULIN. A fluorescent body, occurring in the seed-coverings of *Spergula vulgaris* and *S. maxima*, and produced at the time when the seeds blacken and are nearly ripe. It has not been obtained in crystals. It is very soluble in ethyl alcohol, both anhydrous and aqueous, also in methyl alcohol, less soluble in amyl alcohol, nearly insoluble in ether and in petroleum. Strong sulphuric acid dissolves it, forming a dark blue liquid. Its solution in common alcohol, when viewed by transmitted light, appears nearly colourless with a shade of olive-green, but by reflected light it exhibits an intense dark-blue fluorescence, which remains permanent more than a year if the liquid be kept in darkness, but is rapidly destroyed in sunshine, and more

slowly in diffused daylight. Small quantities of alkalis and alkaline carbonates added to the alcoholic solution transform the spergulin into a body exhibiting an emerald-green fluorescence; the alcoholic solution gives a precipitate with acetate of lead. An alcoholic solution of spergulin (1 : 8) exhibits strong absorption, almost wholly in the violet, differing considerably in this respect from chlorophyll, phyllocyanin, and phylloxanthin.

Spergulin gives by analysis 61·85 per cent. carbon and 7·05 hydrogen, agreeing approximately with the empirical formula $C^8H^7O^2$. It appears to be related to chlorophyll, and is perhaps closely allied to phyllocyanin. It may be regarded as a weak acid which exhibits blue fluorescence in the free state and in its acid salts, green fluorescence in its neutral salts, and none at all in its basic salts (C. O. Harz, *Chem. Centr.* 1879, 24).

SPESSARTIN. A variety of garnet from St. Marcel in Piedmont (p. 846).

SPHÆROCOBALTITE, or *Cobalt-spar*, is a native carbonate of cobalt belonging to the calc spar-group, black on the outside, red within; occurring, together with rosasite, in the Daniel Mine near Schneeberg. After deducting the iron as limonite, the analytical values (A) lead to the formula $CoCO_3$, the numbers calculated from which are given under B:

	CoO	CaO	Fe ² O ³	CO ²	H ² O
A.	58·86	1·80	3·41	34·65	1·22 = 99·94
B.	63·06	—	—	36·94	— = 100

(C. Winkler, *J. pr. Chem.* [2], xvi. 89). By examination with the microscope, A. Weisbach found the small spherical masses to consist of rhombohedral crystals R.0R. Sp. gr. = 4·13 (*Jahrb. f. Min.* 1877, 409).

SPHEROLITE. A volcanic glass from the lava of Antisana (sp. gr. 2·386) analysed by G. vom Rath (*Zeitschr. geol. Ges.* xxvii. 295), with the following results:

SiO ²	Al ² O ³	Fe ² O ³	CaO	MgO	K ² O, Na ² O	H ² O
77·01	12·90	1·88	0·21	0·29	7·26	0·45 = 100

SPHEROSIDERITE. This mineral occurs in a tertiary clay at Stein in Carinthia, in small globules mixed with sand, and containing, besides traces of manganese, water, and organic substance:

FeCO ³	Fe ² O ³	CaCO ³	MgCO ³	Insoluble
72·96	2·03	9·68	3·18	11·94 = 99·79

(F. Ullik, *Min. Mitth.* 1873, 281).

Manganiferous sphærosiderites from Hungary have been analysed by Schröckinger a. Dietrich (*Min. Mitth.* 1877, 114).

1-3. From Felsőbánya: dirty-white or yellowish-brown globules, on antimony-glance or heavy spar. 4. From Kapnik: grey or yellowish stalactites with concentrically scaly texture:

FeCO ³	MnCO ³	CaCO ³	MgCO ³	H ² O
53·07	44·36	1·15	1·49	— = 100·07
46·64	38·07	9·96	4·78	— = 99·45
62·12	27·76	7·05	2·41	— = 99·34
56·84	39·84	0·55	1·29	0·67 = 99·19

SPIAUTERITE. A variety of zinc sulphide. See ZINC.

SPIEGELEISEN. Manganiferous cast-iron, in which the proportion of manganese does not exceed 26 per cent. See IRON METALLURGY (pp. 1108-1111).

SPINEL. The spinel of Tiriolo in Calabria is opaque, dark greenish-blue, faintly lustrous, and brittle with irregular fracture. Sp. gr. = 3·7 at 12°. Its analysis gave:

Al ² O ³	ZnO	MgO	FeO	Si ² O ³
63·64	21·28	12·34	4·53	0·34 = 102·13

agreeing nearly with the formula $(Zn, Mg, Fe)_3Al_2O_4$ (Munro, *Gazz. chim. ital.* ix. 70).

Spinel occurs abundantly in the dolomitic limestone of Svinetic in the Böhmerwald (Helmhacker, *Min. Mitth.* 1873, 275).

On pseudomorphs of Spinel after Corundum, see CORUNDUM (p. 570).

Artificial Formation.—J. Aumann (*Chem. News*, xxxviii. 108) has obtained crystals of magnesium aluminate, $MgAl_2O_4$, in regular octohedrons which scratched glass readily, by igniting magnesia packed in a crucible of hard carbon and having a lump of aluminium imbedded within it.

SPIRÆA. According to Nietzki (*Arch. Pharm.* [3], iii. 429), the ethereal oil

of meadow-sweet (*Sp. ulmaria*) contains not salicylic aldehyde as stated by Wicke (v. 167), but a mixture of a hydrocarbon with a salicylic ether, probably methyl salicylate.

SQUILL. On the Carbohydrate obtained from this plant, see SINISTRIN (p. 1802).

STÄDELER'S BLUE. Städeler obtained this colouring matter by heating 1 mol. azobenzene with 2 mols. aniline hydrochloride at 170° – 230° (vi. 270). A similar compound, having the composition of triphenylene-diamine, $C^{18}H^{12}N^2$, is produced, together with sal-ammoniac, by heating 2 mols. aniline with 1 mol. nitrobenzene and dry hydrochloric acid in sealed tubes for six hours at 230° ; also by heating diphenylamine with nitrobenzene and dry hydrochloric acid at 230° , and by the action of dry hydrochloric acid on azodiphenyl blue at 215° .

STANNOISOBUTYL-COMPOUNDS. See BUTYL-COMPOUNDS (p. 358).

STANNOPROPYL-COMPOUNDS. A number of these compounds, obtained by Cahours, have already been described (vii. 1014).

Stannotetrapropyl, $Sn(C^3H^7)^4$, is prepared by heating stannotripropyl iodide with zinc-propyl:

When separated from the product by potash-solution, it forms a colourless mobile liquid, having a pungent ethereal odour, a density 1.179 at 14° , and boiling at 222° – 225° . When gently heated with nitric or sulphuric acid, it is strongly attacked, with formation of crystalline products, probably salts of stannotripropyl (Cahours, *Compt. rend.* lxxvi. 133).

STARCH, $nC^6H^{10}O^5$. On the formation of Starch in Chlorophyll-granules, see PLANTS (p. 1644).

On the occurrence of Starch in Egg-yolk, see EGGS (p. 704).

Composition of the Starch-granule (Brown a. Heron, *Chem. Soc. J.* xxxv. 610). Starch-granules are built up of distinctly stratified layers, mainly consisting of a substance designated by C. Nägeli* as granulose. The outer layers are for the most part denser than those nearer to the nucleus, and increase from without inwards in the amount of water which they contain. Every part of the granule contains, besides granulose, a small quantity of another substance, very closely allied to granulose, and distinguished by recent observers as starch-cellulose. The outer layers, which consist mainly, if not wholly, of this latter substance, are the oldest in point of growth, the starch-granule increasing by intussusception, i.e., the formative material, absorbed from without during the growth of the starch-grains within the protoplasm of the plant cell, is deposited between the already existing particles in the direction of the surface of the layers (Nägeli). To the presence of this protective coating of cellulose is to be attributed the fact that starch-granules when intact are absolutely unacted upon by cold water. Although water is absorbed to a very large extent by the granulose, none of this substance, which is to the highest degree colloidal, is able to diffuse into the surrounding medium. When, however, the outer layer of the granule is ruptured by attrition, the contents become much swollen from absorption of water, and a small quantity of matter having all the properties of *soluble starch* goes into solution. By repeated treatment of the ruptured starch-grains with cold water, the greater part of the granulose may be removed, most of the cellulose being left behind in the form of extremely thin layers, which, unlike the granulose, acquire, when treated with iodine, only a dirty yellow colour. Granulose itself, and water which has been only for a short time in contact with it, are coloured deep indigo-blue on addition of a solution of iodine. Fr. Schulze (Henneberg's *Journ. Landwirth.* New Ser. vii. 214) has obtained starch-cellulose by digesting starch for several days at 60° with a saturated solution of common salt containing 1 per cent. of hydrochloric acid. Nägeli also obtained the same substance by acting on starch at 45° – 55° with saliva, which contains an active agent (ptyalin) capable of attacking and dissolving only the granulose. Lastly, Fitz (*Ber.* x. 282) has recently observed that certain schizomycetes easily ferment the granulose of starch-paste, but leave the starch-cellulose unattacked.

The action of malt-extract on starch-paste in the cold affords a ready means of obtaining the cellulose of the starch-granule in large quantities. When a starch-paste containing from 5 to 6 grams of starch per 100 c.c. is treated, when quite cold, with about one-tenth of its volume of freshly prepared normal malt-extract, the mixture becomes perfectly limpid in from four to eight minutes, and can then be easily filtered. The flocculent matter left on the filter, after being freed from malt-extract and the

* *Die Stärkekörner.*

products of transformation of the granulose, by washing with cold water, consists of the so-called starch-cellulose. The filtered liquid, at first perfectly bright, becomes turbid in a few minutes from the separation of a further quantity of flocculent matter, which does not appear to differ, except in want of structure, from that previously separated by filtration. This further separation of cellulose is due to the fact that soluble starch and the higher dextrins, the first products of the action of malt-extract upon granulose, are capable of holding some of the cellulose in solution; as the soluble starch and the higher dextrins are broken up, most of this separates in the insoluble form. The matter left upon the filter consists of fine laminae still retaining the shape of the swollen starch-granules, whilst the precipitated portion is amorphous.

Starch-cellulose after separation in this way is perfectly insoluble both in cold water and in water at 70°–80°, also in solutions of soluble starch or of the higher dextrins. That it is capable, under certain conditions, of entering into solution is shown, however, by the facts mentioned above, and by the impossibility of preparing it with a very dilute starch-paste, *i.e.*, 1 to 1.5 gram per 100 c.c.*

Insoluble starch-cellulose is not acted upon by malt-extract in the cold, or at a temperature of 60°; the soluble modification appears, however, to be acted upon by malt-extract, somewhat slowly indeed in the cold, but rapidly at temperatures from 50°–70°.

Boiling with water converts starch-cellulose to a great extent into soluble starch, the solution having all the optical properties of that body, and yielding the characteristic indigo-blue reaction with iodine. After repeated boiling with water and frequent washing, there is left a body upon which a continuation of this treatment has no further effect. This body, amounting to about one-fifth of the original substance acted upon, is readily soluble in a solution of potash, under the action of which it is slowly converted into soluble starch on digestion at an elevated temperature.

Insoluble starch-cellulose evidently consists of at least two substances, one readily acted upon by boiling water, and the other not. Both these bodies must be very closely allied to granulose, since all these substances, under favourable conditions, yield soluble starch as the first product of their transformation.

When starch-cellulose is dissolved in liquid potash-solution, the greater part of it can be reprecipitated by the addition of acetic acid, or by passing carbon dioxide into the liquid. If the alkaline solution is kept at ordinary temperatures and reprecipitated immediately with acid, about 30 per cent. is found to have been converted into soluble starch. If the solution is digested at a moderately elevated temperature, precipitation with acid indicates the formation of a larger quantity of soluble starch. In one case digestion for half an hour at 60° resulted in the recovery of only 57.3 per cent. of the original quantity of cellulose.

The specific rotatory power of an alkaline solution of starch-cellulose appears to be very variable, but always increases on digestion at a high temperature. The specific rotatory power of a freshly prepared solution, calculated on the quantity of carbohydrate present, is sometimes as low as $[\alpha]_D = 146^\circ$, but increases on digestion for a few minutes at 60° to $[\alpha]_D = 173.6^\circ$. The rise of angle under these conditions is due to the conversion of cellulose into soluble starch. The entire optical activity of the solution cannot, however, be due to the presence of this latter substance; the cellulose itself must, when held in solution with potash, exert some effect upon polarised light.

When potato-starch is transformed under the influence of malt-extract at temperatures above 45°, cellulose separates out only when the paste is of a high degree of consistency, and the malt-extract is deficient in quantity: hence it is evident that starch-cellulose, at the moment of its separation from granulose, must under these circumstances be readily soluble.

Starch-paste.—When starch is treated with hot water, the contents of the granules, owing to a large absorption of water, swell up enormously, and ultimately rupturing the outer layer, form a very viscous liquid which is known as starch-paste. Marked differences in the viscosity of this paste are produced by slight variations in the treatment of the starch during the processes of purification and drying. When it has been treated with potash and acid, a paste is produced of less viscosity, *ceteris paribus*, than when no such treatment has been adopted. Great variations in the consistency of the resulting paste are also produced by slightly altering the manner of drying the starch. Starch which has been dried slowly and at a low temperature always yields a more viscid solution than that which has been dried at a higher temperature. As the technical value of a starch depends to a considerable extent on its power of pro-

* Nägeli's *granulose* is evidently identical with the *amidone* of Payen & Persoz (*Ann. Chim. Phys.* lvi. 337, 1854), and with Guérin Varry's *amidine* (*Ann. Chim. Phys.* lvi. 225); the *amidin tégumentaire* and *amidin soluble* of the latter author being identical with the soluble and, insoluble modifications of starch-cellulose.

ducing a more or less viscid paste, these variations of viscosity may prove to be of great importance in the manufacture of starch.

The specific rotatory power of starch in a solution containing 10 grams in 100 c.c. for the transition-tint is 207.3° – 208.8° at ordinary temperatures, and is increased by boiling to 219.5° . The addition of potash to the solution diminishes the rotatory power, which, however, rises again to its original height, or sometimes a little higher, when the alkali is neutralised with acetic or carbonic acid.

Soluble Starch. Delffs in 1859 (*Pogg. Ann.* cix. 648) described a method of preparing a solution of starch by prolonged trituration of starch with sand and a quantity of cold water sufficient to convert the whole into a rather thin paste, and leaving it at rest for twenty-four hours, so that the suspended particles might settle down and not stop the filter. He found that the solution thus obtained differed in its reactions from those of dextrin, especially in giving a blue colour with iodine, and supposed that it contained a peculiar soluble modification of starch, for which he proposed the name *amylogen*. Flückiger (*Zeitschr. Ch. Pharm.* 1861, 104) prepared a similar solution by drenching starch-grains with a concentrated solution of calcium chloride, assisting the action by frequent agitation. On decanting the calcium chloride solution from the resulting gummy mass, and agitating the latter with 100 to 150 times its weight of water, a stiff jelly was obtained, and with a larger quantity of water, a clear filtrable solution which was turned blue by iodine, and exhibited all the characters of the amylogen solution described by Delffs.

According to Musculus, on the other hand (*Bull. Soc. Chim.* [2], xxii. 26; *Ann. Chim. Phys.* [5], ii. 385), the so-called amylogen is not actually soluble in water, inasmuch as its concentrated solutions stop up a filter, and the compound precipitated from it by alcohol and dried is no longer soluble in water even at the boiling heat; he supposes that the amylogen still retains the original structure of starch. Truly soluble starch, free from organised substance, is obtained by boiling ordinary starch with very dilute sulphuric acid, saturating the solution with chalk, and evaporating to a syrup. This syrup, after long standing, deposits extremely small granules which gradually increase in size; and on pouring off the syrup, washing the residue with cold water, dissolving it in hot water, and precipitating the amylogen with a little alcohol, the remaining solution yields on evaporation a perfectly white mass, which is insoluble in cold water, but dissolves readily in water at 50° , and does not separate out again on cooling. The residue left on evaporating this solution, or the precipitate obtained from it with alcohol, redissolves completely in warm water. On cooling the solution to a low temperature, the dissolved starch settles down completely as a thick sediment exhibiting the same relations of solubility. If contaminated with dextrin or glucose, it no longer exhibits its peculiar characters. It does not exert a reducing action. Its rotatory power is four times as great as that of glucose. Diastase acts upon it in the same manner as on ordinary starch, but more quickly. Its dilute solutions are coloured red by iodine, strong solutions violet. Moderately strong solutions, mixed with a quantity of iodine sufficient to give them a dark red-brown colour, assume, when evaporated in the air, a violet, and finally a blue tint, which, on dilution with water, changes again to violet and then to red. Calcium chloride throws down from the red solution a blue precipitate, apparently not identical with ordinary iodide of starch.

Bondonneau (*Compt. rend.* lxxx. 671) has prepared amylogen according to the process of Musculus, and finds that the syrup, if dried before the granular mass described by Musculus has separated out, is at first completely soluble in water, but afterwards only partially. Hence it seems probable that the body insoluble in water does not pre-exist in the starch, but is formed only in the viscid liquid. Moreover, this substance is produced only in those syrups which are turned violet by iodine, not in those which are coloured red. Amylogen prepared by the action of dilute acids or alkalis, or of water under increased pressure, is translucent after drying, and dissolves for the greater part in hot or cold water, provided it be first very finely divided, completely, however, though with various degrees of facility, in solution of sodium carbonate or zinc chloride. Amylogen prepared with sodium carbonate, and subsequent neutralisation with an acid, dissolves readily in cold water, but becomes almost insoluble therein, and very difficultly soluble in hot water, after the mass has been pressed. In the dialyser, dissolved starch behaves exactly like a colloid substance; and this circumstance affords an explanation of an experiment made by Payen, in which a filter cut out of a hyacinth-bulb was found to separate starch completely from its solution, the bulb, in fact, acting as a dialyser. The action of acids and alkalis on the starch-granule—from which, in its perfect state, water does not extract anything—depends upon their degree of concentration, and on the final rupture of the cellulose-coating, the starch in the interior being then easily dissolved.

Oxidation.—The action of various oxidising agents on soluble starch, prepared with nitric acid, has been studied by Reichardt (*Ber.* viii. 1020). Potassium permanganate in acid, neutral, or alkaline solution, also chromic acid, chlorine, and cuprous oxide, give rise to humous substances; dilute nitric acid, to carbonic and oxalic acids; bromine and silver oxide, to dextronic acid (vii. 424).

Fuming nitric acid converts soluble starch into a *mononitro-derivative*, $C_6H_7(NO_2)O_5$, which appears to differ from the corresponding compound prepared in like manner from ordinary starch by its solubility in boiling alcohol and in ether. Reichardt finds that 1 pt. of soluble starch requires for solution about 40 pts. of water at 20°.

On the Fermentation of Starch under the influence of Schizomycetes, see FERMENTATION (p. 777).

Reactions of Starch with Iodine. A. Vogel (*N. Rep. Pharm.* xxii. 349; xxv. 565) draws attention to the fact—observed also by others—that dry starch is coloured blue by a weak alcoholic tincture of iodine, but not by a solution of iodine in absolute alcohol, or even in alcohol of sp. gr. 0.830 (86 p. c. by weight). Further, the decoloration of a solution of starch iodide by sunlight or by heat takes place more quickly in dilute than in concentrated solutions. If the heating has been continued for a short time only, the blue colour reappears on cooling; but if the heating has been prolonged, the colour is restored only on addition of nitric acid, chlorine, &c. On heating the solution, iodine escapes at first, but its evolution does not continue, and even a solution which has been completely decolorised by boiling and evaporated to dryness is still found to contain iodine. The decoloration appears to depend upon the fact that the iodine is converted into a mixture of iodic and hydriodic acids, which subsequently act upon one another in such a manner as to liberate iodine.

H. Pellet (*Monit. scient.* [3], vii. 988) regards starch iodide as a definite compound analogous in its chemical relations to the iodides of the heavy metals, mercury and silver for example, being soluble in excess of soluble starch, just as these metallic iodides are soluble in excess of potassium iodide, and reprecipitated from the solution by acids.

According to Bondonneau (*Compt. rend.* lxxxv. 671), starch iodide is a definite chemical compound represented by the formula $(C_6H^{10}O^5)_2I$. It is obtained pure when a solution of starch, prepared by the action of caustic soda on starch suspended in fifteen to twenty times its amount of water, is mixed with excess of iodine solution, then acidulated and filtered, and the resulting starch iodide is washed with water containing a little hydrochloric acid, and finally dried in the air, whereby, however, it loses a small quantity of iodine, so that its composition agrees with the formula above given only when it is moist. Starch iodide thus prepared is a hard black-violet mass, which swells up in water and then recovers its blue colour. When heated at 100° it loses 16–18 per cent. of hydriodic acid and water, and at 190° the loss amounts to 46 per cent., the colour changing to black. The black substance thus obtained yields on oxidation saccharic and oxalic acids; sulphuric acid converts it into glucose. When the iodide is heated under pressure, carbon dioxide, hydriodic acid, and iodine are evolved, and when heated to 100° with water under pressure, it partly splits up into iodine and starch, and is partly converted into glucose and hydriodic acid. Water at the ordinary temperature slowly converts it into α -dextrin and hydriodic acid. It is decomposed by diastase, yielding glucose, β - and γ -dextrin, hydriodic acid, and an organic iodide not yet separated.

Conversion of Starch into Dextrin and Sugar by the action of Diastase and of Dilute Acids. Musculus stated in 1860 that starch when boiled with dilute acid is converted into dextrin and glucose, according to the equation,

and he supposed that diastase acted upon starch in the same manner (vi. 1081). Schulze a. Märker, however (vii. 1008), found that the ferment of malt-extract does not, like sulphuric acid, convert the whole of a given quantity of starch into sugar, but only the half of it, and O'Sullivan showed (*ibid.*) that the ultimate product of the action of malt-extract upon starch is not glucose, but maltose, a substance isomeric with cane- and milk-sugar, and capable of reducing only two-thirds of the quantity of cupric salt that is reduced by dextrose.

Further experiments by Musculus a. Gruber (*Compt. rend.* lxxxvi. 1459) have led them to the conclusion that, under the influence of boiling dilute sulphuric acid, or of diastase, the following substances are produced from starch.

1. *Soluble Starch.*—Insoluble in water at 50°–60°. Coloured wine-red by iodine in aqueous solution, and blue in the solid state. Dried in the air with excess of

iodine, it assumes violet, yellow, or brown tints. Rotatory power $[\alpha]_D^{20} = +218^\circ$, reducing power 6.

2. *Erythrodextrin*, which constitutes half of the dextrin of commerce, always strikes a red colour with iodine, whether it be solid or in solution. It is never insoluble in water. Very easily attacked by diastase.

3. *Achroodextrin*, α . Not coloured by iodine. Rotatory power $[\alpha]_D^{20} = +210^\circ$; reducing power, 12. Partially convertible into sugar by diastase, but less easily than soluble starch or erythrodextrin.

4. *Achroodextrin* β . Not attacked by diastase, at least during the first twenty-four hours. Rotatory power $[\alpha]_D^{20} = +190^\circ$; reducing power, 12.

5. *Achroodextrin* γ . Not attacked by diastase at all; changed into glucose by boiling with dilute sulphuric acid for several hours. Rotatory power $[\alpha]_D^{20} = +150^\circ$; reducing power, 28.

6. *Maltose*, $(C^{12}H^{22}O^{11} + H^2O)$.—Attacked with difficulty by diastase; fermentable. Rotatory power $[\alpha]_D^{20} = +150^\circ$; reducing power, 66.

7. *Glucose*, $(C^6H^{12}O^6 + H^2O)$.—Fermentable. Rotatory power $[\alpha]_D^{20} = +56^\circ$; reducing power, 100.

Musculus a. Gruber regard starch as a polysaccharide of the formula $n(C^{12}H^{20}O^{10})$, in which the exact value of n , apparently not less than 5 or 6, remains to be determined. Under the influence of diastatic ferments and of dilute acids, this carbohydrate takes up water by successive stages, and breaks up into maltose and a new dextrin of successively smaller molecular weight, n becoming less at each stage, until the transformation has gone as far as the production of achroodextrin γ , which is probably transformed into maltose by simple hydration, the maltose then in its turn taking up water and splitting up in the manner shown by the equation: $C^{12}H^{20}O^{10} + H^2O = 2C^6H^{12}O^6$.

In the action of diastase on starch a large quantity of maltose is produced, together with only a small quantity of dextrose, whereas when sulphuric acid is used, dextrose is produced in considerable quantity.

M. A. Petit (*Bull. Soc. Chim.* [2], xxiv. 519) finds that when starch is subjected for several hours to the action of diastase at 50° , and the liquid is subsequently boiled, the starch is almost wholly converted into sugar, so that alcohol throws down from the solution only 5 per cent. of dextrin. The sugar solution was found to contain, besides maltose, a fermentable sugar which did not reduce Fehling's solution, even after boiling for five minutes with dilute sulphuric acid. The quantity of this sugar amounted to about three-fourths of the maltose obtained. When treated with yeast, it gave off a quantity of carbon dioxide equal to that which would have been evolved from the same quantity of glucose.

According to Herzfeld (*Ber.* xii. 2120), the final products of the action of diastase on starch are maltose and achroodextrin. At temperatures above 65° , another body appears also to be produced in the form of a slightly-coloured uncrystallisable gummy mass, very soluble in water, having a faint sweet taste, due perhaps to its partial conversion into sugar. It has about one-third the reducing power of maltose. This body, which Herzfeld calls *maltodextrin*, is identical with Bondonneau's γ -dextrin. Its acetyl-compound differs from those of erythro- and achroodextrin in not separating out from its solution in hot alcohol, even when considerable quantities of it are dissolved.

From later experiments by O'Sullivan (*Chem. Soc. J.* 1876, xxx. 125), it appears also that the only products of the action of diastase on starch are dextrin and maltose; further, that malt-extract prepared without the aid of heat does not alter ungelatinised starch, but acts upon starch only at the temperature of gelatinisation, which is different for the several varieties of starch, and even for starch-granules of different sizes: for potato-starch it is 63° – 64° . On starch-paste diastase acts even at 10° – 20° , producing maltose and dextrin in the ratio of 67 : 32 per cent., which, however, by prolonged action and further addition of malt-extract, is raised to 82 : 18. If the solution is formed at 63° , and cooled after a few minutes, the quantities of maltose and dextrin obtained are constantly 67.85 and 32.15, agreeing nearly with equation A (below). If the temperature of the reaction lies between 64° and 68° – 70° , the quantities of the two products are 34.54 and 65.46 per cent. (equation B.); at 68° – 70° they are 17.4 and 82.6 (equation C.); and under other circumstances (not specified) proportions of maltose and dextrin have been observed agreeing with equation B'.

The optical rotatory powers and cupric reducing powers of these dextrins are as follows:—

	Optical rotatory power	Reducing power
α -Dextrin	218·8° and 219·5°	0·14 to 0·018
β -Dextrin i.	210°	12
β -Dextrin ii.	216°-217·5°	3·0 to 3·6
β -Dextrin iii.	215°-217°	2·5 to 0·6

From a study of the action of malt-extract on these transformation-products, O'Sullivan infers that the theory advanced by Musculus a. Gruber of the breaking down of the starch-molecule into dextrin-molecules which become smaller and smaller at every step, is not in accordance with all the facts observed; and he regards these bodies, not as a series of polymerides, but rather as a series of bodies of the same molecular weight, in which the differences of behaviour must be accounted for by differences in the arrangement of the molecules, probably in solution only. It may be supposed that the molecule of soluble starch, or the dextrin which gives a purple colour with iodine, is simply $\text{C}^{12}\text{H}^{20}\text{O}^{10}$; but that these molecules in solution are arranged in groups of six sixes, all the groups being in an intimate state of tension one with another, so that the motion affecting one under certain conditions, likewise affects all under the same condition.

Brown a. Heron (*Chem. Soc. J.* xxxv. 620-654), from a study of the transformation of soluble starch by malt-extract, conclude that the most probable formula of soluble starch is $10\text{C}^{12}\text{H}^{20}\text{O}^{10}$. The first action of the transforming agent of malt-extract is the hydration of one of the ten groups $\text{C}^{12}\text{H}^{20}\text{O}^{10}$, and the consequent production of maltose, $\text{C}^{12}\text{H}^{22}\text{O}^{11}$, the other nine groups forming erythrodextrin α . This dextrin on further hydration splits up into a molecule of maltose and erythrodextrin β , consisting of eight groups $\text{C}^{12}\text{H}^{20}\text{O}^{10}$; and this last in its turn splits up into a dextrin formed of seven such groups, which is the first achroodextrin. In this way the degradation of the original molecule proceeds, until by successive stages of hydration maltose is reached.

The number of distinct dextrins which, according to this hypothesis, are possible depends upon the molecular weight of the lowest possible dextrin. If a dextrin is capable of existing containing the same number of carbon-atoms in its molecule as maltose, nine distinct stages in the transformation may be expected; whereas, if the lowest dextrin contains double as many carbon-atoms as maltose, there can only be eight.

The following table represents the values of the specific rotatory power $[\alpha]_{386}^*$, and cupric reducing power, K_{386} , for the joint products of each of these theoretical transformations, the resulting dextrins being enumerated in the last column.

No. of transformation	$[\alpha]_{386}$	K_{386}	Resulting dextrin
Soluble starch	216·0°	0	—
(1)	209·0	6·4	Erythrodextrin α
(2)	202·2	12·7	" β
(3)	195·4	18·9	Achroodextrin α
(4)	188·7	25·2	" β
(5)	182·1	31·3	" γ
(6)	175·6	37·3	" δ
(7)	169·0	43·3	" ϵ
(8)	162·6	49·3	" ζ
(9)	156·3	55·1	" η
Maltose	150·0	61·0	—

Of these possible transformations the experiments of Brown a. Heron have unmistakably established the existence of Nos. (2), (3), (4), and (8), whilst indications of (5) and (6) have frequently been obtained in various ways, but not with the same amount of certainty as in the other cases.

* The number 3·86 is the divisor required to convert the specific gravity of the solution into grams of dry substance in 100 c.c., or the value of x in the equation $x=10\left(1-\frac{1}{y}\right)$ where y is the specific gravity.

The dextrans corresponding to Nos. (1) and (2) are erythrodextrans; all the others are achroodextrans.

R. Sachsse (*Chem. Centr.* 1877, 732) infers, from the quantity of sugar obtained by treating starch with hydrochloric acid, that the molecular formula of dry starch is $C^{36}H^{62}O^{91}$. Starch in its ordinary state he regards as a hydrate, $C^{36}H^{62}O^{91} + 12H^2O$, inasmuch as potato-starch in drying sustains a loss of weight amounting to 17.7 per cent., the formula just given requiring 17.5 per cent. This view is supported by the observation that when dry starch is brought in contact with a small quantity of water, a rise of temperature is produced amounting to 15° – 40° or upwards. Perhaps the constitution of dried starch might be represented by the formula $C^{36}H^{60}O^{90}, H^2O$, and that of the hydrate by $C^{36}H^{60}O^{90}, H^2O + 12Aq$, 1 mol. of the water being basic, and the rest less intimately combined, like water of crystallisation; or these formulae might be doubled to accord with the results obtained by Brown and Heron.

Tollens, by precipitating an alkaline solution of gelatinous starch with alcohol and ether, has obtained compounds containing 4 or 5 at. $C^6H^{10}O^5$ to 1 at. K or Na, whence he infers that the molecule of starch must contain 24 or 30 atoms of carbon.

Estimation of Starch. On the Estimation of Starch by Bloch's Feculometer, see Cloez (*Dingl. pol. J.* cxxi. 397; *Zeitschr. anal. Chem.* 1874, 337); also Bondonneau (*Bull. Soc. Chim.* [2], xxi. 147; *Zeitschr. anal. Chem.* 1874, 467). On the amount of Starch in Potatoes, see POTATOES (p. 1669); also Siewert (*Landw. Versuchs.-St.* xxiv. 427; *Chem. Soc. J.* xxxviii. 512); Behrend, Maercker and Morgen (*Landw. Vers.-St.* xxv. 107–165; *Chem. Soc. J.* xxxviii. 513); in Sausages (Medicus and Swale, *Ber.* xii. 1285; *Chem. Soc. J.* xxxvi. 939).

Manufacture. The present state of the Starch-manufacture is described by C. Scheibler in Hofmann's *Entwicklung der chemischen Industrie*, iii. 152; that of the Rice-starch Manufacture by M. Adlung (*Dingl. pol. J.* cxxi. 58, 543; *Chem. Soc. J.* xxx. 675; xxxi. 363); the manufacture of Wheat-starch in Halle, by Adlung (*Dingl.* cxxiv. 304; *Jahresb. f. Chem.* 1877, 1207).

STAUROLITE. According A. v. Lasaulx (*Min. Mitth.* 1872, 173), most staurolites contain a considerable number of microscopic enclosures (chiefly quartz, with garnet, mica, magnetic iron oxide, and brookite), and to these he attributes the variations in the analytical values, especially that of the silica (v. 412). From an analysis of staurolite from Monte Campiano, near Faido, which microscopical examination showed to be the purest, he deduces the formula:

The analysis gave:

SiO^2	Al^2O^3	Fe^2O^3	FeO	MgO	H^2O	Sp. gr.
29.81	48.26	5.31	12.03	3.25	0.86 = 99.52	3.71

Rammelsberg finds (*Ber.* vi. 127) that when staurolites rich in enclosed silica are treated with hydrofluoric acid, the free silica is dissolved, and a residue is left agreeing in composition with pure staurolite from the St. Gothard. In staurolites which contain only a small quantity of free silica, the hydrofluoric acid partly decomposes the silicate, but in this case also a summation of the constituents of the decomposed and undecomposed portions leads to the same composition (No. 5):

	TiO^2	SiO^2	Al^2O^3	FeO	MgO	H^2O	
1.	0.56	29.46	52.29	13.42	2.29	1.42 =	99.44
2.	30.24		52.59	13.86	2.81	1.60 =	101.10
3.	0.16	30.23	52.85	14.65	2.41	—	—
4.	0.39	30.23	51.16	14.66	2.73	1.26	—
5.	1.00	31.76	50.03	14.18	2.07	0.96	—

1 and 2. Gothard. 3. Pitkaranda; the residue left after treatment with hydrofluoric acid amounts to 61 per cent. The acid dissolved out—together with 35.2 per cent. SiO^2 —only 1.3 Al^2O^3 , 2.4 FeO , and 0.1 MgO . 4. Bretagne; original amount of silica 50.75 per cent. 5. Bretagne.

Staurolite from the Culsagee mine, where it occurs in small blue grains of sp. gr. 3.711, interstratified with damourite, has been analysed by F. A. Genth (*J. pr. Chem.* [2], ix. 49) with the following results:

SiO^2	Al^2O^3	Fe^2O^3	FeO	MgO	CaO	Loss by ignition
27.91	52.92	6.87	7.80	3.23	trace	1.59 = 100.37

STEARIC ACID, $\text{C}^{18}\text{H}^{36}\text{O}^2$. Occurrence.—Stearin, the glyceride of this acid

occurs, together with palmitin and olein, in the fat of parsley seeds (E. v. Gerichten, *Ber.* ix. 1125).

Formation from Ricinoleic acid.—When phosphorus and iodine are gradually added to a warm emulsion of ricinoleic acid with a small quantity of water, a yellow oil is formed, consisting of *iodostearidenic acid*, $C^{18}H^{33}IO^2$, and this acid, treated with nascent hydrogen (zinc-foil and dilute hydrochloric acid), is converted into stearic acid. Iodostearidenic acid easily takes up 2 at. bromine, forming the acid $C^{18}H^{33}Br^2IO^2$ (Claus a. Hassenkamp, *Ber.* ix. 1916).

Decomposition by Heat.—Stearic acid may be distilled under ordinary atmospheric pressure, almost without decomposition, but when distilled four times or more in a closed vessel, it is almost wholly resolved into hydrocarbons, water, and carbon dioxide, together with small quantities of acids and ketones. The liquid portion of the product thus obtained was found to contain, besides water ($\frac{1}{2}$ of the whole weight), all the members of the paraffin series from C^6 to C^{15} , and all those of the olefine series from C^5 to C^{15} . Lower members of both series were contained in the resulting gases (G. Johnston, *Chem. Soc. J.* xxix. 8).

On the Manufacture of Stearic acid, see Ramdohr (*Dingl. pol. J.* ccxix. 518; *Jahresb. f. Chem.* 1876, 1092).

On the separation of Stearic from Oleic acid in mixtures produced by the saponification of Fats, see OLEIC ACID (p. 1432).

STEAROLIC ACID, $C^{18}H^{32}O^2$. This acid, discovered by Overbeck (vi. 1038), is converted, by oxidation with fuming nitric acid, into a greenish oil coagulating to a semi-solid mass from which water extracts azelaic acid, $C^9H^{16}O^4$. The alcoholic solution of the residue deposits stearoxylic acid, $C^{18}H^{32}O^4$, in greenish laminae; and the mother-liquor separates into two layers, viz. an alcoholic liquid containing only a small quantity of stearoxylic acid, and an oily layer, which does not contain azelaic aldehyde, $C^9H^{16}O^3$, as stated by Overbeck, but, on saponification, yields pelargonic acid, $C^9H^{18}O^2$, together with nitrosopelargonic acid, $C^9H^{16}(NO)O^2$ (vi. 903), which detonates when heated. Ethyl pelargonate, $C^9H^{17}O^2.C^2H^5$, is also formed in this reaction (L. Limpach, *Liebig's Annalen*, exc. 294).

STEPHANUS SEEDS, ALKALOIDS OF. The alkaloids of the seeds of *Delphinium Staphisagria* have been examined by Marquis (*Russ. Zeitschr. Pharm.* xvi. 449, 481, 513). The bruised seeds (1–2 kg.) were repeatedly exhausted with four times their weight of alcohol of 90 per cent. containing 5 to 10 grams of tartaric acid; the resulting alcoholic solution was distilled in a vacuum; the residue, which contained a green oily layer, was separated from the latter in a tap-funnel, then immediately mixed with acid sodium carbonate in quantity sufficient to give it a slight alkaline reaction, and agitated with ether. The ethereal solution thus obtained left on spontaneous evaporation crystals of delphinine; the mother-liquor contained delphinoïdine or delphisine; and the liquid exhausted with ether yielded to chloroform the amorphous base, staphisagrine. The oil, which holds in solution a considerable quantity of alkaloids, is shaken with water very slightly acidulated with sulphuric acid to separate these bases, and the resulting solution is treated as above. In favourable cases, 2·5 kg. of seeds thus treated yield 18·1 grams of alkaloids soluble in ether, and 10·59 grams of crude staphisagrine, altogether 1·15 per cent. of alkaloids.

The *delphinine* crystallised from ether is purified by treatment with the same solvent; the uncrystallisable mother-liquors are evaporated down; the residue is dissolved in water containing tartaric acid to separate resinous decomposition-products of *delphinoïdine*, then immediately saturated with acid sodium carbonate, and again digested with ether; and the residue insoluble therein is dissolved in a small quantity of pure chloroform and then mixed with a four- or five-fold quantity of ether, whereupon *staphisagrine* separates out, and *delphinoïdine* is left on evaporation. This last base, when pure, is colourless, completely soluble in acidulated water, and dissolves in ether free from alcohol, yielding a solution which is not rendered turbid by excess of the solvent. To purify the staphisagrine, the contrary method is adopted; that is to say, it is repeatedly precipitated by ether from solution in chloroform; it has not been obtained colourless.

Delphinine, $C^{22}H^{38}NO^6$ (at 100°). This base crystallises in the orthorhombic system, with the axial ratio $a : b : c = 0.63736 : 1 : 0.80402$. Most frequent combination $P. O.P. \infty P \infty$. It decomposes at 120° without fusion. At 20° it dissolves in 5000 pts. water, 20·8 alcohol of 98 per cent., 11·1 ether, and 15·8 chloroform. Its alcoholic solution is optically inactive, and exhibits only a slight alkaline reaction. It tastes, at first, purely bitter, but afterwards produces a cooling and benumbing sensation. It dissolves in pure sulphuric acid, with faint brownish colour, changing to reddish and violet, but does not produce any other conspicuous colour-reactions. The *aurochloride* has the composition $C^{22}H^{38}NO^6.HCl.AuCl^3$; the *mercurioidide*,

$C^{22}H^{38}NO^6, HI, HgI^2$. From gravimetric saturation-experiments, the composition of the *sulphate* appears to be $3C^{22}H^{38}NO^6, H^2SO^4$; that of the *nitrate*, $3C^{22}H^{38}NO^6, 2HNO^3$; of the *hydrochloride*, $3C^{22}H^{38}NO^6, 2HCl$, but volumetric determinations gave different formulæ for the sulphate and nitrate.

Delphinoidine, $C^{42}H^{68}N^2O^7$ (?) This base dissolves in alcohol in all proportions, in water in the proportion of 1 : 6475, in absolute ether 1 : 3, and still more abundantly in alcoholic ether; easily also in chloroform. In alcoholic solution it has an alkaline reaction, a bitter taste, with after-taste like that of delphinine, and is optically inactive. It melts between 110° and 120° (?). Its colour-reactions are those which were formerly ascribed to delphinine. Sulphuric acid dissolves it with dark brown colour changing to red-brown. With sugar and sulphuric acid it becomes first brown, then green; with sulphuric acid and bromine-water it produces a splendid violet colour. It decomposes during drying. Its *platinochloride*, like that of delphinine, is very soluble in water, and extremely unstable. The *aurochloride* has the composition $C^{42}H^{68}N^2O^7, 3HCl, 2AuCl^3$. Saturation-experiments gave for the *sulphate* the formula $C^{42}H^{68}N^2O^7, H^2SO^4$; for the *nitrate*, $C^{42}H^{68}N^2O^7, 2HNO^3$; for the *hydrochloride*, $C^{42}H^{68}N^2O^7, 2HCl$, and for the *acetate*, $C^{42}H^{68}N^2O^7, 2C^2H^4O^2$.

Delphinine, $C^{27}H^{46}N^2O^1$ (?) This alkaloïd, in one instance, when fresh seeds had been used, crystallised from the mother-liquors of delphinine. It resembles delphinoidine in its colour-reactions, and is not much less soluble than the latter in alcohol and in chloroform, but contains a much larger proportion of nitrogen.

Staphisagrine, $C^{22}H^{38}NO^5$, is always amorphous, dissolves in 200 pts. of water, and 855 pts. of ether, and in all proportions of alcohol and chloroform; tastes like delphinine; melts at a temperature somewhat above 90° . In alcoholic solution it is optically inactive, and has an alkaline reaction. It differs from delphinoidine in its colour-reactions, being coloured by sulphuric acid cherry-red to violet, less strongly the purer it is—by sugar and sulphuric acid only dirty brown—and by sulphuric acid and bromine only faintly and transiently reddish. Nitric acid colours it red to brown. Its *aurochloride* has the composition $C^{22}H^{38}NO^5, HI, AuCl^3$; the *mercuriodide* $C^{22}H^{38}NO^5, HgI^2$ (?) Its other salts, analysed as above, appear to be composed as follows: *sulphate*, $(C^{22}H^{38}NO^5)^2H^2SO^4$; *nitrate*, $C^{22}H^{38}NO^5, HNO^3$; *hydrochloride*, $C^{22}H^{38}NO^5, HCl$; *acetate*, $C^{22}H^{38}NO^5, C^2H^4O^2$.

STERNBERGITE. See SILVER SULPHIDES.

STERLINGITE. See VERMICULITES.

STILBENE ALCOHOLS, $C^{14}H^{14}O^2 = C^{14}H^{12}(OH)^2$. *Hydrobenzoin*s.—The experiments of Forst a. Zincke and of Zincke a. Breuer on these alcohols have already been described in this volume under DIPHENYLENE ALCOHOLS (p. 679). The following additional results have been obtained by Breuer (*Inaugural dissertation*, Marburg, 1877).

The two solid products (*anhydrides*) obtained from hydrobenzoin and isohydrobenzoin by the action of dilute sulphuric acid, have the composition $(C^{14}H^{12}CH^2)^2O$, and boil at 181° and 100° respectively. They are but slightly acted upon by benzoic and acetic anhydrides; but hydrobenzoin-anhydride heated with *benzoic acid* for seventeen hours at 230° – 240° , yields the corresponding benzoic ether melting at 240° – 243° ; and with acetic acid at 160° – 170° the acetic ether which melts at 134° . The reaction with benzoic acid also yields stilbene. Isohydrobenzoin-anhydride reacts differently with benzoic and acetic acid, yielding stilbene, together with bitter almond oil (recognisable by its odour), but only very small quantities of ethereal products. With

benzoyl chloride, both these anhydrides yield stilbene chloride, $(C^{14}H^{12})^2 \begin{matrix} \diagup CHCl \\ | \\ \diagdown CHCl \end{matrix}$, melt-

ing at 192° . *Phosphorus pentachloride*, heated with hydrobenzoin-anhydride for half an hour at 130° , yields chiefly stilbene chloride; with isobenzoin-anhydride it yields first a chloride, convertible by acetic acid and silver acetate into hydrobenzoin, while stilbene chloride is produced only at a later stage of the reaction. Both the anhydrides, when heated for eight hours at 200° with hydriodic acid and phosphorus, are converted into dibenzyl (m. p. 51° – 52°). Both, when treated with chromic and glacial acetic acid, yield, as chief product (together with benzoic acid), a body having the composition $C^{28}H^{22}O^2$, which dissolves sparingly in hot alcohol, and crystallises therefrom in small felted needles melting at 155° , easily soluble in benzene, slightly in petroleum-ether. This body, heated for 12 hours in a sealed tube at 200° with hydriodic acid and amorphous phosphorus (1 gram of substance, 0.5 phosphorus, and 2.5 hydriodic acid), yields, together with dibenzyl, a substance melting at 144° – 145° , and separable from the dibenzyl by distillation with steam, in which it does not volatilise. This last substance appears to have the composition $C^{16}H^{14}O^2$, and to be formed as a third oxidation-product of the anhydrides.

The liquid product, *diphenylacetaldehyde*, $(C^6H^5)_2CH-CO\cdot H$, obtained from hydrobenzoin and isohydrobenzoin by the action of dilute sulphuric acid (p. 681), boils at 315° , and gradually decomposes on keeping. It dissolves in acid potassium sulphite, forming a crystalline compound which, however, is very unstable, and has not been obtained pure. It reduces an ammoniacal silver solution, and is converted by oxidation with moist silver oxide, potassium permanganate, and chromic acid, into benzophenone, benzoic acid being also produced when permanganate is employed as the oxidiser. With alcoholic potash at $120^\circ-130^\circ$, the aldehyde yields benzhydrol, together with diphenylmethane and diphenylacetic acid.

The above-described anhydrides and aldehyde are also produced by heating the hydrobenzoins in alcoholic solution with zinc chloride and hydrochloric acid at $130^\circ-150^\circ$ (Breuer).

Stilbene Sulphide, $C^{14}H^{12}S$, also called *Sulphostilbene*, separates, according to Barbier (*Ann. Chim. Phys.* [5], vii. 522), from the products of the dry distillation of benzyl sulphide, $(C^6H^5)_2S$, which have been used for the preparation of stilbene (p. 676). It forms light white needles melting at $168^\circ-169^\circ$, unites with picric acid, forming red opaque needles, and with Fritzsche's reagent, forming light yellow rhombic lamellæ. According to Forst, the sulphur-compound obtained as above is not stilbene sulphide, but probably impure tolyl-allyl sulphide, $(C^6H^5.C)^2S$.

STILBITE. See ZEOLITES.

STORAX. The constituents of liquid storax have been investigated by W. v. Miller (*N. Rep. Pharm.* xxiv. 1; *Ber.* ix. 274; more fully, *Liebig's Annalen*, clxxxviii. 184; clxxxix. 338). This substance contains, in addition to the previously known constituents, styrolene, cinnamic acid, and styracin (i. 497, 986), the following bodies: (1). Phenyl-propyl cinnamate in somewhat considerable quantity; (2). Ethyl cinnamate in small quantity; (3). A crystallisable substance combining with acid sodium sulphite, smelling like vanillin, and melting at 65° (ethyl-vanillin?) in very small quantity; (4). A resinous body, whose composition could not be determined, accompanying the last in moderately large quantity; (5). Two alcoholic bodies (α - and β -storesinol) in very considerable quantity; (6). The cinnamic ethers of these alcohols in not inconsiderable quantity; (7). The sodium-derivative of storesinol in very small quantity.

Styrolene from liquid storax, and cinnamene from cinnamic acid, are regarded by v. Miller as identical; van't Hoff's *styrocumphone* (*Bull. Soc. Chim.* [2], xxv. 175), described as a lavogyrate substance having the composition $C^{10}H^{18}O$ or $C^{10}H^{16}O$, is perhaps not an original constituent of storax, but is formed subsequently by decomposition of phenylpropyl cinnamate.

Testing of Liquid Storax.—To detect the presence of turpentine, H. Hager (*Zeitschr. anal. Chem.* 1874, 247) mixes the liquid storax in a test-glass with half its volume of absolute alcohol, and agitates the mixture repeatedly with several times its volume of petroleum-ether. If the storax is pure, the residue left on evaporating this solvent is colourless with a bluish opalescence, and has a pleasant odour, but in presence of turpentine it is yellowish, and has an unmistakable odour of that substance. With good liquid storax the residue amounts to about 50 per cent.; if it exceeds this proportion, the presence of adulteration may be suspected.

STORESINOL, $C^{36}H^{56}O^3 = C^{36}H^{55}(OH)^3$, is the residue left after exhausting liquid storax successively with caustic soda, cold alcohol, cold petroleum-ether, and hot petroleum-ether. It melts between 160° and 168° , and is oxidised in glacial acetic acid solution by chromic acid, with evolution of carbon dioxide and formation of three acids not yet examined. With acetyl chloride it yields a mono- and a tri-acetyl derivative. Bromine converts it into a bromide having the composition $C^{36}H^{55}Br^3$.

STRENGITE. This mineral occurs in an isolated ironstone and psilomelane-block in the silicious slate of the great brown iron-ore deposit of Dünsberg, near Giessen, in globular, reniform, and radio-fibrous aggregations, having a drusy surface and often accompanied by very fine cacoene. Rarely isolated crystals are found, possessing a strong vitreous lustre. These crystals are transparent or translucent, red in various shades (pomegranate-red and carmine-red), also white, and occasionally colourless; streak yellowish-white; hardness 3-4; sp. gr. 2.87. Before the blowpipe the mineral fuses easily to a black, shining globule, colours the flame bluish-green, and gives the reactions for iron. On heating it in the matrass, much water is evolved, whilst hydrochloric acid dissolves it easily, especially when hot, but it is not easily attacked by nitric acid. In order to obtain pure material for analysis, selected portions

of the mineral were treated with stannous chloride solution, which dissolved out the brown iron-ore and left the small isolated crystals of strengite behind. An analysis of these showed the mineral to have the following composition :

Fe ² O ³	P ² O ⁵	H ² O
43.18	37.42	19.40 = 100.00

from which the formula $\text{Fe}^2\text{O}^3\text{P}^2\text{O}^5 + 4\text{H}^2\text{O}$ is obtained. Strengite belongs therefore to the same class of minerals as scorodite, ($\text{Fe}^2\text{O}^3\text{As}^2\text{O}^5 + 4\text{H}^2\text{O}$), and the barrandite of von Zepharovich, $\left\{\frac{2}{3}\text{Fe}^2\text{O}^3\right\}\text{P}^2\text{O}^5 + 4\text{H}^2\text{O}$; it crystallises in the rhombic system, the forms observed in combination being $\infty \bar{P} \infty . \infty \bar{P} 2 . P . m\bar{P} \infty$; the latter could not be accurately determined. Cleavage indistinct, parallel to $\infty \bar{P} \infty$, a pearly, vitreous lustre characterising the cleavage-planes. The habit of isolated crystals is 'thin-tabular' through $\infty \bar{P} \infty$, but the commonest occurrence is a sheaf-like aggregation on which only the faces of P are visible. Numerous measurements of the crystals were made, with the following results :

Angle of the terminal edge of P in the macrodiagonal = $102^\circ 14'$

brachydiagonal = $115^\circ 8'$

Angle " of the prism " " " " = $118^\circ 36'$

Mean ratio of the lengths of the axes obtained from the above measurements, $a : b : c = 1 : 1.1855 : 1.1224$, whence are calculated the angles as follows, viz. :

Macrodiagonal terminal edge of P = $101^\circ 38'$

Brachydiagonal " " = $115^\circ 36'$

Lateral edge of P " " = $111^\circ 30'$

These calculated angles agree very closely with the measurements obtained with scorodite by Breithaupt, Miller, von Zepharovich, von Kokscharow, and vom Rath, viz. :

Macrodiagonal terminal edge of P = $102^\circ 28'$

Brachydiagonal " " = $114^\circ 28'$

Lateral edge of P " " = $111^\circ 42'$

It appears, therefore, that strengite and scorodite are isomorphous. Their resemblance in form and occurrence is very striking, and their complete isomorphism may be regarded as a further proof of the close analogy of arsenic acid and phosphoric acid to each other. They are probably the final members of the series of phosphatic minerals to which pyromorphite and mimetesite belong (A. Nies, *Jahrb. f. Min.* 1877, 8).

STRIGOVITE. This mineral occurs at Strigau in Silesia. An analysis by Websky (*Jahrb. f. Min.* 1874, 302) of a specimen from a recently opened druse gave :

SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	CaO	MgO	Li ² O
28.425	16.604	11.432	26.211	7.247	0.364	0.364	9.309 = 99.956

Neglecting the slight excess of water over 2 mols., the empirical constitution of strigovite dried at 100° is $\text{H}^1(\text{M}')^2(\text{R}')^4\text{Si}^2\text{O}^{11}$, in which $(\text{M}')^2 = \frac{2}{3}\text{Fe} + \frac{1}{3}(\text{Mn}, \text{Ca}, \text{Mg})$, and $(\text{R}')^4 = \frac{2}{3}\text{Al} + \frac{1}{3}\text{Fe}$. Among species nearly allied to strigovite, Websky enumerates aphrosiderite from Weillburg; delessite from La Grève, near Mielin; cronstedtite from Przibram; thuringite from Reichmannsdorf and Schmiedefeld, and owenite from the Potomac river.

STROMEYERITE. A silver-copper glance, forming the principal ore of a mine on the Hoyada, in the north of the province of Catamarca, Argentine Republic. It occurs, partly with small quantities of copper pyrites and galena, intergrown in tile-ore, partly in the interior of nodules consisting externally of chrysocolla with a small quantity of cerusite. An analysis by Siewert gave :

Ag	Cu	S	Insol.	Sp. gr.
52.60	31.61	14.38	1.07 = 99.66	6.15-6.19

(A. Stelzner, *Min. Mitth.* 1873, 250).

STRONTIANITE. H. Laspeyres describes crystals of strontianite (strontium carbonate) from Hamm, in Westphalia, which, contrary to the usual acuminated forms of this mineral, exhibit obtuse pyramids and brachydromes (*Jahrb. f. Min.* 1876, 431). According to F. Hessenberg (*ibid.* 1870, 626), nineteen forms are observed on strontianite, whereas on the isomorphous mineral, aragonite, only fifteen can be recognised. Sandberger (*ibid.* 589) describes strontianite as the petrifying material of an ammonite from the liroconite of Wasseralfingen.

STRONTIUM. This element has been detected in the sun's atmosphere by

C. A. Young (*Sill. Am. J.* [3], iv. 356). It exists, together with barium, in all primary rocks, in sufficient quantity to be easily determined in a single gram of felspar, mica, gneiss, granite, or syenite (Dieulafoy, *Ann. Chim. Phys.* [5], xv. 530; *Chem. Soc. J.* xxxvi. 444). Sea-water also contains strontium, both as carbonate and as sulphate, and when it is evaporated, either spontaneously or with the aid of heat, the strontium carbonate is precipitated, together with the calcium carbonate and sulphate, whilst the deposits of sodium chloride and those from the mother-liquors are free from it. From the sea-water it passes and has passed into the shells of conchylia, recent and fossil, which, as well as the gypsums of various formations, all contain strontium. Strontium has also been detected in certain mineral springs, and may be assumed to exist in all, since, according to Dieulafoy, these springs derive their saline constituents chiefly, and in most cases exclusively, from the sedimentary rocks, all of which, being deposits from ancient seas, contain strontium (*Compt. rend.* lxxxiv. 1303).

Preparation and Properties of the Metal.—Benno Franz (*J. pr. Chem.* cvii. 253) has prepared strontium in considerable quantities by heating an amalgam of the metal in an iron crucible through which a stream of well-dried hydrogen is passed. The strontium then remains in the form of a fused cake, easily removable from the crucible. The strontium-amalgam is prepared by heating a saturated solution of strontium chloride with sodium-amalgam at 90°, repeating this treatment several times, then washing the resulting strontium-amalgam well with water, and drying it thoroughly between bibulous paper.

Strontium prepared as above is a faintly yellowish metal which resembles barium, and may with moderate facility be beaten out into thin laminae. In contact with the air it oxidises rapidly, with great evolution of heat, and burns away with emission of sparks. It melts at a moderate red heat, but does not volatilise even at a bright red heat. Sp. gr. = 2.4.

Estimation and Separation.—On the estimation of strontium as sulphate, see P. Schweitzer (*Proceedings of the American Association for the Advancement of Science*, 1877). Strontium sulphate dissolves on the average in 8,000 pts. of cold water; but the solubility varies, according to circumstances, from 7,500 to 10,288 pts. water.

On the separation of Strontium from Barium as Chromate, see BARIUM (p. 142).

Oxides.—*Strontia*, SrO (also lime and baryta), may be obtained in crystals belonging to the regular system by heating the nitrate (15 to 20 grams) in a covered porcelain crucible placed in a coke fire. The crystals thus obtained cleave parallel to the cubic faces, and the best specimens are perfectly transparent. The specific gravities and specific volumes of the three crystallised oxides are as follows:

	CaO	SrO	BaO
Specific gravity	3.251	4.750	5.722
Specific volume	17.225	21.789	26.739

The values for strontia are very nearly the means between those for lime and baryta (Brügelmann, *Wiedemann's Annalen*, iv. 277).

Hydroxide, SrH^2O^2 .—On the Heat of Formation of this Compound, see p. 959; on the Heat of Formation of the Hydrate, $\text{SrH}^2\text{O}^2 + 9\text{H}^2\text{O}$, see p. 982; on its Heat of Solution, p. 1001.

The dry hydroxide is not attacked by chlorine, but the hydrates with 5 and 8 mols. water of crystallisation are converted by chlorine into chlorate and chloride of strontium, together with a small quantity of hypochlorite (Konig, Weisberg, *Ber.* xii. 511).

The *peroxide*, SrO^2 , is formed when strontium carbonate is heated in a platinum crucible only so far as to make the bottom of the crucible red-hot; at a higher temperature it is decomposed. The carbonates of calcium and barium are converted by similar treatment into peroxides, that of barium having a yellow colour (H. Struve, *Zeitschr. anal. Chem.* 1872, 22).

On the Industrial Uses of Strontium-Compounds, see Biedermann (*Hafmann's Entwicklung der chemischen Industrie*, ii. 514).

STROPHANTIN. A poisonous substance extracted from the seeds of *Strophantus hispidus*, which are used in Africa as an ordeal. It forms colourless crystals, soluble with neutral reaction in water and alcohol, and not exhibiting the properties either of an alkaloïd or of a glucoside. The seeds also contain a non-poisonous alkaloïd called *ineine* (Hardy a. Gallois, *Compt. rend.* lxxxiv. 261). See also T. R. Fraser (*Arch. Pharm.* [3], iii. 229).

STRUVITE. Native ammonio-magnesium phosphate, $(\text{NH}^4)^2\text{Mg}^2\text{P}^2\text{O}^8 \cdot 12\text{aq.}$

(iv. 570). The occurrence of this mineral in an old dung-pit at Brunswick is noticed by E. J. Ottmer (*Jahrb. f. Min.* 1873, 400) and by R. Otto (*Ber.* 1873, 783). According to A. Sadebeck (*Min. Mitth.* 1877, 950), the axial ratio $a:b:c = 0.5567:1:0.9121$. The cleavage according to OP is more distinct than that according to the brachydiagonal, which has hitherto been regarded as the principal direction of cleavage. Twins occur according to OP, the individual crystals being grown together sometimes at the upper, sometimes at the lower end. From the results of corrosion-experiments, it appears that struvite is not hemihedral.

STRYCHNINE, $C^{21}H^{22}N^2O^2$. *Detection*.—For the detection of strychnine in chemical-legal investigations, J. St. Clair Gray (*Zeitschr. anal. Chem.* 1873, 125) triturates the suspected substances with water to a pulp, mixes this with excess of acetic acid, digests the mixture at 27° for about twenty-four hours; and then pours it into a dialyser. After forty-eight hours, the dialysate is evaporated down to a drachm and repeatedly shaken with chloroform. The aqueous solution is then made alkaline with ammonia, and again agitated with chloroform, and the residue left on evaporation may be examined for strychnine by the usual tests. According to J. B. Lyman (*ibid.* 126), potassium permanganate, silver oxide, and hydrated manganese dioxide produce with strychnine the same colour-reactions as chromates, and in many respects are even superior to the latter as tests for that alkaloid.

On the detection and separation of Strychnine in mixtures of Alkaloids, see PLANT-BASES (p. 1635).

Reaction of Strychnine with Nitric Acid.—When strychnine is added to nitric acid, and the liquid—on completion of the reaction, which is attended with copious evolution of nitrous fumes—is diluted with water, an amorphous body is thrown down, the solution of which in glacial acetic acid deposits, after dilution, a basic substance, perhaps consisting of nitrostrychnine. When strychnine is boiled for some time with strong nitric acid, and the solution is concentrated by evaporation, it deposits a crystalline acid having the composition $O^{16}H^{14}N^4O^{18}$, which melts with decomposition above 300° , and forms red amorphous salts (R. Schiff, *Gazz. chim. ital.* viii. 82).

Strychnine Tri-iodide, $C^{20}H^{22}N^2O^2.HI^3$, prepared by triturating 2 pts. strychnine with 1 pt. iodine, and crystallising the mixture from alcohol, forms violet needles resembling potassium permanganate, and is identical with that described by Tilden, and probably also with that obtained by Herapath (v. 441). It is unstable in solution, but in the solid state it may be heated without alteration to 135° . It dissolves with red colour in nitric and sulphuric acids, and when heated with alcoholic iodine-solution, appears to be converted into a higher iodine-compound (II. R. Bauer, *Arch. Pharm.* [3], v. 289).

Polyhydrosulphide, $C^{21}H^{22}N^2O^2.H^2S^8$. Hofmann, who obtained this compound by mixing a cold-saturated solution of strychnine in strong alcohol with an alcoholic solution of ammonium sulphide containing free sulphur, assigned to it the formula $C^{21}H^{22}N^2O^2.H^2S^8$ (vi. 1040). E. Schmidt (*Ber.* v. 1267) found that an alcoholic solution saturated with hydrogen sulphide deposited after some time orange-red needles, to which he assigned the formula $2C^{21}H^{22}N^2O^2.3H^2S^8$. Hofmann, however (*Ber.* x. 1087), finds that the compound prepared by Schmidt's method is identical in colour, composition, facility of decomposition, and chemical behaviour in general, with that obtained by his own. To determine which of the two formulæ above cited is the true representative of its composition, weighed quantities of the compound were treated with a solution of arsenic trioxide in hydrochloric acid, and the resulting precipitates were weighed and analysed; moreover, the polyhydrosulphide was decomposed with a solution of lead acetate in glacial acetic acid, and the resulting black precipitate was weighed. Numerous analyses showed that the arsenic precipitate has the composition As^3S^{18} , and is formed in quantity corresponding with the equation $3H^2S^8 + As^2O^3 = 3H^2O + As^2S^{18}$, and that the lead precipitate has the composition PbS^8 . Hence Hofmann now represents the polyhydrosulphide by the formula $(C^{21}H^{22}N^2O^2)^2.H^2S^8$, which agrees very closely with the results of the elementary analysis. The compound is probably however not a salt of the acid H^2S^8 , for although when decomposed by acids it yields a clear oil having a peculiar odour, and agreeing in its essential properties with hydrogen persulphide, it does not, on the other hand, yield by double decomposition any compounds that can be regarded as salts of the acid H^2S^8 . The polyhydrosulphide is most probably analogous in constitution to the periodides, and may perhaps be formulated as $2C^{21}H^{22}N^2O^2.H^2S^8.S^4$, in which case the oil separated from it by acids must be regarded as a solution of the additional sulphur in hydrogen disulphide. E. Schmidt, also (*Ber.* x. 1288), now admits the identity of Hofmann's polyhydrosulphide of strychnine, prepared by means of hydrogen sulphide, with his own compound obtained with ammonium sulphide, and attributes the inferior

stability of the latter to the circumstance that it separates in less compact crystals, which are therefore more easily attacked by reagents. Compare **BRUCINE HYDRO-SULPHIDES** (p. 353).

Hydrates of Strychnine or Hydrostrychnines (Gal a. Etard, *Compt. rend.* lxxvii. 362). Strychnine takes up 2 and 3 mols. H^2O , forming compounds which act as distinct bases, uniting with acids to form crystallisable salts. They are formed by heating finely pulverised strychnine with ten times its volume of cold-saturated solution of baryta for about forty hours at 135° – 140° in sealed tubes freed from air as completely as possible. The liquid freed from baryta by carbon dioxide, filtered in a stream of that gas, and distilled in a vacuum, finally deposits white crystals of dihydrostrychnine, $C^{21}H^{28}N^2O^4 = C^{21}H^{22}N^2O^2.2H^2O$, which may be purified by recrystallisation from water. This compound forms microscopic prisms, dissolves easily in hydrochloric acid, forms a well-crystallised hydrochloride, and a sparingly soluble tartrate which also crystallises well. Trihydrostrychnine, $C^{21}H^{28}N^2O^5 = C^{21}H^{22}N^2O^3.3H^2O$, contained in the mother-liquors of the preceding compound, forms yellowish prisms, and yields a well-crystallised tartrate.

Both these bodies are moderately stable in the solid state, but extremely liable to alter in solution, especially the trihydro-compound, so that in their preparation, &c., it is necessary to protect them from the air as completely as possible. Both of them give a specular deposit with silver nitrate, and reduce the chlorides of gold and platinum, with violet coloration. They do not give the strychnine reaction with sulphuric acid and potassium chromate. They appear to possess the character of aldehydes, as is further shown by their behaviour with sodium bisulphite, and they are probably identical with Schützenberger's oxy- and dioxystrychnine respectively (iv. 320).

STRYCHNOS. The fat extracted by ether from the seeds of *Strychnos Nux vomica* consists of the glycerides of oleic, palmitic, capric, caprylic, caproic, and butyric acids, and that of an acid containing 76.89 per cent. carbon, and having a melting point higher than that of stearic acid (F. Meyer, *Russ. Zeitschr. Pharm.* 1875, 417, 449).

STYCKERIN, $C^9H^{12}O^3 = C^6H^5.CHOH.CHOH.CH^2OH$. Syn. with **PHENYL-GLYCEROL** (p. 1562).

STYPHNIC ACID, $C^6H(NO^2)^2(OH)^2$. Syn. with **TRINITROBESORCINOL** (p. 1750).

STYRACIN, STYRYL CINNAMATE, or CINNYL CINNAMATE, $C^{18}H^{16}O^2 = C^8H^7O^2.C^9H^9 = C^6H^5.CH=CH.CO^2C^9H^9$. This compound is contained, together with styrolene, free cinnamic acid, and other bodies, in liquid storax, and may be separated therefrom by methods already described (i. 986). W. v. Miller (*N. Rep. Pharm.* xxiv. 1), after distilling off the styrolene with vapour of water, heats the resinous residue on the water-bath with one-tenth of its weight of crystallised sodium carbonate, till the mass no longer froths; decants the aqueous solution which contains the greater part of the free cinnamic acid in the storax; heats the residue with a solution of 1 pt. caustic soda in 40 pts. water to remove the rest of the cinnamic acid, and free the styracin from the greater part of the resin; treats the residue with cold alcohol, and crystallises the portion insoluble therein from hot alcohol. The crystals of styracin thus obtained are purified by pressure between filter-paper and further treatment with cold alcohol, which removes any portion of resin that may still adhere to them. The styracin thus obtained melts at 44° . It unites with bromine, yielding a dibromide and a tetrabromide, the latter in the form of a resin which has not been obtained pure. The constitution of styracin and its two bromine-compounds may be represented by the following formulæ:

The dibromide is converted by reduction into phenyl-propyl cinnamate [phenyl-acrylate], $C^6H^5.CH=CH.COOC^9H^9(C^6H^5)$, and the tetrabromide into phenyl-propyl phenylpropionate, $C^6H^5.CH^2.CH^2.COOC^9H^9(C^6H^5)$. Styracin itself is but little inclined to take up hydrogen.

The action of bromine on phenyl-propyl cinnamate in ethereal solution gives rise

to phenyldibromopropyl cinnamate, $C^9H^7.COOC^2H^4.Br^2(C^6H^5)$, and other products still richer in bromine. By the prolonged action of bromine-vapour, phenylpropyl cinnamate is converted into styracin tetrabromide (W. v. Miller, *Liebig's Annalen*, clxxxviii. 184).

STYROCAMPHEME. See STORAX (p. 1827).

STYROLENE, C^8H^8 . Syn. with CINNAMENE (p. 497). It is formed, together with benzene, naphthalene, phenanthrene, and anthracene, by passing a mixture of ethylene and diphenyl vapour through a porcelain tube heated to bright redness (Barbier, *Compt. rend.* lxxix. 660). On its occurrence in Storax, see p. 1827.

A compound of styrolene with *acid sodium sulphite*, $C^8H^8.NaHSO^3$, is formed by heating 1 mol. styrolene (from cinnamic acid) for several hours with a solution of 1 mol. of the acid sulphite (concentration 2 : 5), best at about 120° . It crystallises from water in nacreous laminae, melts at 306° , dissolves easily in water and in hot alcohol, and is soluble also in ether. Styrolene obtained from liquid storax, or by distillation of metastyrolene, appears to react with sodium bisulphite somewhat differently from that which is prepared from cinnamic acid, yielding, when heated with the bisulphite solution at 110° , small quantities of crystals different in appearance from those above described; moreover, the most favourable temperature for the formation of the crystals in the preparation from styrolene obtained from liquid storax or from metastyrolene is about 155° (W. v. Miller, *N. Rep. Pharm.* xxiv. 31).

STYROLENE ALCOHOL, $C^8H^{10}O^2 = C^6H^5.CHOH.CH^2OH$. Syn. with PHENYL-GLYCOL (p. 1563).

SUBERIC ACIDS, $C^8H^{14}O^4$. Ordinary suberic acid (m. p. 140°), originally obtained by oxidising cork with nitric acid, is also produced by the action of fuming nitric acid at temperatures not exceeding 110° , on paraffin (p. 1489).

The two following acids, isomeric with it, have been obtained synthetically :

(1). Diethyl-succinic acid, $\begin{array}{c} CH^3.CH^2.CH.CO^2H \\ | \\ CH^3.CH^2.CH.CO^2H \end{array}$. The ethylic ether of this acid

is obtained by heating ethyl α -bromobutyrate or α -iodobutyrate at 120° – 130° in a sealed tube with finely divided silver and methyl iodide, which latter assists the reaction, but takes no direct part in it :

It boils, after rectification, at 233° – 235° (C. Hall, *Ber.* vi. 28).

(2). Tetramethyl-succinic acid, $\begin{array}{c} (CH^3)^2C.CO^2H \\ | \\ (CH^3)^2C.CO^2H \end{array}$. The ethylic ether of this acid is produced in like manner from ethyl bromisobutyrate :

By subjecting the product to repeated fractional distillation, the ethylic tetramethyl-succinate is obtained as a liquid boiling at 230° – 231° (uncorr.), and having $n_{D^{20}}$ gr. of 1.012 at 0° , 1.0015 at 13.5° . The suberic acid obtained from it forms, after three crystallisations from hot water, small, hard, frequently spherical groups of crystals, apparently consisting of quadratic tablets with pyramidal summits. It melts at 95° , and resolidifies at a somewhat lower temperature. It is not volatile at ordinary temperatures, very slightly at 100° , but sublimes at higher temperatures in broad feathery laminae. It is extremely soluble in alcohol, ether, and hot water, less soluble in cold water, 100 pts. water at 11° dissolving 2.2 pts. of it. The ammonium, potassium, and sodium salts are also very soluble; the barium, calcium, and lead salts are white bulky precipitates; the copper salt is a bluish-green precipitate; the silver salt a white precipitate which quickly turns brown on exposure to light, and dissolves in 2,500 pts. water at 10° (Hell a. Wittekind, *Ber.* vii. 319).

SUCCINIC ACID, $C^4H^6O^4 = \begin{array}{c} CH^2.COOH \\ | \\ CH^2.COOH \end{array}$. This acid has been found in the

juice of unripe grapes gathered in June (Brunner a. Brandenburg, *Ber.* ix. 982); also among the products of the schizomycetic fermentation of mannitol (p. 777), and in urine after asparagus has been eaten (Hilger, *Liebig's Annalen*, clxxi. 208).

Succinic acid is formed : a. By the oxidising action of dilute nitric acid on normal

butyric acid, and, together with acetic acid, by the action of the same acid on normal caproic acid; but in both cases, unless special precautions are taken, the action goes further, and the succinic acid is oxidised to carbonic acid and water (Erlenmeyer, Sigel a. Belli, *Ber.* vii. 696). β . By heating ethyl chlorocarbonate, bromoacetic acid, and finely divided silver in molecular proportions at 130° in a sealed tube. The reaction takes place according to the equation:

the chlorocarbonic ether taking no direct part in it, but being resolved into CO^2 and $\text{C}^2\text{H}^4\text{Cl}$. A fetid brominated liquid is formed as a secondary product (A. Stelzner, *Ber.* vi. 184).

The preparation of succinic acid from ethylene cyanide by decomposition with alcoholic potash (Simpson's method, v. 454) takes a long time when large quantities of material are operated on; and, according to Jungfleisch (*Bull. Soc. Chim.* [2], xix. 197), the conversion of the ethylene cyanide into succinic acid may be much more quickly effected by gradual addition of nitric acid diluted with an equal bulk of water:

The use of nitric acid has the further advantage of decomposing colouring matters which would otherwise contaminate the product.

Reactions. 1. Succinic acid, like other diatomic bibasic acids, is converted by the action of acetyl chloride, benzoyl chloride, succinyl chloride, and acetic anhydride into the corresponding anhydride, the reactions being represented by the following general equations:

In this manner succinic acid and isodibromosuccinic acid are easily converted into anhydrides by acetyl chloride at ordinary temperatures; isosuccinic acid, $\text{CH}^3.\text{CH}(\text{CO}^2\text{H})^2$, and ordinary dibromosuccinic acid, are not attacked; succinyl chloride and succinic acid yield succinic anhydride; and *acetic anhydride*, heated for several hours in sealed tubes (mostly at 125° – 150°) with succinic and isodibromosuccinic acid, converts them into their anhydrides. Ordinary dibromosuccinic acid, heated with acetyl chloride, yields acetyl bromide, acetic acid, and monobromomaleic anhydride (Anschütz, *Ber.* x. 325, 1881).

On the reaction of Succinic acid with *Paraphenylenediamine*, see **PHENYLENE-DIAMINES** (p. 1560); with *Phthalic Anhydride* (p. 1615).

SUGARS. *Distribution in Plants.*—V. Jodin (*Ann. Chim. Phys.* [5], 491), from a comparison of the known facts relating to the distribution of sugars in the vegetable kingdom, has arrived at the following conclusions:

1. A great number, if not all, the plants belonging to the higher classes contain, distributed through their organisms, sugar consisting of a mixture of saccharose and inverted sugar.

2. In the same plant the average amount of sugar in the leaves is very small, but it attains its maximum in the flowers, fruits, stems, and roots, which possess the chlorophyllic function in a slight degree only.

3. The smallness of the quantity of sugar in the leaves cannot be regarded as evidence against the direct production of sugar by these organs.

4. The constant presence of a certain quantity of sugar in fungi appears to prove that the glycogenic and chlorophyllic functions are independent of each other. In the green leaf these two functions exist together, but are not mutually dependent.

The quantity of sugar contained in the 'nectar' of various flowers (the sweet-tasting liquid secreted within the cups of flowers which are fertilised by insects) has been determined by A. S. Wilson, with the following results:

	Total mgm.	Fruit- sugar	Cane-sugar (as fruit-)
1. Fuchsia, per flower	7.59	1.69	5.9
2. <i>Claytonia Alsinoïdes</i> , ditto	0.413	0.175	0.238
3. Everlasting pea, ditto	9.93	8.83	1.60
4. Vetch (<i>Vicia Cracca</i>) per raceme	3.16	3.15	0.01

6. Red clover, per head	7.93	5.95	1.98
7. Ditto, per floret	0.132	0.099	0.033
8. Monkshood, per flower	6.41	4.63	1.78

Saccharose, Cane-sugar, Beet-sugar. This kind of sugar exists, together with dextrose, in vine-leaves. In one experiment a kilo. of the leaves yielded 9.2 g. saccharose and 26.5 g. dextrose; in another, more quickly carried out, 15.80 saccharose and 17.49 glucose. Cherry and plum leaves were also found to contain both kinds of sugar; 1 kilo. of plum-leaves gave 33 g. saccharose and 12 g. dextrose (Petit, *Compt. rend.* lxxvii. 944). Researches on the distribution of saccharose in the sugar-beet have been published by C. Violette (*Compt. rend.* lxxix. 899; *Ann. Chim. Phys.* [5], iii. 546; *Chem. Soc. J.* 1875, 376).

Specific Gravity.—According to Maumené (*Bull. Soc. Chim.* [2], xxii. 23), the specific gravity of cane-sugar is 1.5951 at 15°, whereas former determinations gave 1.606 (v. 470). The dissolution of sugar in water is attended with diminution of volume, unless the sugar and water are brought together in equal proportions by weight. With excess of water, contraction takes place; with excess of sugar, expansion; both however in small proportion only.

Solubility in Water.—According to Courtonne (*Compt. rend.* lxxxv. 959), 100 g. water at 12.5° dissolve 198.547 g. cane-sugar, a result agreeing very nearly with the proportion 1 : 2 found by Berthelot and by Scheibler, not with Maumené's result (1 : 3). At 45°, 100 g. water dissolve 245 g. sugar.

On the Crystallisation of Cane-sugar on the large scale (preparation of sugar-candy), see Weitz (*Dingl.* cxxxi. 452; *Chem. Soc. J.* xxxvi. 844).

Reactions.—1. When well-dried ammonia-gas is passed over perfectly dry saccharose, the sugar becomes opalescent at first, and viscid after about twelve hours. The maximum amount of ammonia taken up is 7.83 per cent. by weight of the sugar, but part of this is given off when the strength of the current of gas is diminished, and when the sugar is exposed to the air, the increase of weight sinks to 1.2 per cent. After three months the sugar was found to retain 0.37 per cent. ammonia, and to have a strong bitter taste (E. Laborde, *Compt. rend.* lxxviii. 82).

2. **Conversion into Glucose.**—Experiments by H. Pellet (*Ann. Chim. Phys.* [5], xiii. 394) on the action of various substances on cane-sugar as influenced by temperature and the duration of the action, have led to the following conclusions:

(1). Under the influence of heat, weak solutions of saccharose alter more rapidly than concentrated solutions.

(2). Glucose assists in the transformation of saccharose into glucose, in proportion to its pre-existing quantity, but its action becomes *nil* when the sugar-solution is saturated (Gunning).

(3). Mineral salts act strongly on saccharose at a certain temperature. Chloride of potassium appears to be more energetic in its action than the nitrate. Ammonium nitrate has a very energetic action. By boiling for thirty minutes a mixture of 100 c.c. of water, 10 grams of sugar, and 5 grams of ammonium nitrate, all the sugar is transformed into glucose.

(4). Organic salts have a very weak action.

(5). The quantity of glucose found in the molasses from the refinery is determined by the total influence of time, heat, and mineral salts, in addition to the quantity of glucose pre-existing in the unrefined sugar.

3. **Inversion and Fermentation.**—Cane-sugar is readily inverted by certain ferments, such as *Penicillium glaucum* and *Aspergillus niger*; several species of *Mucor*, however (*M. mucedo*, *M. circinelloides*, &c.), have no action upon it. Two species, *M. spinosus* and *M. circinelloides*, resemble one another in their action on beer-wort, but the second is much the more active. When these bodies are placed in liquids destitute of free oxygen, their mycelium takes the form of cells which multiply with great rapidity; the mycelium, however, reverts to the ordinary form directly the liquid is aerated. In solutions of dextrose and levulose, alcoholic fermentation is set up, as in beer-wort, but in a solution of cane-sugar there is no fermentation; if, however, spores of *Torulas*, or of any other ferment capable of inverting cane-sugar, be added, the ordinary alcoholic fermentation commences. Hence it appears that cane-sugar is not directly fermentable (U. Gayon, *Compt. rend.* lxxxvi. 52).

Detection.—To detect sugar in glycerin, R. Böttger (*Zeitschr. anal. Chem.* x. 508) mixes 5 drops of the glycerin with 100 drops of distilled water, 1 drop of nitric acid of sp. gr. 1.3, and 30 to 40 mg. ammonium molybdate, and boils the mixture. If sugar is present, the liquid assumes a deep blue colour.

Estimation.—1. By *Ferric Chloride*. The property of sugar to prevent the precipitation of ferric chloride by ammonia may be made available for the estimation of sugar. 100 milligrams of iron in the state of ferric chloride require 2.587 g. sugar to keep the liquid clear on addition of ammonia. Accordingly, to this quantity of the sugar to be examined—after addition of ammonium oxalate to separate any lime

that may be present—ammonia is added in excess, and then solution of crystallised ferric chloride as long as the liquid remains clear. The number of mgm. of iron added without the formation of a precipitate will then give the percentage of real sugar in the sample: the solution must not be heated. If the ferric chloride has been decomposed by prolonged heating at 100° , 2.710 g. sugar will be required to keep 100 mgm. iron in solution. As invert-sugar acts much more strongly in this way than crystallisable sugar (0.387 g. saccharose after inversion acting as strongly as 2.587 g. before inversion), the saccharose must, previous to titration, be freed from invert-sugar by treatment with cold alcohol (E. Riffard, *Compt. rend.* lxxvii. 1103).

2. C. Nicol (*Zeitschr. anal. Chem.* 1875, 179) finds by comparative experiments that the inversion of sugar, with a view to its determination by Fehling's solution, is best effected by heating it in sealed tubes at 130° , the inversion being then complete either with or without the addition of an acid, whereas if the sugar is heated in an open vessel, the addition of an acid is necessary. No difference was observed between the action of sulphuric and that of hydrochloric acid.

On the comparative merits of various methods of estimating cane-sugar, see G. C. Stewart (*Chem. News*, xxxi. 212, 223), H. C. Humphrey (*Amer. Chemist*, vi. 203; *Chem. News*, xxxiii. 205). A table of the properties of different varieties of cane-sugar, founded on an investigation by Lotmann, is given by R. F. Smith (*Chem. News*, xxxiii. 225). On the estimation of sugar in coloured liquids containing glucose, see Pellet a. Parquier (*Monit. scient.* [3], vii. 1074; *Jahresb. f. Chem.* 1877, 1193).

Estimation of the yield of Pure Crystallisable Sugar from various raw Beet-sugars. C. Scheibler (*Zeitschr. des Vereins für die Rübenzucker-industrie*, 1872, 297; *Dingl. pol. J.* cxi. 48) describes an improved method of carrying out the process devised by Payen in 1846, by which the syrup adhering to the already crystallised sugar is removed by washing with an acid saturated solution of sugar in alcohol of about 85 per cent. For Payen's single washing fluid and tared filter, Scheibler substitutes the following fluids and apparatus:—(1). Alcohol of 99–100 per cent.; (2). Alcohol of 96 per cent. saturated with sugar; (3). Alcohol of 92 per cent. also saturated; and (4). Alcohol of 85 per cent. mixed with 5 vols. per cent. of ordinary acetic acid and saturated with sugar. About 20 grams of the sugar to be tested is weighed into tared tubes about 2 centimeters wide and 15 centimeters long, having a narrow tube fused on to them at one end, and containing a plug of felt or cotton-wool just above the junction of the wide and narrow portions. These tubes are connected by their narrow ends with bottles, in which a partial vacuum can be created by some convenient means, such as a Bunsen water-pump, while their wide upper extremities are closed by corks carrying two tubes, one of which serves for the admission of dry air, and the other (carrying a stopcock) for the introduction of the washing fluids by means of a pipette. The sugar is first covered with absolute alcohol and left to stand for fifteen minutes; this liquid is drawn off and replaced by No. 2, which is followed by No. 3, and then by No. 4. This last, which is the effective solvent of the syrup, is left on the sugar for fifteen or twenty minutes, and is then allowed to run off slowly; more is added and run off, and so on, till the sugar imparts no more colour to the liquid. The remaining portions of (4) are then displaced by the other liquids, used in reverse order, and the nearly pure sugar left is dried by passing air through it while the tube is surrounded by a metallic casing filled with steam. The weight of the residue so obtained is obviously that of the sugar which existed ready crystallised in the original specimen plus sand and other impurities insoluble in spirit. It is now only necessary to 'polarise' this residue to determine the quantity of sugar which it contains, and so obtain all the data required to ascertain how much crystallised sugar was contained in the original.

Estimation of Saccharose in Coloured Liquids containing Glucose.—The following method is recommended by Pellet a. Pasquier (*Monit. scient.* [3], vii. 1074). (1). 100 grams of the liquid under examination (molasses) are diluted with water to a total volume of 500 c.c. (2). 100 c.c. of this liquid are mixed with 40 c.c. of a solution of lead acetate (sp. gr. 1.150–1.200) diluted with water to 200 c.c. and filtered. (3). Of this filtrate, 100 c.c. are mixed with 10 c.c. acetic acid, and examined in the saccharimeter, the observed rotation being reduced to 100 c.c. of the normal liquid, and the sugar calculated for 100 g. of normal molasses. (4). 50 c.c. of the liquid obtained as in (2) are mixed with 10 c.c. hydrochloric acid, inverted at 70° ; slightly supersaturated with soda when cold; acidulated with acetic acid; diluted to 100 c.c.; mixed (if too strongly coloured) with 1 g. animal charcoal; filtered; introduced into the saccharimeter; the temperature determined; and the quantity of crystallisable sugar calculated according to the following formulæ (the first applying to Soleil's, and the second to Laurent's saccharimeter), in which S denotes the sum of the saccharimetric readings

before and after inversion—i.e. the entire diminution of rotation—and T the temperature of the inverted solution at the time of observation:

Formula for Soleil:

$$P = \frac{200 S}{288 - T} \text{ and } \frac{P \cdot 16.35}{100} \text{ or } P \cdot 0.1635 = \text{Sugar for 100 c.c.}$$

Formula for Laurent:

$$P = \frac{200 S}{288 - T} \text{ and } \frac{P \cdot 16.20}{100} \text{ or } P \cdot 0.1620 = \text{Sugar for 100 c.c.}$$

(5). To determine the normal glucose, 10 c.c. of No. 2 are mixed with sodium carbonate and diluted to 100 c.c., of which 30 c.c. are to be mixed with 30 c.c. copper solution, warmed in the water-bath, and the copper precipitate weighed. (6). To estimate the total sugar, 10 c.c. of liquid No. 2 are mixed in a flask of 250 c.c. capacity with 10 c.c. sulphuric acid (100 g. H_2SO_4 in the litre) and 50 c.c. water; the mixture is heated in the water-bath for half to three-quarters of an hour, then diluted to 250 c.c.; the total glucose estimated as above in 30 c.c. of the liquid, after cooling, and calculated to 100 g. of the molasses; the original amount of glucose deducted; and the difference calculated to crystallisable sugar. The ratio of the normal glucose to the difference between the crystallisable sugar determined by the saccharimeter and that determined by the copper solution, affords the means of estimating the rotatory power belonging to the reducing sugar.

On the Estimation of Saccharose and Glucose by the Optical Saccharimeter, see Landolt ('Das optische Drehungsvermögen Organischer Substanzen,' Braunschweig, 1879, 148–188).

Sugar manufacture.—On the Refining of Sugar, see Wichelhaus (*Neue Zeitschrift für die Rübenzucker Industrie*, 1878, 177–318; *Jahresb. f. Chem.* 1879, 1149; *Chem. Soc. J.* xxxiv. 690); by the use of Alumina: Kohlrausch (*Chem. Centr.* 1878, 185).

2. Lactose, or **Milk-sugar**, $\text{C}^{12}\text{H}^{22}\text{O}^{11}$. This sugar, when boiled with dilute sulphuric acid ($\frac{1}{2}$ acid diluted with 2 vols. water), the water being continually renewed as it evaporates, till a light brownish coloration is produced, splits up into two sugars or glucoses, $\text{C}^6\text{H}^{12}\text{O}^6$, viz. Dextrose and Galactose. To separate these, the solution is neutralised with calcium carbonate, mixed with baryta water, then treated with carbon dioxide, concentrated, left to crystallise slowly, and finally mixed with alcohol, whereupon the galactose separates in the form of a crystalline mass; and the mother-liquor, especially on addition of absolute alcohol, yields a second crystallisation, consisting of dextrose. The separation of these glucoses may also be effected by means of alcohol of 95–98 per cent., in which the latter is the more soluble of the two.

Galactose crystallises in prisms, melts at 118° – 120° in the air-dried state, at 142° – 144° after drying at 100° . It reduces only 4 mols. cupric sulphate, whereas dextrose reduces 5 mols. By oxidation with nitric acid it is converted into mucic acid. Heated at 160° for twenty-four hours with acetic anhydride, it is converted into pentacetyl-galactose, $\text{C}^6\text{H}^7(\text{C}^2\text{H}^3\text{O})^5\text{O}^6$, a pale gum-like substance, which softens at 62° , and melts at 66° – 67° . The dextrose from milk-sugar was at first regarded as a distinct modification, and called *Lactoglucose*; but subsequent experiments have shown that it is identical with grape-sugar. It melts in the air-dried state at 70° – 71° , and at 132° – 135° after drying at 100° (Fadakowski, *Ber.* ix. 42, 278; xi. 1069).

Synthesis of Lactose.—When the mixture of galactose and dextrose obtained

as above is heated to boiling with 3 pts. of acetic anhydride (b. p. 146° – 150°) in a reflux apparatus till the mass is completely dissolved, and the product is then treated with water, a viscid ether is formed having the composition $C^{22}H^{38}O^{19} = C^{12}H^{14}(C^2H^3O)^8O^{11}$, and identical with that which Schützenberger obtained by heating milk-sugar with excess of acetic anhydride (vi. 1045). The two products agree in melting point (52°), and in specific rotatory power, the ether prepared as above giving $[\alpha]_D = +30.82^{\circ}$, Schützenberger's ether $+31^{\circ}$; both readily give off acetic acid when exposed to the air, and when saponified with alkalis yield one and the same product, viz. milk-sugar. The specific rotatory power of the lactose thus obtained from the ether prepared as above described was found to be $[\alpha]_D = +56.7^{\circ}$, that of natural milk-sugar being $+56.4^{\circ}$. The synthetically prepared lactose, heated for two hours at 140 – 145° , yielded an anhydride, $C^{12}H^{22}O^{11}$, having a specific rotatory power $[\alpha]_D = 60.05^{\circ}$; that of dehydrated milk-sugar is, according to Biot, $[\alpha]_D = +60.28^{\circ}$; according to Berthelot, $+59.3^{\circ}$ (Demole, *Ber.* xii. 1935).

On the Alcoholic Fermentation of Milk-sugar, see MILK (p. 1325).

3. **Maltose**, $C^{12}H^{20}O^{11} + H^2O$. This isomeride of saccharose and lactose is the final product of the action of malt-extract on starch. It is less soluble in alcohol than dextrose, has a specific rotatory power of $+154$ to $+155^{\circ}$ for the transition-tint, and its cupric oxide reducing power is to that of dextrose in the ratio of 62 or 63 to 100. By the prolonged action of acids it is converted into dextrose (O'Sullivan, *Chem. Soc. J.* xxv. 579; xxxv. 771). See also STARCH (pp. 1821–1823).

4. **Melezitose**, $C^{12}H^{20}O^{11}$. This kind of sugar, first obtained from the manna of various species of Eucalyptus growing in Tasmania (vii. 869), has also been obtained from a Persian manna, originating from a leguminous plant called *Alhagi Maurorum*. The aqueous extract of the manna evaporated to a syrup and treated with animal charcoal, yields, after several months, a crop of monoclinic crystals which, after recrystallisation from alcohol of 60 per cent., are quite pure, and have the composition $C^{12}H^{22}O^{11} + H^2O$. The water of crystallisation escapes readily at 100° , or in a vacuum over sulphuric acid, slowly at ordinary temperatures.

Melezitose melts at a temperature a little above 140° , and has a dextrorotatory power of $94^{\circ} 48'$ for the transition-tint, $88^{\circ} 5'$ for the line D. When boiled with dilute acids, it yields nothing but dextrose; with nitric acid it gives oxalic but no mucic acid.

The manna, above mentioned was found to contain also saccharose and a syrupy sugar which reduced Fehling's solution, but was not fermentable. The saccharose was extracted by dissolving the mother-liquor of the melezitose in alcohol, and adding ether till the solution became turbid, the saccharose then crystallising out after a few days (A. Villiers, *Compt. rend.* lxxxiv. 35; *Ann. Chim. Phys.* [5], xii. 43).

5. Another sugar isomeric with saccharose is formed when a solution of perfectly pure glucose in absolute alcohol, well cooled with ice, is saturated in the dark with dry hydrogen chloride. The saturated solution is heated; the acid evaporated in a vacuum over sulphuric acid; the coloured syrup is saturated with caustic baryta, and repeatedly dissolved in alcohol of 94 per cent.; and the solution, after being left to evaporate without heating, is treated with ether to remove a substance having a strong bitter taste. The sugar thus obtained is colourless, has the aspect and taste of gum, is very hygroscopic, and dissolves very readily in water. At 100° it gives off $\frac{2}{3}$ of its weight of water, and becomes hard and transparent; but to obtain it perfectly anhydrous, it must be dried for several days at 130° in a stream of carbon dioxide. It is not fermentable. Its aqueous solution does not reduce Fehling's liquid. When heated at 160° , it decomposes according to the equation $C^{12}H^{22}O^{11} + H^2O = 2C^6H^{12}O^6$, yielding a sugar having the composition of glucose, but not identical therewith, inasmuch as, though it reduces a solution of copper, it has a very sweet taste and is very difficult to ferment. The compound $C^{12}H^{14}(C^2H^3O)^8O^{11}$ which Schützenberger obtained by heating cane-sugar with a large excess of acetic anhydride (vii. 1195), is perhaps the octaacetyl-derivative of this sugar, its formation being analogous to that of the aldanes (vii. 32) from the aldehydes of the fatty series (Gautier, *Bull. Soc. Chim.* [2], xxxii. 33).

Glucoses, $C^6H^{12}O^6$. **Dextroglucose** or **Dextrose**. *Occurrence*.—According to E. Mach (*Dingl. pol. J.* cccxxv. 470), the sugar of the grape in the unripe state is chiefly dextrose; at the time of the general gathering it is almost wholly invert-sugar, while during the time of over-ripening the levulose becomes predominant. During fermentation the levulose is first attacked, afterwards the dextrose; cane-sugar added to the mixture remains unaltered till the middle of the fermentation, and then disappears. Must of wine mixed with cane-sugar yields a laevorotatory wine; must mixed with grape-sugar, a dextrorotatory wine.

Dextrose occurs in *cinchona barks*, probably as a decomposition-product of quino-tannic acid (Carles, *Pharm. J. Trans.* [3], iii. 643).

Formation and preparation from Saccharose.—Durin (*Compt. rend.* lxxxvii. 754) finds by direct experiment that the conversion of the saccharose of sugar-juices into glucose is due, not to fermentation, but to purely chemical action, and that it is accelerated by heat. The presence of previously formed glucose has no influence on the result, but the reaction of the solution is of importance, the conversion being much quicker in acid or neutral than in alkaline solutions.

Neubauer (*Zeitschr. anal. Chem.* 1876, 188) prepares pure dextrose by adding white cane-sugar in fine powder by successive portions to a mixture of 500–600 c.c. alcohol of 80 per cent. and 30–40 c.c. fuming hydrochloric acid. The liquid when saturated is poured off, and left to crystallise in a covered vessel; and the crystals of dextrose thus obtained are washed with alcohol till the liquid runs off neutral, then dried, and recrystallised from boiling alcohol.

According to O. Hesse (*Lieb. Ann.* xcii. 169), the melting points of glucoses of various origin are not identical, but are always comprised between the limits 80° and 84°. *Honey-sugar* melts at 83°. *Starch-sugar*, after purification with alcohol and water, agrees with honey-sugar in every respect. On the rotatory power of these sugars, see p. 1221.

Sodium-glucose, $C^6H^{11}NaO^6$, is obtained on adding sodium ethylate to a solution of dextrose in absolute alcohol, as a white bulky precipitate, which, when quickly filtered, washed with absolute alcohol, and dried over sulphuric acid, forms a white or yellowish-white powder, extremely hygroscopic, soon becoming glutinous when exposed to the air, and apparently decomposing into sodium hydroxide and glucose. When heated in a stream of hydrogen at the temperature of the water-bath, it gives off 2 mols. water, and yields a brown amorphous mass, the formation of which begins at a temperature a little above 70°. Sodium glucosate dissolves in an alcoholic solution of bromine, yielding bromoform, and the compound $C^{12}H^{10}O^{12}NaBr$, which separates after a while in white laminar crystals (Hönig u. Rosenfeld, *Ber.* x. 871).

Acetonitrose, $C^6H^7(C^2H^3O)^4O^5NO^3$, is formed by the action of fuming nitric acid on aceto-chlorhydrose, $C^6H^7(C^2H^3O)^4O^5Cl$, the product of the action of acetyl chloride on glucose (vii. 12). The aceto-chlorhydrose required for the purpose need not be quite pure, but merely freed from acetic acid by heating it to 120°, and passing a stream of air through it. It is then to be mixed in a vessel cooled by ice, with 15 to 20 times its volume of fuming nitric acid, and the mixture, after standing for several hours, poured into ice-cold water. White flocks are then deposited, quickly changing to a heavy powder, which may easily be freed from a small quantity of unaltered aceto-chlorhydrose by crystallisation from ether and alcohol. Acetonitrose crystallises in white oblique prisms, or large rhombic plates. It is tasteless, insoluble in water, sparingly soluble in alcohol and ether, not explosive by heat or by percussion. It melts at 145°, has a density of 1.3487 at 18°, and is dextrogyrate, $[\alpha]_D = +150$. Heated to 100° in aqueous or alcoholic solution, it is converted into a body which reduces copper-solution, and is blackened by alkalis. Nascent hydrogen decomposes it with evolution of ammonia (A. Colley, *Compt. rend.* lxxvi. 437).

Detection.—For the detection of dextrose in presence of dextrin and allied bodies, C. Barfoed (*Zeitschr. anal. Chem.* 1873, 27) uses a solution of cupric acetate, which, when mixed with a solution of dextrose, gives, after a short time, a precipitate of cuprous oxide, whereas a solution of dextrin similarly treated remains unaltered for several days. Moreover, a solution of cupric acetate, very slightly acidulated with acetic acid, gives when boiled with dextrose and left to stand for a short time, a precipitate of cuprous oxide, whereas pure dextrin gives no reduction. Gum, cane-sugar, and milk-sugar behave in the same manner as dextrin. Barfoed points out that the ordinary methods of testing dextrin for dextrose are untrustworthy, inasmuch as Fehling's solution is reduced at ordinary temperatures even by very weak solutions of dextrin.

To detect glucose in presence of saccharose, R. Böttger (*J. pr. Chem.* lxx. 432) mixes the liquid with an equal volume of sodium carbonate solution (1 pt. of the crystallised salt to 3 of water), adds a pinch of *basic bismuth nitrate*, and heats the liquid to the boiling point. Under these circumstances, the slightest blackening or grey coloration of the bismuth-salt may be regarded as a sure indication of the presence of glucose. In the application of this test to the detection of glucose in urine and other animal fluids, or in vegetable juices, the blackening of the bismuth may arise from the action of sulphur resulting from the decomposition of albuminoids. To eliminate this source of error, E. Brücke (*Wien. Akad. Ber.* 1875, 52) makes use of a solution of *potassium-bismuth nitrate*, which precipitates albumin and its derivatives. This reagent is prepared by dissolving basic bismuth nitrate in a hot solution of potassium iodide, with addition of hydrochloric acid. The liquid under examination is acidulated with the same acid, then treated with the reagent, and filtered. The

filtrate should not be clouded either by a drop of dilute hydrochloric acid or by a drop of the test-liquid. This condition being fulfilled, the liquid is to be supersaturated with a concentrated alkali-solution, whereby a white flocculent precipitate is produced, and boiled. The presence of glucose will then be indicated by a blackening of the liquid from reduced bismuth.

Estimation.—(a). By *Fehling's Solution*.—C. Kraus (*Zeitschr. anal. Chem.* 1873, 323) mixes a measured volume of the sugar-solution with excess of Fehling's solution, and collects the separated cuprous oxide on a filter, dissolves it, after washing, in nitric acid, supersaturates with ammonia, and titrates with potassium cyanide. F. Mohr (*ibid.* 296) proceeds in the same manner, excepting that he oxidises the cuprous oxide with ferric sulphate or solution of iron-alum, and determines the resulting ferrous sulphate by titration with a normal solution of potassium permanganate.

Loiseau points out (*Compt. rend.* lxxvi. 1602) that the estimation of small quantities of dextrose by Fehling's solution may become inexact if the liquid contains a considerable quantity of caustic soda. If the sugar-solution be added by drops to the strongly alkaline copper-solution, a larger quantity of it will be required to destroy the blue colour than when the titration is quickly performed. If the separated cuprous oxide be boiled with strong soda-ley, and the liquid then left at rest for some time in contact with the air, it will recover its blue colour. Water alone, and a solution of normal sodium tartrate, do not exhibit this reaction. These sources of error may be avoided by reducing the alkalinity of the solution to such a point that 1 litre of the copper-solution shall be neutralised by 240 c.c. of decinormal sulphuric acid.

Boivin a. Loiseau (*Compt. rend.* lxxix. 1263) observe that Fehling's solution, when diluted with distilled water and boiled, deposits cupric oxide, and becomes more or less decolorised, but that this decoloration does not take place when river-water (Seine-water) is used instead of distilled water. They attribute the decoloration to a dissociation of the alkaline copper-solution by the pure water, which is prevented by the presence of a small quantity of soluble salts. G. Missaghi (*Gazz. chim. ital.* 1875, 414) suggests, as a more rational mode of preventing the decomposition in question, the addition of a few drops of a solution of tartaric acid or Rochelle salt to the reagent.

Champion a. Pellet (*Compt. rend.* lxxx. 181) attribute the non-decoloration of the solution in presence of certain salts, especially calcium salts, to the formation of a blue precipitate, which indeed is easily proved by adding a sufficient quantity of the salt and filtering, the liquid then running through colourless. Salts which, like the chlorides of potassium and sodium, give rise to the formation of cupric chloride, produce on boiling a greenish tinge in the liquid.

Possoz (*Compt. rend.* lxxv. 1836) observed that Fehling's solution, when it contains excess of alkali, precipitates cane-sugar as well as glucose. To prevent this, he mixes the solution with an alkaline bicarbonate, or passes carbon dioxide into it. The resulting solution of potassio-cupric tartrate + alkali-carbonate has no action on cane-sugar at 60°–90°, and may therefore be used for the estimation of glucose in presence of cane-sugar. The liquid to be tested is mixed with this solution, and kept for about three-quarters of an hour at 75°; and the cuprous hydrate formed is collected on a filter, washed, transferred while still moist to a basin, and treated with hydrochloric acid and potassium chlorate, whereby it is converted into cupric chloride, which may be titrated with stannous chloride (Champion a. Pellet, *loc. cit.*)

P. Lagrange (*ibid.* 1005) prepares a very stable Fehling's solution, not reduced by boiling either alone or with cane-sugar, by dissolving 10 pts. pure cupric tartrate in 400 caustic soda and 500 distilled water, and keeping the solution at the boiling heat for twenty-four hours, renewing the water as it evaporates. The cupric tartrate is prepared either by decomposing the sulphate with normal sodium tartrate, or by dissolving recently precipitated and well-washed cupric hydrate in the required quantity of sodium tartrate. According to Missaghi (*loc. cit.*) the only way of preserving this test-liquid from alteration is to keep it in sealed vessels.

β. With *Mercuric Iodide*.—This method is adopted by R. Sachse (*Dingl. pol. J.* cccxi. 570; *Jahresb. f. Chem.* 1877, 1087). The reagent is prepared by dissolving 18 g. pure mercuric iodide and 28 g. potassium iodide in water, adding 80 g. potassium hydroxide, and diluting to a litre. The reaction is complete when a drop of the mixture no longer produces a brown precipitate in an alkaline solution of stannous oxide. 40 c.c. of the test-solution contain 0.72 g. mercuric iodide, and are equivalent to 0.1342 g. grape-sugar.

According to Strohmmer a. Klauss (*Chem. Centr.* 1877, 713), this method is applicable only to the estimation of dextrose in pure solutions of that substance, not in solutions which also contain saccharose. It may, however, also be applied to the

estimation of invert-sugar, provided that no other kind is present in the liquid. Erythro- and achroo-dextrin (the constituents of commercial dextrin) may be boiled for a quarter of an hour with a Fehling's solution containing only half the quantity of Rochelle salt usually added to it, without producing any alteration in it, so that the estimation of dextrose by means of a copper-solution may be effected in presence of these two bodies, whereas Sachse's method would be inapplicable in such a case. In the valuation of different sorts of starch-sugar also, the results obtained by Sachse's method are too high, whereas Fehling's solution, applied with all the precautions already indicated, gives satisfactory results.

According to Heinrich, on the other hand (*Chem. Centr.* 1879, 409), dextrose and invert-sugar may be correctly determined in the presence of very varying amounts of saccharose by the use of an alkaline solution of mercuric iodide containing a smaller proportion of potash than that directed by Sachse. The test-liquid contains 25 grams potassium iodide, 18 grams mercuric iodide, and 10 grams potassium hydroxide in 1000 c.c. water. For the determination of small quantities of invert-sugar not more than 5 c.c. (preferably 2.5 c.c.) of the standard liquid should be employed, which should be previously titrated against a very dilute sugar-solution prepared by inverting saccharose. If less than 0.1 per cent. invert-sugar be present in the liquid under examination, 2.5 c.c. of a solution prepared by dissolving 10 grams KHO in 1000 c.c. water, should be added to each 2.5 c.c. of the standard solution before titration. The standard potassio-mercuric iodide liquid containing only 10 grams KHO per litre is not affected by ammonium salts.

Levulose, $C^6H^{12}O^6$. According to Krusemann (*Ber.* ix. 1465), the rotatory power of levulose (prepared by heating inulin from elecampane-root with water under pressure) varies with the time during which the heating has been continued, increasing at first up to a certain point, and afterwards diminishing; thus:

After heating for .	8	16	24	32	40	48	56	64 hrs.
The rot. power was	10° 27'	15° 23'	15° 44'	16° 15'	15° 24'	15° 21'	15° 17'	14° 51'

Levulose dissolved in water, and treated with sodium-amalgam at ordinary temperatures, is converted into mannitol, $C^6H^{14}O^6$. Dextrose undergoes the same transformation (Krusemann, *Ber.* ix. 1465).

Invert-sugar. **Fruit-sugar.** The mixture of equal parts of dextrose and levulose, known by these names, occurs, together with acid malates and triticein, in the root of couch-grass (H. Müller, *Arch. Pharm.* [3], ii. 500; iii. 1).

The conversion of saccharose into invert-sugar may be effected in pure solutions by heat; it is favoured by the presence of glucose, provided the saccharose-solution is not at its highest degree of concentration; considerably also by mineral salts, such as nitrate and chloride of potassium, slightly by organic salts. The percentage of saccharose inverted is in general much greater in dilute than in concentrated solution. The glucose of refinery molasses is formed by the action of the substances above mentioned (H. Pellet, *Ann. Chim. Phys.* [5], xiii. 394).

Maumené (*Compt. rend.* lxxx. 1139) finds that invert-sugar varies considerably in composition and properties according to the manner in which it is prepared, and that even when a uniform product is obtained by the use of given quantities of acid and sugar, and maintaining the action at the same temperature and for the same time, it will be variously altered by alkalis, according to the nature and quantity of the alkali used, and especially according to temperature. He regards invert-sugar as a variable mixture of dextrose, levulose, and an optically inactive sugar. This last was obtained by mixing 500 g. white honey with 1 litre of alcohol of 90 per cent. at a gentle heat, and cooling the mass nearly to 0°, whereupon a nearly colourless heavy precipitate having a bulk of 116 c.c. separated, which dissolved almost completely in water, and exhibited no rotatory power, but became slightly dextrogyrate when warmed. Milk of lime added to the cooled solution threw down a laevogyrate sugar, while the solution turned the plane of polarisation to the right.

Invert-sugar is oxidised by nitric acid to oxalic acid, by manganese dioxide and sulphuric acid, and by lead dioxide to formic acid (H. Müller, *Arch. Pharm.* [3], iii. 1).

On the Estimation of Invert-sugar by means of a solution of Potassio-mercuric Iodide, see above.

Inosite and **Nucite**, $C^6H^{12}O^6$. Tanret a. Villiers (*Compt. rend.* lxxxvi. 486) found that inosite from muscular flesh and from green peas is crystallographically identical with nucite obtained from the leaves of the walnut (p. 1421). They also find that inosite is accompanied in plants by a fermentable sugar which reduces Fehling's solution, on which account they consider that inosite may be a product of the transformation of glucose.

Matezite, $C^{10}H^{20}O^9$. This sugar has been found by Aimé Girard (*Compt. rend.* lxxvii. 995) in the caoutchouc of Madagascar, accompanying bornesite and dambonite (vii. 206, 421), which it closely resembles. Matezite is white, crystallisable, easily soluble in water, sparingly in alcohol, from which it separates in groups of crystalline nodules, hard and grating between the teeth. It melts at 181° , and, when cautiously heated, sublimes at 200° – 210° . It is lævogyrate, its rotatory power being 79° . With sulphuric acid, nitric acid, copper-solution, and ferments, it reacts in the same manner as dambonite and bornesite. Heated with fuming hydriodic acid in a sealed tube at 110° , it is resolved into methyl iodide and another sugar, $C^9H^{18}O^9$, called matezodambrose:

Matezodambrose is sweet, easily crystallisable, more soluble in water than dambose or borneodambrose. It is dextrogyrate, with a rotatory power of 6° . It melts at 235° , and behaves to reagents like dambose and borneodambrose. The following table exhibits a comparison of the properties of matezite and its analogues, and of the three sugars produced from them by the action of hydriodic acid:

	M. p.	Rot. power		M. p.	Rot. power
Dambonite, $C^4H^8O^6$. . .	205°	none	Dambrose, $C^8H^{16}O^8$. . .	212°	none
Bornesite, $C^7H^{14}O^6$. . .	200	+32°	Borneodambrose, $C^6H^{12}O^6$. . .	220	none
Matezite, $C^{10}H^{20}O^9$. . .	181	–79°	Matezodambrose, $C^9H^{18}O^9$. . .	235	+6°

SULPHACETAMIDE, $CH^3.CS.NH^2$. See THIAMIDES.

SULPHACROLEINSULPHUROUS ACID,

The potassium salt of this acid is formed by adding 1 mol. acrolein by small portions to a well-cooled concentrated solution of 2 mols. sodium-hydrogen sulphite, and is precipitated from the resulting solution by alcohol in the form of a thick mud which gradually solidifies to crystalline nodules. On its products of decomposition, see OXYPROPANESULPHONIC ACID (p. 1473) (Max Müller, *Ber.* vi. 1441).

SULPHALKYLACETIC ACIDS, $R^1.S.CH^2.COOH$ (Claesson, *Ber.* viii. 120). *Sulphethylacetic acid*, $C^4H^8SO^2 = C^2H^3.S.CH^2.COOH$.—The ethylic ether of this acid, first noticed by Blomstrand (*ibid.* iv. 717), is formed with great evolution of heat, on mixing the alcoholic solutions of ethyl monochloracetate and sodium mercaptide:

On filtering the liquid from the separated sodium chloride and adding water, the ether separates as an oily liquid; and by heating it in sealed tubes with baryta-water, precipitating the excess of baryta with carbonic acid, and decomposing the barium salt with sulphuric acid, the sulphethylacetic acid is obtained in the form of an uncrystallisable oil. It dissolves readily in alcohol and ether, with moderate facility in water, is partly decomposed when volatilised alone, but may be distilled with vapour of water. Its salts are very easily soluble in water and in alcohol, and do not bear so high a temperature as those of the corresponding phenylated acid (p. 1842). They are oxidised by nitric acid, and yield a brown viscid precipitate with iron salts.

The *potassium salt*, $C^2H^5S.CH^2.CO^2K$, forms deliquescent crystalline crusts slightly soluble in alcohol. The *silver salt*, $C^4H^8SO^2Ag + H^2O$, is a crystalline precipitate which does not give off its water over sulphuric acid. The *barium salt*, $(C^4H^8SO^2)^2Ba$, and the *calcium salt*, $(C^4H^8SO^2)^2Ca$, form radiate groups of needles; the *lead salt* is a viscid mass. The *magnesium salt*, $(C^4H^8SO^2)^2Mg + 3H^2O$, and the *zinc salt*, $(C^4H^8SO^2)^2Zn + 2H^2O$, are crystalline masses. The *cadmium salt*, $(C^4H^8SO^2)^2Cd + H^2O$, is less soluble than the preceding salts, and crystallises in prisms which melt and give off their water at 85° . The *manganese salt* exhibits similar characters. The *cobalt salt*, $(C^4H^8SO^2)^2Co + 2H^2O$, forms small violet-red very soluble prisms. The *nickel salt*, $(C^4H^8SO^2)^2Ni + 2H^2O$, is greenish, and in other respects resembles the cobalt salt. The *copper salt*, $(C^4H^8SO^2)^2Cu + 2H^2O$, forms small shining rhombic plates, which melt at 90° , and decompose with great facility. The *ethylic ether*, $C^4H^8SO^2.C^2H^5$, prepared as above described, is a strongly refracting oil having a powerful odour, a density of 1.0469 at 4° , and boiling at 187° – 189° . It is not acted upon by iodine, but bromine attacks it strongly. Ammonia converts it into *sulphethylacetamide*, $C^2H^3.S.CH^2.CO.NH^2$, which crystallises in long thin prisms melting at 44° , easily soluble in water and in alcohol, decomposing partially when volatilised. On heating this ether and methyl iodide in molecular proportion in a sealed tube at 120° , and leaving the product to evaporate in a vacuum, yellowish crystals are ob-

tained, consisting of *ethylic diethylsulphiniiodacetate*, $(C^2H^5)^2I \cdot S \cdot CH^2 \cdot COOC^2H^5$, which, when shaken with silver oxide, yield a strongly alkaline solution.

Sulphamylacetic acid, $C^6H^{11}S \cdot CH^2 \cdot CO^2H$, is a thick liquid. Its *ethylic ether* boils at 230° , and has a density of 0.797 at 4° . Its salts, excepting those of its alkalis, are but sparingly soluble. The *zinc* and *cadmium salts* are white precipitates; the *copper salt* crystallises in slender needles. The lead salt is very easily fusible.

Sulphphenylacetic acid, $C^6H^5SO^2 = C^6H^5 \cdot S \cdot CH^2 \cdot COOH$.—The *ethylic ether* of this acid, prepared like that of sulphethylacetic acid, from ethyl chloracetate and sodium phenylmercaptide, is converted by alcoholic potash into a potassium salt which separates in crystalline spangles, and by decomposing this salt with hydrochloric acid, the free acid is obtained as an oil which soon solidifies to a crystalline mass, and separates from a hot dilute solution on cooling in thin brittle plates. It melts at 43.5° , and resolidifies at 28° ; dissolves in all proportions in alcohol and ether, sparingly in cold water, easily in hot water; the solutions have a strong acid reaction. It is not distillable alone, but volatilises with vapour of water. It is not decomposed by boiling with dilute acid.

The metallic sulphphenylacetates are for the most part slightly soluble in water, insoluble in alcohol; they may all, except the copper salt, be heated to 100° without alteration, but begin to blacken and decompose at 200° . The *potassium salt*, $C^6H^5S \cdot CH^2 \cdot CO^2K$, crystallises in thin needles having a silky lustre, moderately soluble in hot water; it is not decomposed either by boiling its solution, or by fusing it with potash. The *sodium salt*, $C^6H^5SO^2aN$, which may be obtained directly by decomposing sodium monochloracetate with an alcoholic solution of sodium phenylmercaptide, forms crusts made up of nodular groups of crystals. The *silver salt*, $C^6H^5SO^2Ag + H^2O$, is a white precipitate. The *barium salt*, $(C^6H^5SO^2)^2Ba$, is a crystalline mass of slender needles moderately soluble in hot water. The *calcium salt*, $(C^6H^5SO^2)^2Ca$, forms groups of oblique tablets. The *lead salt*, $(C^6H^5SO^2)^2Pb$, is an amorphous precipitate which quickly hardens and melts at 60° . The *magnesium salt*, $(C^6H^5SO^2)^2Mg + 3H^2O$, forms shining scales; the *zinc salt*, $(C^6H^5SO^2)^2Mg + 2H^2O$, radiate groups of long silky needles; the *cadmium salt*, $(C^6H^5SO^2)^2Cd + H^2O$, shining scales. The *manganese salt*, $(C^6H^5SO^2)^2Mn + 5H^2O$, is a bulky mass of oblique tables. The *copper salt*, $(C^6H^5SO^2)^2Cu$, is a green amorphous easily alterable precipitate, becoming viscid when exposed in the moist state to the air, and being converted by warming with water into tarry masses consisting of a basic salt. The normal salt dissolves readily in ammonia, the solution when left to evaporate in a vacuum leaving blue prisms. The *cobalt*, *nickel*, *aluminium*, *ferrie*, and *chromic salts* are amorphous precipitates. The *ethylic ether*, $C^6H^5S \cdot CH^2 \cdot CO \cdot OC^2H^5$, is a liquid boiling with partial decomposition at 276° – 278° , and having, when pure, a sweetish, aromatic, not unpleasant odour. Sp. gr. = 1.136 at 4° ; 1.1269 at 15° . The *amide*, $C^6H^{11}S \cdot CH^2 \cdot CO \cdot NH^2$, prepared from it, crystallises from alcohol in small plates melting at 104° , easily soluble in alcohol, less soluble in water, very slightly in ether.

Bromosulphphenylacetic acid, $C^6H^4Br \cdot S \cdot CH^2 \cdot COOH$.—The *ethylic ether* of this acid is formed, with brisk reaction, on adding bromine to a solution of *ethylic sulphphenyl acetate* in carbon sulphide, and by converting it into the potassium salt with alcoholic potash, and decomposing this salt with hydrochloric acid, the free acid is obtained in shining, sparingly soluble needles which melt at 112° .

Oxidation-products of the Sulphalkylacetic Acids. By acting on a salt of either of the preceding acids with potassium permanganate (not with nitric acid, potassium chromate, &c.), it is possible to oxidise the sulphur to SO or SO^2 , without completely breaking up the molecule. In this way the following acids have been obtained.

Sulphonethylacetic acid, $C^4H^5S^2O^4 = C^2H^5 \cdot SO^2 \cdot CH^2 \cdot COOH$.—This acid, separated from its zinc salt by hydrogen sulphide and concentrated in a vacuum, forms a thick uncrystallisable liquid, which, as well as most of its salts, is very soluble in water. The *potassium salt*, $C^4H^5S^2O^4K$, crystallises from alcohol in small colourless very hygroscopic tablets; the *barium salt*, $(C^4H^5S^2O^4)^2Ba$, in small nodules; the *copper salt*, $(C^4H^5S^2O^4)^2Ca + 2H^2O$, in rather large bluish tablets, which give off their water at 140° . The *zinc salt* and the *silver salt* are moderately soluble; the latter crystallises in small needles. The *lead salt* forms small very soluble tablets.

Sulphonephenylacetic acid, $C^6H^5S^2O^4 = C^6H^5 \cdot SO^2 \cdot CH^2 \cdot COOH$, separates on adding an acid to the concentrated solution of its potassium salt, in the first instance as an oil; and on dissolving this in ether and leaving the ether to evaporate, the acid remains in the form of an oil which quickly solidifies. By recrystallisation from water it is obtained in small monoclinic crystals, which melt at 100° , have a very sour taste, and dissolve readily in alcohol and ether. Its salts are more soluble than those of

sulphphenylacetic acid, the potassium and zinc salts being even deliquescent. The *copper salt*, $(C^6H^5SO^2)^2$, forms small green moderately soluble tablets.

Sulphphenylacetic acid, $C^6H^5SO^2 = C^6H^5.SO.CH^2.COOH$, prepared by oxidising sulphphenylacetic acid with half the quantity of permanganate required for the production of the acid last described, forms colourless crystals melting at 74° . The *copper salt* is a greyish amorphous precipitate.

SULPHAMIDES. The action of phosphorus pentachloride on some of these bodies has been studied by Wallach a. Huth (*Ber.* ix. 424), with results leading to the following general conclusions: (1). Under certain circumstances, phosphorus pentachloride acts like a mixture of chlorine and the trichloride. (2). The production of phosphoretted intermediate products in this reaction appears to be dependent on the particular amidogen-residue attached to the sulpho-group. (3). The oxygen of the group SO^2NH^2 cannot be replaced by chlorine.

Benzenesulphanilide and PCl^5 act upon one another at about 100° in the manner represented by the equation:

The resulting *benzenesulphomonochloranilide* may be obtained by precipitation from the alcoholic solution with water, or better from the benzene solution by precipitation with petroleum-ether, and repeated slow crystallisation from benzene, in splendid crystals melting at 120° – 121° . From ether it crystallises in pyramids. When decomposed by hydrochloric acid it yields monochloraniline melting at 70° :

Benzenesulphomonochloranilide may also be prepared synthetically from monochloraniline and benzenesulphochloride. The isomeric compound, *chlorobenzenesulphanilide*, $C^6H^4Cl.SO^2.NH.C^6H^5$, prepared from parachlorobenzenesulphochloride and aniline, forms needle-shaped crystals melting at 104° .

The action of phosphorus pentachloride on *benzenesulphamide* is in its first stage the same as that which takes place between PCl^5 and benzenesulphotoluide, being represented by the equation:

but the compound $C^6H^5.SO^2.NHCl$ is not obtained in the free state, as it is further acted upon by the phosphorus trichloride in the manner represented by the equation:

whereas on benzenesulphochloranilide phosphorus pentachloride exerts scarcely any action.

Wallach a. Huth have confirmed the statements of Limpricht a. von Usler (*v.* 486) respecting the action of phosphorus pentachloride on *sulphobenzamide*, $C^6H^5N^2SO^2 = C^6H^5(SO^2NH^2)(CONH^2)$, which takes place according to the equation:

the resulting compound forming a yellow syrup, which is further decomposed during distillation, yielding $POCl^3$ and chlorobenzonitril.

On *Mesitylene-sulphamide*, $C^6.CH^3.H.CH^3.H.CH^3.SO^2NH^2$, and *Parasulphamine-mesitylenic acid*, $C^6.CO^2H.H.CH^3.SO^2NH^2.CH^3.H$, see pp. 1284, 1285.

Sulphamine-isophthalic acids, $C^6H^5NO^5 = C^6H^5(CO^2H)^2(SO^2NH^2)$, are formed by oxidation of sulphaminetoluic acids, $C^6H^5(SO^2NH^2)(CH^3)(CO^2H)$, and these again by oxidation of xylenesulphamides, $C^6H^5(SO^2NH^2)(CH^3)^2$ (*q.v.*)

SULPHIDES. Rammelsberg (*Ber.* vii. 152) draws attention to the analogy which exists between the dimorphism of iron disulphide and that of the native sulpharsenides of iron, nickel, and cobalt. There are, in fact, two series of minerals of the general formula $RA^2S(RSbS)$, in which $R = Fe, Ni, Co$, either singly or mixed in various proportions, the minerals of the one series being similar in crystalline form, tendency to hemihedry, and thermoelectric properties to cubical iron pyrites, while those of the other series are similar to marcasite (*iii.* 402). Since RA^2S may be regarded as $RA^2 + RS^2$, it follows that the metallic arsenides are isomorphous with the disulphides. But the composition of the arsenides of the above metals varies between wide limits, whilst the crystalline form remains the same, as is shown by the following examples: Fe^2As^4 (from Przibram), $FeAs^2$ (Schladming), R^2As^3 (smaltine from Reichelsdorf), RA^2S (Schneeberg), RA^2S (Reichelsdorf), $CoAs^3$ (Norway). This would indicate that the arsenides themselves are *isomorphous mixtures*, and, therefore, that though iron and arsenic separately crystallise in different systems, they are yet capable of crys-

tallising isomorphously when allied together. This is further shown by the occurrence of NiAs and NiSb in the hexagonal system, or isomorphous with arsenic and antimony themselves.

These considerations both explain, and receive support from, the almost invariable occurrence of sulphur, in the most variable proportions, in the natural arsenides of iron, &c. Thus Rammelsberg has found gersdorffite (amoibite) to have the formulæ $\text{Ni}^2\text{As}^2\text{S}^2$, $\text{Ni}^2\text{As}^2\text{S}^2$, $\text{Ni}^2\text{As}^2\text{S}^2$, &c. These compounds may be regarded as formed by the union of RS^2 with x molecules of the isomorphous compound R^mAs^n .

Heat of Formation of Metallic Sulphides.—The following determinations of the quantities of heat evolved in the action of hydrogen sulphide on metallic oxides in solution have been made by Berthelot (*Compt. rend.* lxxviii. 1175, 1247).

			kil.-deg.
Na^2O (1 mol. in 1 litres)	+	H^2S (dissolved in 16 litres)	3·85
2NH^3	+	H^2S	3·1
BaO (1 mol. in 10 litres)	+	H^2S	3·9
MnO (precipitated)	+	H^2S	5·1
FeO	+	H^2S	7·3
ZnO	+	H^2S	9·6
PbO	+	H^2S	13·3
CuO	+	H^2S	15·8
HgO	+	H^2S	24·35
Ag^2O	+	H^2S	27·9

On comparing these numbers with the heats of neutralisation of the same bases with other acids, as hydrochloric, nitric, sulphuric, and acetic acid (p. 957), it is found that the heat evolved in the formation of the alkali-metal sulphides in solution is much less than that which is evolved in the formation of the corresponding chlorides, sulphates, acetates, &c.; and accordingly these sulphides are entirely or almost entirely decomposed by hydrochloric, sulphuric, and acetic acid. The thermal determinations showed that the quantity of heat evolved in this reaction is nearly equal to the difference between the heats of neutralisation of the two acids by the alkaline base.

The action of hydrogen sulphide on metallic salts differs considerably according to the nature of the metals and acids, as well as according to the concentration of the solution. Hydrogen sulphide precipitates the dilute solutions of lead, copper, mercury, and silver salts, the reaction being always attended with evolution of heat, which is in accordance with the results of calculation for the solid anhydrous salts. The action of gaseous hydrogen sulphide on the solid acetates of lead and copper gives rise to evolution of heat, and consequently decomposes them. For the chlorides of lead, copper, and mercury on the other hand, negative results are obtained, and accordingly these chlorides are decomposed by hydrogen sulphide only in dilute solution, while on the other hand the corresponding sulphides are decomposed by gaseous hydrogen chloride and even by fuming hydrochloric acid. In like manner solid silver sulphide is decomposed by gaseous hydrogen chloride, bromide, and iodide with evolution of quantities of heat, least with the chloride, greatest with the iodide.

Decomposition in presence of Water.—According to De Clermont a. Frommel (*Compt. rend.* lxxxvii. 230) metallic sulphides in contact with water are first converted into hydrates, which then decompose with separation of hydrogen sulphide, the water in which they are suspended not taking any part in the reaction. On boiling sulphides with water in a vacuum, decomposition was observed to take place at the following temperatures: with arsenious sulphide at 22° ; iron sulphide at 56° ; silver sulphide at 89° ; antimonious sulphide at 95° . The decomposition of arsenious sulphide by boiling with water exhibits certain peculiarities. The evolution of hydrogen sulphide, which is rapid at first, gradually diminishes in consequence of the formation of an oxy-sulphide of smaller dissociation-tension, the decomposition of which is slower, but nevertheless goes on till the whole of the arsenious sulphide is removed. The decomposition of the sulphide goes on more quickly after addition of crystallised arsenious oxide, than on addition of the vitreous oxide resulting from decomposition of the sulphide. Artificial arsenious sulphide prepared by fusion is but slightly decomposed by water; the native sulphide has a higher tension of dissociation. Native crystallised realgar gave at first a small quantity of hydrogen sulphide, the evolution of which, however, soon ceased, and was probably due to a slight admixture of orpiment, the bisulphide itself not appearing to be decomposed, *Arsenic pentasulphide*, which was never obtained pure, either by precipitation from arsenic acid or from soluble sulpharsenates, yielded as products of decomposition merely arsenious acid and sulphur, never arsenic acid.

On the reduction of the Noble Metals by Metallic Sulphides in Mineral Veins, see METALS (p. 1287).

Action of Acid Potassium Sulphite.—The evolution of hydrogen sulphide observed by Jannettaz (p. 1169) on triturating galena with a solution of this salt, takes place also with other native sulphides, briskly with alabandine, MnS , less strongly in the case of zinc-blende, ZnS , greenockite CdS , and millerite ZnS (Jannettaz, *loc. cit.*)

Action of Ether.—The action of ether on sulphur and various sulphides of iron has been studied by Berthelot (*Compt. rend.* lxxxviii. 890). In every case, on the evaporation of the filtered liquid, crystals of pure sulphur were first deposited, and afterwards a compound containing carbon, hydrogen, and a considerable proportion of combined sulphur. This compound is the result of the chemical action of the sulphur on the solvent, aided by the influence of atmospheric oxygen. The reaction is analogous to that which occurs between free oxygen and hydrocarbons, alcohols, ethers, or aldehydes, by which various ill-defined resinous compounds are produced. In the case of iron sulphides treated with ether, the oxygen of the air unites with the metal, setting free the sulphur, which simultaneously acts on the organic solvent. It is evident, therefore, that the so-called neutral solvents do sometimes act chemically on the substances with which they are placed in contact. Hence statements respecting the pre-existence in meteorites of crystallisable hydrocarbons capable of extraction by organic solvents must be received with great caution.

Oxidation.—Use of Metallic Sulphides as Fuel.—A new application of rapid oxidation by which sulphides may be utilised for fuel has been made by J. Hollway (*Journal of the Society of Arts*, February 1879). When air is blown into molten ferrous sulphide, oxidation proceeds rapidly, in accordance with the equation $\text{FeS} + \text{O}^2 = \text{FeO} + \text{SO}^2$, much heat being evolved. This reaction may be utilised by melting iron pyrites with coke in a cupola furnace, transferring the molten ferrous sulphide thus produced to a Bessemer converter, turning on the blast, and from time to time throwing in charges of pyrites and sandstone. In this way, large quantities of pyrites are oxidised without the use of fuel other than that required to heat the blast. A siliceous slag is produced, a quantity of mixed slag and regulus, and a regulus containing nearly the whole of the copper, silver, and gold present in the original pyrites. Preliminary experiments show that the process is of wide application. The special form of plant to be adopted has not yet been determined, the Bessemer converter having been employed only in preliminary trials. The pyrites and sandstone may be thrown into the vessel in lumps.

The experiments hitherto made establish the following points:

When air is blown into a thin stratum of molten ferrous sulphide, the whole of the oxygen is utilised for oxidation. Pyrites being thrown in, as already described, about one-half of the sulphur contained therein is expelled in the free state, with the more volatile metallic sulphides, *c. g.*, lead and arsenic sulphide together present in the pyrites. The plant may be so arranged that this sulphur may be condensed and removed.

The remainder of the sulphur, about 20 per cent. in all, with the exception of that found in the regulus, is principally evolved as sulphur dioxide. The regulus generally contains about 22 per cent. of sulphur; the pyrites about 33 per cent. About 14 per cent. of the escaping gases consists of sulphur dioxide, the remainder being nitrogen. The sulphur dioxide may of course be utilised in the manufacture of sulphuric acid; or it may be condensed in coke towers.

In the ordinary method of burning pyrites, although about 45 per cent. of the sulphur is oxidised, the gases produced contain only about 16 per cent. of sulphur dioxide and 84 per cent. of nitrogen.

If an excess of iron sulphide is always present, copper, silver, gold, nickel, and certain other metals are all concentrated in the regulus. Even if these metals be added in the form of oxide or silicate, it is very probable that these compounds will be converted into sulphides, and that the metals will be concentrated in this form in the regulus. If this be proved experimentally, the process will be suitable for working poor copper ores, slags containing copper, silicates of nickel, &c.

The slag consists chiefly of ferrous ortho-silicate, generally containing traces of copper, small quantities of lead, zinc, &c., and a small percentage of sulphur. The slag being perfectly fused, only small quantities of copper are entangled therein. The small difference between the specific gravity of the slag and that of the regulus (average 4.1 and 4.8 respectively) prevents the complete separation of the latter. It might, however, be possible to add a larger proportion of silica, and so produce a lighter slag.

The exact character of the lining to be used in the furnace remains to be settled:

if sufficient silica be added to produce a slag containing a proportion of silica larger than that required by the formula $\text{SiO}_2 \cdot 2\text{M}^{\text{ro}}\text{O}$, the molten slag will exert little or no action on a siliceous lining. In one experiment a peculiar slag was obtained, having the composition $13\text{FeO} \cdot \text{FeS} \cdot 7\text{SiO}_2$, a density of 4.2, a metallic aspect, and crystallised in confused prisms.

Double Sulphides. Sulphur Salts. R. Schneider (*Pogg. Ann.* cxxxvi. 460; cxlviii. 625; cxlix. 381; cli. 437; cliii. 588; *Jubelbd.* 1874, 158; *J. pr. Chem.* [2], vii. 214; ix. 209; x. 55).

1. Containing Bivalent Metals. The *potassium-zinc salt*, $\text{K}_2\text{S}_3\text{ZnS}$, is formed by fusing 1 pt. zinc sulphate, 24 potassium carbonate, and 24 sulphur, at a bright red heat for ten minutes, and remains, on treating the cooled melt with water, in colourless, rhombic laminae, which may be separated by levigation from unaltered zinc sulphide. It is permanent in the air at ordinary temperatures, not even losing its lustre, and appears to undergo only superficial oxidation when heated to redness in an open vessel. It likewise remains unaltered when heated to redness in a stream of hydrogen. It resists the action of water, but is decomposed by mineral acids, even when very dilute, with violent evolution of hydrogen sulphide. When suspended in water holding nitrate of silver or copper in solution, it is converted into the salts Ag_2S , 3ZnS , and CuS , 3ZnS respectively. It is not attacked by mercuric chloride, lead nitrate, or thallous sulphate. The corresponding *sodium salt*, $\text{Na}_2\text{S}_3\text{ZnS}$, is obtained in the same manner as the potassium salt, but is far inferior to the latter in permanence and in external beauty.

Cadmium sulphide, fused with potassium carbonate and sulphur yields, not a double sulphide, but only the crystallised cadmium sulphide formerly obtained in the same manner by Schüller (*Liebig's Annalen*, lxxxvii. 34); the crystals are hexagonal prisms with pyramidal summits. By fusing 1 pt. cadmium sulphide with 12 pts. dry sodium carbonate and 12 pts. sulphur, the double sulphide $\text{Na}_2\text{S}_3\text{CdS}$ is produced, but it has not been obtained quite pure, as it is decomposed by water, and dilute alcohol, though it does not decompose the compound, fails to remove a certain quantity of sodium sulphate formed simultaneously with it.

Nickel-potassium Sulphide, $\text{K}_2\text{S}_3\text{NiS}$, is prepared by fusing 1 pt. crystallised nickel sulphate over a lamp urged by a blast of air, with 9 pts. pure potassium carbonate and 9 pts. sulphur, keeping the mass in red-hot fusion for about ten minutes, and treating the cooled melt with cold de-aërated water. The double sulphide then remains in crystalline laminae, which have a speiss-yellow colour and metallic lustre, and when examined under the microscope appear partly hexagonal, and frequently split in the direction of three lines running from three alternate summits to the centre of the hexagon; partly lozenge-shaped, and then often joined together in rows. This compound alters very quickly in contact with air and water; when ignited in a stream of hydrogen, it gives off only one-fourth of its sulphur. When nickel sulphide is fused with sulphur and *sodium carbonate* (in the proportion 1 : 6 : 6), crystalline laminae are obtained, resembling the potassium compound just described, but of somewhat darker colour, and becoming nearly black-brown when dry.

Cobalt-potassium Sulphide has not been obtained, at least not in the pure state. When metallic cobalt or cobaltous chloride is fused with potassium carbonate and sulphur, a very pure cobalt sesquisulphide, Co_2S_3 , is easily obtained, forming iron-grey crystalline laminae, which appear under the microscope like fissured hexagons, mostly with jagged edges. They are but slightly attacked by hydrochloric acid, or even by aqua regia.

Manganese-potassium Sulphide, $\text{K}_2\text{S}_3\text{MnS}$.—Völker obtained this compound in dark-red anhydrous laminae, by fusing anhydrous manganous sulphate with potassium carbonate, lamp-black, and sulphur (*Gmelin's Handbook*, English Ed. iv. 237). Schneider, by fusing 1 pt. manganous sulphate with 12 pts. K_2CO_3 and 12 pts. sulphur, obtained, not a double salt, but only manganous sulphide in the form of a green crystalline powder, appearing under the microscope to consist of groups of needles. The *sodium salt*, $\text{Na}_2\text{S}_3\text{MnS}$, was obtained by Völker (*loc. cit.*) in small shining light-red needles, by a process similar to that employed for the preparation of the potassium salt. Schneider, by fusing together 1 pt. crystallised manganous sulphate, 6 pts. sodium carbonate, and 6 pts. sulphur at a bright-red heat, obtained the compound $\text{Na}_2\text{S}_3\text{MnS}$, in small thin flesh-coloured shining crystals having a strong tendency to oxidise.

2. Containing Trivalent Metals. *Potassio-indic Sulphide*, $\text{K}_2\text{S}_3\text{InS}_3$, is prepared by very intimately triturating 1 pt. indium oxide with 6 pts. pure potassium carbonate and 6 pts. sulphur, and fusing the mixture for eight or ten minutes, first at a moderate heat and finally at a very high temperature. The melt on cooling is found to be filled with numerous light hyacinth-red highly lustrous crystalline

laminae, which remain behind on treating the mass with water, and are obtained quite pure by washing. The laminae are quadratic, mostly very sharply defined, and often joined together in fan-shaped or rosette-shaped groups; translucent with reddish-yellow colour in thin layers. They yield nothing soluble to water, are permanent in the air at ordinary temperatures, and in closed vessels may be heated even to redness without fusion or loss of sulphur, and after cooling appear somewhat darker-coloured than before. When heated in contact with the air, they are slowly converted into a powder which is red-brown white hot, yellow-brown after cooling, and when treated with water, gives up a large quantity of potassium sulphate, but no indium. In hydrogen gas, the double sulphide may be heated to redness without decomposition. It is very easily decomposed by acids, which, if dilute, separate indium sulphide from it, but if concentrated dissolve the whole. It is not attacked by cupric sulphate, thallous sulphate, or lead nitrate, but aqueous silver nitrate converts it, without alteration of form or lustre of the crystals, into black *argento-indic sulphate*, $\text{Ag}^2\text{S}, \text{In}^2\text{S}^8$.

Sodio-indic Sulphide, $\text{Na}^2\text{S}, \text{In}^2\text{S}^8$.—A mixture of 1 pt. indium oxide, 6 pts. sodium carbonate, and 6 pts. sulphur, fused over a blast-lamp, yields a nearly homogeneous red-brown melt; and on treating this with cold distilled water, a clear yellow-brown solution is obtained, which, however, soon becomes turbid, and deposits a large quantity of a dirty-white, somewhat bulky flocculent powder, not unlike freshly-precipitated zinc sulphide. This powder, after washing and drying, has the composition $\text{Na}^2\text{S}, \text{In}^2\text{S}^8 + 2\text{H}^2\text{O}$, and at a somewhat higher temperature is easily converted into the anhydrous compound.

The white precipitate formed by ammonium sulphide in solutions of indium sulphide containing tartaric acid and supersaturated with ammonia, is, according to Schneider, not indium hydrosulphide, as commonly supposed, but ammonium-indium sulphide.

Thallosio-thallic Sulphide, $\text{TI}^6\text{S}^7 = \text{TI}^2\text{S}, 2\text{TI}^4\text{S}^8$.—When an intimate mixture of 1 pt. thallous sulphate, 6 dry sodium carbonate, and 6 sulphur is fused over a blast-lamp, a melt is obtained, appearing reddish-brown and quite homogeneous when cold, but converted by prolonged treatment with water into a yellow solution free from thallium, and a yellow powder which gradually changes to a network of bulky flocks, and when continuously washed with water, yields up all its sodium sulphide, leaving a residue of thallosio-thallic sulphide, probably formed from sodio-thallosio-thallic sulphide, $\text{Na} \left\{ \text{S}, \text{TI}^2\text{S}^8 \right\}$, produced in the first instance. Thallosio-thallic sulphide is a dark-brown, amorphous, lustreless powder, permanent in the air at ordinary temperatures. When heated in a close vessel, it melts at first without loss of sulphur, and solidifies to a crystalline mass on cooling. When more strongly heated, best in a stream of hydrogen, it gives off sulphur, and is reduced to the monosulphide TI^2S . Dilute mineral acids decompose the compound TI^6S^7 , with evolution of hydrogen sulphide and separation of sulphur.

Potassio-thallic Sulphide, $\text{K}^2\text{S}, \text{TI}^2\text{S}^8$, is obtained by melting together 1 pt. thallium sulphide or chloride with 6 pts. potassium carbonate and 6 pts. sulphur, and remains, on treating the melt with water, as a dark cochineal-red crystalline powder, which, when examined with a moderate magnifying power, is seen to be wholly made up of sharply defined yellowish-red square tablets. Sp. gr. = 4.203. Heated in hydrogen gas, it is decomposed, according to the equation,

The double sulphide is permanent in the air, is not altered by water, and melts, when heated in a small test-tube, to a black-brown liquid, which gives off only a trace of sulphur when heated to low redness, and solidifies on cooling to an indistinctly crystalline mass. When heated in the air it suffers partial oxidation. It is quickly decomposed by hydrochloric and by nitric acid, but aqueous ammonia and potash do not act upon it. Solution of silver nitrate colours it steel-blue, the potassium and part of the thallium being at the same time replaced by silver.

Thallium sulphate, fused with sulphur and *sodium carbonate*, yields, not the corresponding sodium-compound, but an unstable substance containing only thallium and sulphur, and apparently in the ratio of 4 at. Tl to 5 at. S.

3. Containing Quadrivalent Metals. *Tetraplatinous Sulphostannate*, $\text{Pt}^2\text{SnS}^8 = 4\text{PtS}, \text{SnS}^2$, is obtained, as chief product, when 4 pts. of sodio-hypoplatinous stannate, $\text{Pt}^2\text{O}, \text{Na}^2\text{O}, 2\text{SnO}^2$ (vi. 1097), are fused with 6 pts. sodium carbonate and about 8 pts. sulphur, and must be subjected to careful and prolonged levigation to free it from sodioplutinous sulphostannate, $\text{Na}^2\text{S}, 3\text{PtS}, \text{SnS}^2$, formed at the same time as a secondary product. Tetraplatinous sulphostannate is a blackish-grey crystalline

powder, appearing under the microscope as a uniform aggregate of small shining needles. It is permanent in the air at ordinary temperatures, but is completely decomposed by strong and prolonged ignition with access of air. It offers great resistance to the action of acids.

Tetraplatinous Sulphoplatinate, $\text{Pt}^4\text{S}^6 = 4\text{PtS}, \text{PtS}^2$.—This compound (and not platinumous sulphide, as stated by Vauquelin), is formed on fusing together equal parts of ammonium platinochloride, sodium carbonate, and sulphur. It crystallises in small needles having a dark steel-grey colour and metallic lustre, and apparently belonging to the orthorhombic system. In the dry state it is not altered by exposure to dry air, but quickly oxidises when moist.

Potassio-platinous Sulphoplatinate, $\text{K}^2\text{Pt}^4\text{S}^6 = \text{K}^2\text{S}, 3\text{PtS}, \text{PtS}^2$, and the corresponding sodium salt, also the *Sulphostannates*, $(\text{K or Na})^2\text{S}, 3\text{PtS}, \text{SnS}^2$, have been already described (vi. 1077).

Disodio-platinous Sulphoplatinate, $\text{Na}^4\text{Pt}^4\text{S}^6 = 2(\text{Na}^2\text{S}, \text{PtS}), \text{PtS}^2$, is formed by fusing together spongy platinum, sodium carbonate, and sulphur in the proportion 1 : 6 : 6, and remains, on treating the melt with water, in the form of small thin copper-red needles, which alter somewhat quickly in contact with the air, yielding sodium carbonate and platinum bisulphide:

Hydrochloric acid converts it into the corresponding hydrogen-compound, which is quickly oxidised on exposure to the air:

and

Diargento-platinous Sulphoplatinate, $\text{Ag}^4\text{Pt}^4\text{S}^6$, is obtained by treating the disodium salt with aqueous silver nitrate, in the form of a loose woolly mass of ash-grey thin prismatic crystals which are pseudomorphoses after the sodium-compound. The *thallium salt*, $\text{Tl}^4\text{Pt}^4\text{S}^6$, obtained in like manner with thallous sulphate, also forms pseudomorphoses after the sodium salt, having a steel-grey colour and faint lustre. It is permanent in the air, and when treated with hydrochloric acid, gives up the whole of its thallium without evolution of hydrogen sulphide.

The disodium salt, treated in like manner with *cupric sulphate*, *lead nitrate*, or *mercuric chloride*, yields analogous sulphur-salts; but it is not decomposed by the normal salts of the earth-metals: hence it appears that this salt is decomposed only by the salts of those metals which are precipitated from their neutral solutions by sodium sulphide.

Cuproplatinous Sulphoplatinate, $\text{Cu}^2\text{Pt}^4\text{S}^6 = 2(\text{CuS}, \text{PtS}), \text{PtS}^2$, forms an aggregate of faintly lustrous dark blue-grey needles, which are true pseudomorphs of the disodium salt. They are permanent in the air at ordinary temperatures, and when heated in contact with the air, smoulder away like tinder, giving off sulphur dioxide and trioxide, and leaving a blackish-grey mixture of cupric oxide and metallic platinum. Boiling hydrochloric and nitric acids decompose them partially, abstracting the copper and leaving dark steel-grey needles, and they are not completely decomposed even by boiling aqua regia.

Plumboplatinous Sulphoplatinate, $2(\text{PbS}, \text{PtS}), \text{PtS}^2$, forms a loose aggregate of dark blackish-grey needles, which are permanent in the air at ordinary temperatures, smoulder away with slight decrepitation when heated in the air, giving off sulphur dioxide and leaving a grey mixture of platinum and lead sulphate. This salt is but slightly attacked by hydrochloric acid even at the boiling heat, more strongly by nitric acid, but is not readily decomposed even by aqua regia.

A compound of mercurio-platinous sulphoplatinate with mercuric chloride, agreeing nearly with the formula $2(\text{HgS}, \text{PtS}), \text{PtS}^2 + 2\text{HgCl}^2$, is obtained by the action of a solution of mercuric chloride on disodioplatinous sulphoplatinate. It forms a loose spongy network of thin needles, having a dark ash-grey colour and very little lustre. It is decomposed by aqua regia, but not completely even after long boiling.

Lastly, by treating recently prepared and thoroughly washed disodioplatinous sulphoplatinate immersed in de-aërated water with a dilute solution of sodium-platinochloride, and leaving the resulting black-grey mass at rest for about an hour, merely stirring the platinum solution occasionally, then filtering, pressing the crystals, and drying them out of contact with the air, a compound is obtained which has the composition PtS^2 , but may be regarded as formed from the disodioplatinous salt, by

replacement of the four Na-atoms by a quadrivalent atom of platinum, and represented by the constitutional formula

It forms small, blackish-grey, faintly lustrous, needle-shaped crystals, sometimes partially flattened, and having the form of disiodoplatinous sulphoplatinate. When exposed to the air it takes up oxygen, quickly if moist, especially if heated, more slowly in the dry state, and forms sulphuric acid.

On the *Sulphopalladates*, Na_2S , PdS_2 , &c., see vol. vii., p. 889.

Sulphides of Organic Radicles. The boiling points of several alcoholic sulphides (or alkyl sulphides) have been determined by E. O. Beckman (*J. pr. Chem.* [2], xvii. 439), with the following results:

Sulphides	B. p.	Sulphides	B. p.
Dimethyl	37.1°–37.5°	Ethyl-amyl	159.7°–160.1°
Methyl-ethyl	68°	Di-isobutyl	170.5°
Diethyl	91.9°	Di-isopentyl	213°–214°
Di-isopropyl	120.5°	Ethyl-phenyl	204°

Di-isobutyl sulphoxide, $[(\text{CH}_3)_2\text{CH}.\text{CH}_2]^2\text{SO}$, melts at 68.5°; di-isopentyl sulphoxide, $[(\text{CH}_3)_2\text{CH}.\text{CH}_2.\text{CH}_2]^2\text{SO}$, at 37°.

SULPHINES. The following sulphine compounds of the fatty series have been prepared and examined by Cahours (*Compt. rend.* lxxx. 1317; lxxxi. 1163; *Ann. Chim. Phys.* [5], x. 13) in continuation of his former researches on these bodies (v. 881).

Trimethyl-sulphine bromide, $(\text{CH}_3)_3\text{SBr}$, is formed: 1. By the action of hydrobromic acid on the hydroxide, $(\text{CH}_3)_3\text{SOH}$ (v. 885), also by that of methyl bromide on methyl sulphide; and, together with methyl-benzyl sulphide, $\text{CH}_3.\text{S}.\text{C}^6\text{H}_7$, by heating 2 mols. methyl sulphide with 1 mol. benzyl bromide in a sealed tube at the temperature of boiling water:

If the mixture is diluted with methyl alcohol, methyl-benzyl oxide is formed instead of the sulphide:

2. Together with ethylene sulphide, by heating ethylene bromide with methyl sulphide in a sealed tube at 100°:

3. In like manner, together with methyl thiocetate, from methyl sulphide and acetyl bromide:

4. Together with methyl thiocyanate, by gradually dropping cyanogen bromide into cooled methyl sulphide, and finally heating the mixture at 100° for an hour or two in a sealed tube:

Trimethylsulphine bromide crystallises in prisms easily soluble in water.

Trimethylsulphine iodide, $(\text{CH}_3)_3\text{SI}$, is formed, together with benzyl iodide, by the action of methyl iodide on benzyl sulphide at 100° in a sealed tube; also, like the bromide, by the action of methyl iodide on methyl sulphide. It crystallises from water in large prisms.

Dimethylbenzylsulphine chloride, $(\text{CH}_3)_2\text{S}(\text{C}^6\text{H}_7)\text{Cl}$, is formed by treating the corresponding bromide—which is obtained as a bye-product in the action of methyl sulphide on benzyl bromide—with water and silver oxide, and then with hydrochloric acid. It unites with platinic chloride, forming the compound $[(\text{CH}_3)_2\text{S}(\text{C}^6\text{H}_7)\text{Cl}]^2\text{PtCl}_4$, which crystallises in needles (compare Schöller, p. 322).

The following salts of trimethylsulphine have been prepared by Blackie a. Crum Brown (*Chem. News*, xxxvii. 130). The *oxalate*, $[(\text{CH}_3)_3\text{S}]^2\text{C}_2\text{O}_4 + \text{H}_2\text{O}$, formed by the action of silver oxalate on trimethylsulphine iodide, crystallises in transparent hygroscopic laminae, which give off their water of crystallisation at 110°, and decompose at 140°, yielding methyl sulphide and methyl oxalate. The *chromate* and *iodate* prepared in like manner melt at 140° and then explode.

Trimethylsulphine hydrosulphide, $(\text{CH}_3)_3\text{S.SH}$, is formed by treating the hydroxide with hydrogen sulphide: $(\text{CH}_3)_3\text{S.OH} + \text{H}_2\text{S} = \text{H}_2\text{O} + (\text{CH}_3)_3\text{S.SH}$. Heated with an equivalent quantity of the hydroxide, it is converted into *trimethylsulphine sulphide*, $[(\text{CH}_3)_3\text{S}]_2\text{S}$:

The aqueous solution of this last compound, when left over phosphoric anhydride in an atmosphere of coal-gas, does not yield crystals, but is transformed, at a certain degree of concentration, into methyl sulphide, $[(\text{CH}_3)_3\text{S}]_2\text{S} = 3(\text{CH}_3)_2\text{S}$.

Trimethylsulphine sulphide, when treated with sulphur, takes up 4 at. of the latter, forming a polysulphide, $[(\text{CH}_3)_3\text{S}]_2\text{S}_4$, which, when exposed to the air for several days, gives up 3 atoms of sulphur, and is converted into *trimethylsulphinethio-sulphate*:

This salt is very hygroscopic, and crystallises in transparent four-sided prisms containing 1 mol. H_2O , which is given off over phosphoric anhydride. It is slightly soluble in alcohol, gives all the reactions of a thiosulphate, and, when cautiously heated to 135° , leaves a residue of methyl sulphide.

On Trimethylsulphine-compounds, see also H. Klinger (*Ber.* x. 1880; *Jahresb. f. Chem.* 1877, 523).

Triethylsulphine bromide, $(\text{C}^2\text{H}^5)_3\text{SBr}$, and the corresponding *chloride*, are formed by treating the hydroxide, $(\text{C}^2\text{H}^5)_3\text{SOH}$ (v. 884), with HBr and HCl respectively. The chloride forms—besides the previously known platinochloride (v. 882)—an *aurochloride*, $(\text{C}^2\text{H}^5)_3\text{SCl.AuCl}_3$, which crystallises in long golden-yellow needles, sparingly soluble in cold, moderately soluble in hot water. The *mercurochloride* forms needles having a satiny lustre.

Propyldiethylsulphine iodide, $(\text{C}^2\text{H}^5)(\text{C}^3\text{H}_7)_2\text{SI}$, is formed, like the corresponding methyldiethyl compound, by the action of propyl iodide on ethyl sulphide, $\text{C}^3\text{H}_7\text{I} + (\text{C}^2\text{H}^5)_2\text{S} = \text{C}^3\text{H}_7(\text{C}^2\text{H}^5)_2\text{SI}$, the materials being heated together in sealed tubes for several days at 100° – 120° .

Tripropyl- and Tributylsulphine iodides are formed in like manner by direct combination. Their platinochlorides are crystalline. Mixed sulphides are also formed by the action of the sulphides of propyl and butyl on the iodides of methyl and ethyl.

The two following series of compounds, containing the isomeric monatomic radicles *diethylmethylsulphine*, $\text{S}(\text{C}^2\text{H}^5)_2\text{CH}_3$, and *ethylmethylethylsulphine*, $\text{S}(\text{C}^2\text{H}^5)(\text{CH}_3)(\text{C}^2\text{H}_5)$, have been prepared by F. Krüger (*J. pr. Chem.* [2], xiv. 195), who attributes the differences in their properties to differences in the four affinities of the sulphur-atom.

(1). *Diethylmethylsulphine-compounds*.—When ethyl sulphide and methyl iodide in molecular proportions are heated with a little water on a water-bath, diethylmethylsulphine iodide is obtained as a reddish-brown syrupy uncrystallisable liquid; and on agitating this liquid with moist silver chloride, the corresponding chloride, $\text{S}(\text{C}^2\text{H}^5)_2(\text{CH}_3)\text{Cl}$, is formed, which dries up in a vacuum to a pale syrup. The *hydroxide*, which was obtained by decomposing the iodide with moist silver oxide, is likewise uncrystallisable, and is a powerful base; the *nitrate* and *sulphate* crystallise in a vacuum in long deliquescent needles; the *oxalate* and *picrate* could not be obtained in crystals.

On adding platinic chloride to a solution of the chloride, the *platinochloride*, $[\text{S}(\text{C}^2\text{H}^5)_2(\text{CH}_3)\text{Cl}]_2\text{PtCl}_4$, is obtained as a pale red crystalline powder, which is sparingly soluble in cold water, insoluble in alcohol and ether, and crystallises from hot water in cubes, octahedrons or tetrahedrons, which crumble to a powder on drying. It melts at 214° with decomposition.

The *aurochloride*, $\text{S}(\text{C}^2\text{H}^5)_2(\text{CH}_3)\text{Cl.AuCl}_3$, is readily soluble in alcohol, ether, and hot water, and crystallises in long pale yellow needles, melting with decomposition at 192° .

The *mercurochloride*, $\text{S}(\text{C}^2\text{H}^5)_2(\text{CH}_3)\text{Cl.6HgCl}_2$, is a thick white crystalline precipitate, sparingly soluble in cold water, alcohol, and ether. It crystallises from hot water in prisms resembling rock-crystal, and melting at 198° without decomposition, which takes place only at a higher temperature.

Compound of Diethyl-methyl cyanide with Mercuric iodide, $\text{S}(\text{C}^2\text{H}^5)_2(\text{CH}_3)(\text{CN}).\text{HgI}_2$. When a solution of the crude iodide containing hydriodic acid is mixed with a hot solution of mercuric cyanide, the smell of carbamines and hydrocyanic acid is given off, and a yellow oil is precipitated, which solidifies on cooling, and is insoluble in all solvents. But when cold solutions are mixed, only hydrocyanic acid is evolved, and yellow quadratic crystals separate out, which are insoluble in alcohol, ether, and

carbon sulphide, and very slightly soluble in water, this solution, when evaporated, leaving the compound as an amorphous mass. Its formation is represented by the equation:

It melts at 115° , and decomposes at a slightly higher temperature into mercuric iodide, a carbamine, and a liquid smelling like ethyl sulphide. When treated with hydrogen sulphide in presence of water, it yields mercuric sulphide, which undergoes the known changes of colour, and on continuing the action of the gas, ultimately becomes red, being converted into cinnabar, which, when heated, sublimates as a black mass, yielding again a red powder. Analogous compounds of sulphine-cyanides and mercuric iodide give the same reaction, whereas the double mercuric sulphine-chlorides give black mercuric sulphide.

(2). *Ethylmethylethylsulphine-compounds*. — The iodide, $S(C^2H^3)(CH^3)(C^2H^3)I$, obtained by heating ethylmethyl sulphide with ethyl iodide and a little water, crystallises in a vacuum in long very deliquescent needles. The chloride does not crystallise; the nitrate and sulphate are as deliquescent as the corresponding salts of diethylmethylsulphine.

The *platinochloride*, $(SC^2H^3.CH^3.C^2H^3Cl)^2PtCl^4$, is a dark red crystalline precipitate insoluble in ether and alcohol, and crystallising from water in apparently monoclinic prisms, which on drying crumble to a rose-coloured powder, and melt with decomposition at 186° . When repeatedly recrystallised or heated for some time with water, it changes into the isomeric diethylmethylsulphine-compound.

$SC^2H^3.CH^3.C^2H^3ClAuCl^3$ is a pale-yellow crystalline powder, readily soluble in hot water, alcohol, and ether, and melting with decomposition at 178° .

$SC^2H^3.CH^3.C^2H^3Cl, 2HgCl^2$ is a white crystalline precipitate crystallising from hot water in rhombic plates, melting at 112° ; under water it melts below 100° , and does not then crystallise any more.

$SC^2H^3.CH^3.C^2H^3CN, HgI^2$ is an amber-yellow precipitate consisting of apparently monoclinic prisms; it is insoluble in water, alcohol, and ether, and melts at 98° . When more strongly heated, it yields mercuric iodide, a carbamine, and a sulphide.

On Sulphine-compounds derived from Thiocarbamide, see THIOCARBAMIDE.

SULPHINIC ACIDS, $R.SO.OH$. *Benzenesulphinic acid*, $C^6H^5.SO^2H$, is readily obtained by adding zinc-dust to a cooled alcoholic solution of benzene-sulphonic chloride. The zinc salt thus obtained is well washed with water, in which it is almost insoluble, and then decomposed by sodium carbonate, and the resulting solution is concentrated and mixed in the cold with hydrochloric acid, which precipitates the benzenesulphinic acid. In a similar way toluenesulphinic acid may be prepared.

Benzenesulphinic acid is also produced on adding a little water to a few drops of benzenesulphonic chloride and mixing the product with zinc-dust. After some time a brisk reaction sets in, and the zinc salt separates out. More zinc-dust and chloride are now alternately added, care being taken to have the former always in excess. The corresponding *toluene-compound* may be prepared by an analogous process.

The zinc salts of the two acids crystallise from hot water in small nacreous plates, having the composition $(C^6H^5SO^2)^2Zn + H^2O$ and $(C^7H^7.CH^3.SO^2)^2Zn + H^2O$ (Schiller a. Otto, *Ber.* ix. 1584).

The same method has been applied by Pauly (*Ber.* x. 941) to the preparation of sulphinic acids of the fatty series. *Ethylsulphinate of zinc*, $(C^2H^5SO^2)^2Zn + H^2O$, thus prepared, is soluble in hot water, less soluble in alcohol of 90 per cent., from which it crystallises in soft nacreous scales; it agrees in all respects with the salt which Wischin obtained (*Liebig's Annalen*, cxxxix. 364) by the action of zinc-ethyl on sulphuric anhydride.

Isobutylsulphinate of zinc, $(C^4H^7SO^2)^2Zn$, prepared by the action of zinc-ethyl on isobutylsulphonic chloride, $C^4H^7SO^2Cl$, forms rather large white nacreous laminae, sparingly soluble in cold, more readily in hot water and alcohol. From alcohol it crystallises anhydrous; from water, apparently with water of crystallisation. It melts with decomposition below 100° . *Sodium isobutylsulphinate* crystallises with difficulty in thin laminae easily soluble in water and in alcohol. The *barium salt* exhibits similar characters. Free isobutylsulphinic acid is a faintly-yellow strongly acid syrup, which dissolves easily in water, and bleaches litmus-paper (Pauly).

SULPHOALDEHYDE, $CH^3.CHS$. Syn. with THIOALDEHYDE (*q.v.*)

SULPHOBENZAMIDE, $C^6H^5.CS.NH^2$. Syn. with BENZOTHIAMIDE or THIOBENZAMIDE (*q.v.*)

SULPHOBENZIDE, $C^{12}H^{10}SO^2$. See SULPHONES. (p. 1855.)

SULPHOBENZOIC ACID, $\text{C}^6\text{H}^4\begin{smallmatrix} \text{CO}^2\text{H} \\ \text{SO}^2\text{H} \end{smallmatrix}$ (pp. 293–296). Wiesinger a. Vollbrecht (*Ber. x.* 1715) have obtained the *meta*- and *para*-modifications of this acid, together with benzoic acid, by the action of alcoholic sulphurous acid on the corresponding diazoimidobenzoic acids.

Sulpho-p-chloro- and *Sulpho-p-bromobenzoic acids*.—These acids and some of their salts have been described by Cöllen and by Böttinger (pp. 295, 296). The following derivatives of the brominated acid are described by Böttinger (*Liebigs Annalen*, xcvi. 13). The crude chlorine-compound prepared by the action of phosphorus pentachloride on the sodium salt in the molecular proportion 1 : 4, is resolved by ether into a sparingly soluble and an easily soluble chlorine-compound. The former, *chlorosulpho-p-bromobenzoic acid*, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2\text{Cl}).\text{COOH}$, melts with decomposition at 197°, but softens at a lower temperature. It dissolves very sparingly in water and alcohol, somewhat more freely in cold ether, and with moderate facility in hot ether. Alcohol converts it, with liberation of hydrogen chloride, into *ethoxysulpho-p-bromobenzoic acid*, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2.\text{OC}^2\text{H}^5).\text{COOH}$, which crystallises in lustrous plates melting at 84°.

Amidosulpho-p-bromobenzoic acid, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2.\text{NH}^2).\text{COOH}$, prepared by the action of alcoholic ammonia on the monochlorinated acid above mentioned, crystallises in nodular groups of small white needles melting at 229°–230°. It dissolves with difficulty in cold water, easily in boiling water, and with great facility in aqueous ammonia, forming an ammonium salt, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2.\text{NH}^2).\text{CO}^2\text{NH}^4$, which loses ammonia on evaporation. When the amido-acid is dissolved in warm baryta-water, small hard glittering needles separate out, consisting of the barium salt.

Ethoxysulpho-p-bromobenzamide, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2.\text{OC}^2\text{H}^5).\text{CO}.\text{NH}^2$, is formed at the same time as the amido-acid by the action of alcoholic ammonia on the dichlorinated compound contained in the crude chloride. Being but sparingly soluble in alcohol and almost insoluble in water, it is easily separated from the acid. It crystallises in long colourless needles, which melt at 128°, and are readily soluble in dilute alkalis; the addition of an acid to this solution produces a crystalline precipitate, consisting of long needles, which melt at 262°, and have the same composition as amidosulphopara-bromobenzoic acid; they appear to consist of *hydroxysulpho-p-bromobenzamide*, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2.\text{OH}).\text{CONH}^2$.

The action of phosphorus pentachloride on sulpho-p-bromobenzoic acid gives rise also to a dichlorinated compound, viz. *chlorosulpho-p-bromobenzoic chloride*, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2\text{Cl}).\text{COCl}$; but this compound is easily decomposed by water, the chlorine combined with the CO-group being displaced by OH, producing the monochlorinated acid. That this is the case is conclusively shown by the action of zinc-dust on the alcoholic solution of the monochloride, which gives rise to two compounds: *sulphi parabromobenzoic acid*, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2\text{H}).\text{COOH}$, which is readily soluble in hot, but only slightly soluble in cold water, and *sulphibromobenzaldehyde*, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^2\text{H}).\text{COH}$, which dissolves in warm water, but is partly thrown down again on boiling. The acid forms small colourless needles, which melt at 238°, with partial decomposition. It is a powerful bibasic acid, and forms crystalline salts. The aldehyde, which may be purified by repeated crystallisation of the barium salt, crystallises in long broad plates, melting at 131°. It is both an aldehyde and a monobasic acid; its barium salt forms large colourless prisms, which rapidly effloresce, and are only slightly soluble in cold water. The compound of the aldehyde with acid sodium sulphite crystallises in long needles melting at 78°. Besides the acid and aldehyde, other compounds, not yet investigated, are produced by the action of zinc on chlorosulpho-p-bromobenzoic acid.

Trisulpho-hydroxybenzoic acid, $\text{C}^6\text{H}^3\text{S}^3\text{O}^{12} = \text{C}^6\text{H}(\text{OH})(\text{SO}^2\text{H})^3.\text{COOH}$, is prepared by heating a solution of 10 grams of benzoic acid in 20 g. sulphuric acid with 5 g. phosphoric anhydride and 20 g. sulphuric anhydride in sealed tubes for five hours. The contents of the tubes are boiled with water to expel sulphur dioxide, and the sulphuric and phosphoric acids are removed by addition of calcium carbonate. To obtain the free acid, basic lead acetate is added to the filtrate, and the precipitated lead salt decomposed by hydrogen sulphide.

Trisulpho-hydroxybenzoic acid is a yellow syrupy hygroscopic liquid, which, when dried at 100°, retains 2 mols. water. Both the acid and its salts produce with a drop of ferric chloride a deep carmine colour, which disappears on addition of sodium carbonate. The *basic lead salt*, $(\text{C}^6\text{H}^3\text{S}^3\text{O}^{12})^2\text{Pb}^3 + 6\text{H}^2\text{O}$, forms white opaque needle-shaped crystals which lose their water of crystallisation at 225°. When decomposed by hydrogen sulphide, it is converted into the normal salt, $\text{C}^6\text{H}^3\text{S}^3\text{O}^{12}\text{Pb}^3 + 8\text{H}^2\text{O}$. The *basic potassium salt*, $\text{C}^6\text{H}^3\text{S}^3\text{O}^{12}\text{K}^3 + 2\text{H}^2\text{O}$, crystallises in monoclinic prisms; the *normal salt*, $\text{C}^6\text{H}^3\text{S}^3\text{O}^{12}\text{K}^4 + 2\text{H}^2\text{O}$, separates on adding alcohol to an aqueous solution

of the acid which has been nearly neutralised with potassium carbonate. The *barium salt*, $C^4H^3S^2O^{12}Ba^2$, is decomposed by long-continued heating at 100° , or by boiling with barium carbonate, in the latter case with formation of barium sulphate and barium disulphoxybenzoate, $(C^4H^2S^2O^8)_2Ba + 8H^2O$.

Trisulphoxybenzoic acid appears to be completely decomposed by fusion with potash. On attempting to replace the hydrogen in it by bromine, it splits up into monobromodisulpho- and dibromomonosulphoxybenzoic acids (Kretschy, *Ber.* xi. 858).

SULPHOBUTYRIC ACID, $C^4H^6(SO^3H)(CO^2H)$ (Hemilian, *Ber.* vi. 196, 562; *Liebig's Annalen*, clxxv. 1). Of this acid there are two modifications, viz.:

The α -acid is obtained by the action of sulphuric hydroxychloride, $ClSO^2(OH)$, on normal butyric acid. 120 grams of the hydroxychloride are poured upon 100 g. of the acid contained in a retort, and the action, which slackens after a while, is assisted by heating the mixture on an oil-bath finally at 150° . As soon as the evolution of hydrogen chloride ceases, the liquid is diluted with water, the uncombined butyric acid is distilled off, and the strongly coloured residue is boiled for some time with lead oxide, whereby the greater part of the colouring matter is separated; and on filtering and precipitating the lead with hydrogen sulphide, a solution is obtained having only a light yellow colour. This solution is again saturated with lead oxide, the resulting lead salt decomposed with hydrogen sulphide, the free acid then converted into barium salt, and this latter purified by repeated crystallisation. The several mother-liquors thus obtained were perfectly identical, showing that the action of sulphuric hydroxychloride on butyric acid produces only one sulphobutyric acid.

α -Sulphobutyric acid is also formed, together with disulphopropionic acid, $C^3H^4S^2O^6$, by heating butyramide with fuming sulphuric acid (compare Buckton & Hofmann, v. 569).

α -Sulphobutyric acid, when evaporated in a vacuum over sulphuric acid, remains as an uncrystallisable hygroscopic syrup. Its salts crystallise well. The *barium salt*, $C^4H^4BaSO^3 + 2H^2O$, forms rhombic laminae, gives off its water of crystallisation slowly over sulphuric acid, but remains undecomposed at 200° . 100 pts. water at 16° dissolve 7.11 pts. of the anhydrous salt; aqueous alcohol dissolves only traces. The *calcium salt*, $C^4H^4CaSO^3 + 2H^2O$, separates from the aqueous solution in warty masses; from a solution in alcohol of 50 per cent. mixed with an equal volume of ether in large hemispherical groups of slender needles; this reaction is characteristic of α -sulphobutyric acid. The *silver salt*, $C^4H^4Ag^2SO^3$, is thrown down by alcohol from its aqueous solution as a white amorphous precipitate which soon becomes crystalline. When left in a vacuum and in the dark, it crystallises in large shining quadratic prisms which adhere to the sides of the vessel in stellate groups. The solid salt decomposes at 140° ; the aqueous solution even at ordinary temperatures. The *zinc salt*, $C^4H^4ZnSO^3 + H^2O$, is at first amorphous, but crystallises after some time in large four-sided prisms. The *copper salt*, $C^4H^4CuSO^3 + 4H^2O$, forms a blue-green varnish, or small emerald-green nodules; alcohol separates it from the aqueous solution as a light blue precipitate. The last molecule of water is given off only at a heat above 200° , the salt at the same time undergoing decomposition. The *lead salt*, $C^4H^4PbSO^3 + 2H^2O$, is thrown down by alcohol as an amorphous precipitate. The *magnesium*, *sodium*, and *ammonium salts* are very soluble in water, and crystallise very indistinctly or not at all. The acid heated with alcohol and gaseous hydrogen chloride does not form an ether.

When α -sulphobutyric acid or its barium salt is heated with 2 mols. phosphorus pentachloride, α -chlorobutyric chloride is formed, according to the equation:

and on pouring the distillate—after freeing it from phosphorus oxychloride—into alcohol, ethyl α -chlorobutyrate, $CH^3.CH^2.CHCl.CO.O^2C^2H^5$, is precipitated in the form of an oil which boils at 154° – 158° . The sulpho-acid does not appear to be converted into a hydroxybutyric acid by fusion with potash. Its barium salt, heated for three hours with fuming sulphuric acid and phosphoric anhydride, yields only traces of disulphopropionic acid, $C^3H^4S^2O^6$ (v. 569), which, according to Baumstark, is the sole product of the action of sulphuric hydroxychloride on butyric acid (vi. 1069).

β -Sulphobutyric acid, obtained by boiling ethyl β -hydroxybutyrate with ammonium sulphite, is a transparent hygroscopic jelly. Its lead, barium, and calcium salts are thrown down by alcohol from their aqueous solutions in the form of flocculent non-crystalline precipitates. The *barium salt*, dried at 150° , has the composition $C^4H^4SO^3Ba + H^2O$, and gives off its water at 200° (Hemilian).

SULPHOCAMPHYLIC ACID, $C^9H^{16}SO^6$. This acid, discovered by Walter, and originally called *sulphocamphoric acid*, has been further examined by Kachler (*Liebig's Annalen*, clxix. 178), who prepares it by the action of sulphuric acid on camphoric anhydride, exactly according to Walter's directions (v. 489), excepting that, before saturating the diluted and filtered product of the reaction with lead carbonate, he agitates it with ether, which removes unaltered camphoric acid, and an isomeric acid having the property of Wreden's mesocamphoric acid (vii. 235). Sulphocamphylic acid, separated from its lead salt, forms crystalline crusts and druses having the composition $C^9H^{16}SO^6 + 2H^2O$, and giving off their water in a vacuum over sulphuric acid. An acid lead salt, $(C^9H^{16}SO^6)^2Pb + 4H^2O$, was once accidentally obtained from a solution of the normal salt which had been incompletely decomposed by hydrogen sulphide, in nearly colourless well-defined flat prisms. The acid is strongly attacked at a gentle heat by nitric acid of sp. gr. 1.25, with formation of oxalic acid and sulphomelic acid (p. 1860).

The crystals of sulphocamphylic acid, according to measurements by v. Zepharovich (*Wien. Akad. Ber.* lxxiii. [1 Abth.], 1876, 7), are triclinic. $a : b : c = 0.8515 : 1 : 0.7590$. In the first octant, $\alpha = 82^\circ 38' 5''$; $\beta = 121^\circ 10'$; $\gamma = 111^\circ 36'$. Observed faces, $\infty \bar{P} \infty$, $\infty \bar{P} \infty$, $0P$, $3\bar{P} \infty$, $3P$. Measurements only approximate. Cleavage imperfect parallel to $\infty \bar{P} \infty$.

The acid lead salt forms orthorhombic crystals. $a : b : c = 0.7228 : 1 : 0.8080$. Observed forms, $\infty \bar{P} \infty$, $0P$, $\bar{P} \infty$, $3\bar{P} \infty$, $\frac{1}{2}\bar{P} \infty$, P , $\frac{1}{2}P$, $\frac{3}{2}P$. Angle of optic axes for white light = $78^\circ 17'$. Dispersion and double refraction weak.

SULPHO-CARBAMIC ACID, -CARBAMIDE, -CARBONIC ACID, -CYANIC ACID, &c. See the corresponding THIO-COMPOUNDS.*

SULPHONES, R^2SO^2 , and **SULPHOXIDES**, R^2SO . Sulphones are stable compounds, which may be distilled without decomposition, are not reduced by nascent hydrogen (zinc and dilute sulphuric acid), or by hydriodic acid and phosphorus, or attacked by phosphorus pentachloride, whereas the sulphoxides are reduced by nascent hydrogen, and are easily converted into sulphides by the action of phosphorus pentachloride.

Sulphones of the Fatty group may be prepared by oxidising the sulphides and sulphoxides of alcohol-radicles, C^xH^{2x+1} , with potassium permanganate, and extracted from the products with ether (Beckmann, *J. pr. Chem.* [2], xvii. 439).

Dimethyl sulphone, $(CH^3)^2SO^2$, crystallises from alcohol in long thick colourless shining needles melting at 109° . *Methylethyl sulphone*, $(CH^3)(C^2H^5)SO^2$, dissolves easily in water, alcohol, benzene, and chloroform, sparingly in cold ether and carbon sulphide, and crystallises from ether in slender shining needles melting at 36° . *Diethyl sulphone* crystallises from alcohol in rhombic plates. *Diisopropyl sulphone*, $[(CH^3)^2CH]^2SO^2$, forms colourless inodorous crystals which melt at 36° , forming a liquid which often remains for days without solidifying. It dissolves readily in water, alcohol, ether, benzene, chloroform, and carbon sulphide; also in strong nitric, sulphuric, and acetic acids, and is not precipitated from the acid solutions by water. *Diisobutyl sulphone* is a colourless syrupy liquid having a faint but pleasant odour, and a density of 1.0056 at 18° . It boils at 265° , and solidifies in a freezing mixture to a crystalline mass which melts at 17° . It dissolves in 2 pts. water at ordinary temperatures, but is only slightly soluble in hot water; readily in ether, alcohol, benzene, and carbon sulphide; also in strong nitric, sulphuric, and acetic acids, and is reprecipitated therefrom by water. *Diisopentyl- (or diamyl-) sulphone* crystallises in groups of long needles permanent in the air, odourless, but having a sweetish burning taste; melts at 31° , and boils at 295° . It is nearly insoluble in water and aqueous alkalis, but behaves to other solvents like the preceding compound. *Phenylethyl sulphone*, $(C^6H^5)(C^2H^5)SO^2$, produced by oxidation of phenylethyl sulphide, crystallises in thick colourless plates melting at 42° , behaves to solvents much in the same manner as diisopropyl sulphone, excepting that it is precipitated by water from its solutions in acids.

Ethylenediethyl sulphone, $C^2H^4(SO^2.C^2H^5)^2$, formed by the action of permanganate on ethylenediethyl sulphide, crystallises in short, hard, colourless needles, melts at 136.5° , and volatilises without decomposition. It dissolves sparingly in cold, easily in hot water and alcohol, sparingly in ether, benzene, chloroform, and carbon sulphide; easily in strong nitric and sulphuric acids, less easily in hydrochloric, still less in acetic acid.

* The prefix 'thio' is now generally applied to compounds derived from oxy- or hydroxy-compounds by substitution of S for O; the prefix 'sulpho' to bodies containing the group or radicle SO^2H or its analogues, SO^2Cl , SO^2NH^2 , &c.; e.g.:

$CH^3.CO.SH$
Thiacetic acid.

$C^6H^5.CH^3.SO^2H$
Sulphacetic acid.

Aromatic Sulphones. Beckurts a. Otto (*Ber.* xi. 472, 2066) prepare these bodies by the action of aluminium chloride on a mixture of a sulphonic chloride and a hydrocarbon. In this way they have prepared *diphenyl sulphone* or *sulphobenzide*, *ditolyl sulphone* or *sulphotoluide*, *phenyltolyl sulphone*, $[(C^6H^5)(C^6H^4.CH^3)]^2SO^2$; *chlorosulphobenzide*, which melts at 93° , volatilises at a higher temperature, is insoluble in water, sparingly in cold, easily in hot alcohol; and *phenyltolyl sulphone*, $C^6H^5.SO^2.C^6H^4(CH^3)^2$. This last compound, obtained from metaxylene and benzenesulphonic chloride, forms yellowish-white needles, melts at 80° , distils without decomposition, dissolves readily in ether and alcohol, but is insoluble in water.

Michael a. Adair (*Ber.* x. 583) prepare aromatic sulphones by heating a mixture of a sulphonic acid and a hydrocarbon in a sealed tube at about 200° with phosphoric anhydride; e.g.:

The product is purified by submitting it to the action, first of a stream of aqueous vapour, then of dilute potash-ley, and lastly of alcohol, the pure sulphone then crystallising from the alcoholic solution. In this manner Michael a. Adair have prepared *ditolyl sulphone*, $(C^6H^4)^2SO^2$, by heating paratoluenesulphonic acid and toluene with phosphoric anhydride for six to eight hours at 150° – 170° , and *phenyltolyl sulphone*, $(C^6H^5)(C^6H^4)SO^2$ (p. 1357), from benzenesulphonic acid and naphthalene heated for eight or nine hours at 170° – 190° .

Paratolylphenyl sulphone, $C^6H^5.SO^2.C^6H^4(CH^3)$, is prepared in like manner from *p*-toluenesulphonic acid and benzene, or from benzenesulphonic acid and toluene. The product is exhausted successively with water and ether; the residue crystallised from alcohol; and the crystals which separate are freed from coloured impurities by dissolving them in acetic acid, and treating the solution with potassium permanganate. The sulphone thus prepared forms shining white rhombohedral tablets, or when crystallised from water, slender prisms. It melts at 194.5° ; 1.62 pt. of it dissolves at 20° in 100 pts. of absolute alcohol. Ortho- and meta-compounds are not formed simultaneously with the para-compound.

Paratolyl-phenyl sulphone is reduced by nascent hydrogen and by hydriodic acid and phosphorus to the corresponding sulphide. When treated in acetic acid solution with potassium permanganate it is converted into *p-sulphobenzidecarboxylic acid*

This acid crystallises from alcohol in small prisms melting above 300° ; it dissolves sparingly in water, benzene, and glacial acetic acid, easily in nitrobenzene, and forms a flocculent silver salt, $C^6H^5.SO^2.C^6H^4.CO^2Ag$, very sensitive to light. The lead and copper salts are flocculent precipitates.

Ditolylsulphone or *Sulphotoluide*, $(C^6H^4.CH^3)^2SO^2$ (from paratoluenesulphonic acid and toluene), is converted by oxidation into *sulphobenzide-dicarboxylic acid*, $(C^6H^4.CO^2H)^2SO^2$, which very much resembles the monocarboxylic acid, and likewise melts at a temperature above 300° .

Sulphobenzide-disulphonic acid, $C^6H^5.SO^2.C^6H^4.SO^2.OH$, is formed, together with a small quantity of benzenesulphonic chloride, by heating sulphobenzide with sulphuric hydroxychloride at 120° , and may be extracted from the product by solution in water. Its barium and sodium salts are crystallisable, and have the normal composition Otto a. Knoll, *Ber.* xi. 2075).

On *Hydroxysulphobenzide* (Oxysulphobenzide), $(C^6H^4.OH)^2SO^2$, and its derivatives, see pp. 1474–1477.

Sulphoxides, R^2SO . These bodies, and not sulphones, are formed by the action of strong nitric acid on the sulphides. They combine, at ordinary temperatures, with strong nitric acid, forming compounds which contain 1 mol. of the sulphoxide to 1 mol. NO^3H , and are easily decomposed by water. Beckmann has obtained the sulphoxides of diethyl, diisobutyl, and ethylenediethyl in the form of viscid syrups. *Disopentylsulphoxide*, heated at 150° with nitric acid of sp. gr. 1.5, is partly converted into isopentylsulphonic acid.

Beckmann has also studied the products obtained by the action of permanganates on sulphides containing an acid-residue and an alcohol-residue. *Acetylaldehyde sulphide* (ethyl thiacetate) is but slightly attacked by potassium permanganate, but a solution of silver permanganate, even when very dilute, is immediately decolorised by it, with formation of acetic and ethylsulphonic acids. *Benzoylisopentyl sulphide* (isopentyl

thiobenzoate) is but slightly attacked by the permanganates of potassium and silver, even at the heat of the water-bath; *benzoyl ethyl sulphide* (ethyl thiobenzoate), on the other hand, is attacked by silver permanganate in presence of sulphuric acid, even at ordinary temperatures. *Diacetyl sulphide* (thiacetic anhydride) is oxidised, with incandescence, by barium peroxide; but when the anhydride is diluted with a tenfold quantity of ether, the action begins after some time only, and is attended with only slight evolution of heat, *acetyl persulphide* being formed, probably according to the equation:

Disulphoxides, $\text{R}^2\text{S}^2\text{O}^2$ (Pauly a. Otto, *Ber.* ix. 1639; x. 2181; xi. 2070). *Diphenyl disulphoxide*, $(\text{C}^6\text{H}^5)^2\text{S}^2\text{O}^2$ (*Benzoldisulfoxyd*), which Otto obtained, together with benzenesulphonic acid, by heating benzenesulphonic acid with water (vi. 919), is also produced by the regulated oxidation of phenyl hydrosulphide, $\text{C}^6\text{H}^5\text{SH}$, with nitric acid of sp. gr. 1.3; by the action of strong sulphuric acid or phosphoric anhydride on sodium benzenesulphinat; and by spontaneous decomposition of benzenesulphonic acid, which takes place even in a sealed tube. It melts at 45° , and is resolved by boiling with potash-ley into benzenesulphonic acid, benzenesulphonic acid, and diphenyl disulphide:

Heated in alcoholic solution with zinc-dust, it is quickly and exactly resolved into zinc benzenesulphinat and zinc phenyl mercaptide:

Diphenyl disulphoxide (rather more than 1 mol.) and phenyl hydrosulphide (1 mol.), heated together in alcoholic solution, are exactly resolved into diphenyl disulphide and benzenesulphonic acid:

The same substances heated together directly in the same proportion yield diphenyl-disulphide, benzenesulphonic acid, and decomposition-products of benzenesulphonic acid. Diphenyl disulphoxide is converted by oxidation with potassium permanganate into potassium benzenesulphonate, $(\text{C}^6\text{H}^5)^2\text{S}^2\text{O}^2 + \text{O}^2 + \text{H}^2\text{O} = 2(\text{C}^6\text{H}^5.\text{SO}^2.\text{OH})$.

The reactions of *tolyl disulphoxide* are analogous to those of the phenyl-compound.

SULPHONIC ACIDS, $\text{R}.\text{SO}^2.\text{OH}$ (R denoting an organic radicle). A general method of preparing these acids is given by Hemilian (*Liebig's Annalen*, clxviii. 145). It consists in boiling the corresponding chloro- or iodo-compounds with an aqueous solution of normal ammonium sulphite (1 pt. to 2 pts. water), the reaction taking place according to the equation:

By diluting the product with water, boiling it with lead oxide as long as ammonia continues to escape, filtering from the resulting chloride or iodide of lead, and decomposing the filtrate with hydrogen sulphide, the sulphonic acid is obtained in the free state.

(1). **Sulphonic Acids of the Fatty Series.** *Ethylsulphonic acid*, $\text{C}^2\text{H}^5.\text{SO}^2.\text{OH}$, is formed, together with ethylsulphonic acid and ethyl disulphide, by the action of potash-ley on ethyl disulphoxide (Pauly a. Otto, *Ber.* xi. 2073):

An *ethylene-disulphonic acid*, $\text{C}^2\text{H}^4(\text{SO}^2\text{H})^2$, isomeric with disulphethic acid (v. 566), is formed, together with sulphuric and acetic acids, by oxidising thialdine, $\text{C}^2\text{H}^4\text{NS}^2$ (v. 772), with potassium permanganate. It is a syrupy liquid. The same disulphonic acid appears to be formed by oxidation of thioaldehyde (Guareschi, *Ber.* xi. 1384, 1692).

On *Amido-ethylsulphonic acid*, $\text{C}^2\text{H}^4(\text{NH}^2).\text{SO}^2\text{H}$, see TAURINE.

(2). **Of the Aromatic Series.** On *Benzenesulphonic acids*, see pp. 223-259.

Cymenesulphonic acid, $\text{C}^{10}\text{H}^{12}.\text{SO}^2\text{H}$.—According to Paternò (*Gazz. chim. ital.* 1878, 291), the sodium salt of this acid crystallises, not with 5 mols. water, as stated by Jacobsen (*Ber.* xi. 2049), but with only 3 mols.

Pseudocumenol-sulphonic acid, $\text{C}^6\text{H}(\text{CH}^3)^2(\text{OH}).\text{SO}^2\text{H}$, is formed by dissolving pseudocumenol in strong sulphuric acid, and separates from the solution in small shining crystals having the form of cupric sulphate; on adding water to the solution, a crystalline pulp is precipitated, consisting of the hydrated acid. The *potassium* and *zinc* salts crystallise in rather long elongated laminae; the *copper* salt

in indistinctly crystalline nodules. The *sodium salt* forms easily soluble rectangular tablets; the *barium salt*, thin rhombic tablets, soluble in 20 pts. water at 7°; the slightly soluble *silver salt* consists of rectangular laminae. The *chloride*, $C^6H^{10}(OH).SO^2.Cl$, forms monoclinic prisms melting at 61°; the corresponding *sulphonic acid*, $C^6H^{10}(OH).SO.OH$, melts at 98° (Reuter a. Radloff, *Ber.* xi. 32).

Phloroglucol-sulphonic acid, $C^6H^2(OH)^3SO^3H$. See PHLOROGLUCCOL (p. 1570).

Anthracenedisulphonic acids, $C^{14}H^8(SO^3H)^2$.—Anthracene, treated with sulphuric acid, yields two disulphonic acids which, by fusion with potash, are converted into corresponding dihydroxyanthracenes; and by oxidation of the acetyl-derivatives of these bodies, one of them is converted into chrysazin (p. 108), the other into anthrarufin—a dihydroxyanthraquinone produced also by the action of sulphuric acid on meta-hydroxybenzoic (ordinary oxybenzoic) acid (see APPENDIX) (Liebermann, *Ber.* xi. 1610). To prepare this last-mentioned disulphonic acid, Liebermann a. Böck (*Ber.* xi. 1618) heat 100 pts. anthracene with 300 pts. strong sulphuric acid on a very gently warmed water-bath, till about 20–30 pts. anthracene are dissolved. Several sulpho-acids are thereby produced, but only the lead salt, $C^{14}H^8(SO^3)^2Pb$ (dried at 170°), of the disulphonic acid in question separates from the strongly concentrated solution as a slightly soluble yellow precipitate. The corresponding *sodium salt*, $C^{14}H^8(SO^3Na)^2 + xH^2O$, forms silvery more or less yellow laminae easily soluble in water, the solution exhibiting a strong blue fluorescence, especially when dilute. The *barium salt* crystallises with 4 mols. water in white nacreous laminae. The *free acid* forms easily soluble flocks consisting of microscopic needles.

Naphthalene-sulphonic acids, pp. 1353–1355.

Toluene-sulphonic and Xylene-sulphonic acids, see TOLUENE and XYLENE.

Diazinsulphonic Acids.* This name may be applied to a group of compounds discovered by Griess (*Ber.* xi. 2191), and named by him *Sulphoxybenzenephénols*. They are produced by the action of phenols and their derivatives on diazobenzene-sulphonic acids and other diazo-compounds. Some of them are dye-stuffs, known in commerce as tropæoline, chrysoidine, rocelline, &c.

The positions of the hydroxyl- and sulphonyl-groups in the following compounds with regard to the N^2 -groups may be denoted by figures (as in the naphthalene-derivatives, p. 1375), plain on the right, accented on the left.

i. [$4' - 4$] *Hydroxydiphenyldiazinsulphonic acid*, $C^6H^4(OH).N=N.C^6H^4(SO^3H)$, or $OH \langle \text{---} \rangle N=N \langle \text{---} \rangle SO^3H$. The potassium salt of this acid is obtained by gradually stirring into a solution of phenol in a tenfold quantity of 10 per cent. potash-ley, a quantity of paradiazobenzenesulphonic acid equivalent to the phenol present. The resulting deep yellow-red liquid is left at rest for a short time, then heated and supersaturated with acetic acid, whereupon it yields, after cooling, an abundant crop of light yellow laminae, consisting of the acid potassium salt of the diazinsulphonic acid. The crystals may be separated from the mother-liquor by filtration, and purified by repeated crystallisation from boiling water with the aid of a small quantity of animal charcoal. The free acid may be separated by mixing a hot concentrated solution of this salt with a very large excess of strong hydrochloric acid, and purified by recrystallisation from boiling water containing a small quantity of hydrochloric acid. It is nearly insoluble in hydrochloric acid and in ether, but dissolves readily in water and alcohol, and crystallises from a concentrated aqueous solution in yellow-red prisms with strong violet surface-shimmer. It decomposes when heated, giving off pungent vapours, and leaving a difficultly combustible cinder. Nitric acid, even when diluted with three or four times its volume of water, decomposes it at the boiling heat, forming oily products, which afterwards solidify to yellow crystals. With tin and hydrochloric acid it yields paramidophenol and sulphanilic acid. With bases it forms acid and neutral salts, most of which crystallise well. The *acid potassium salt*,

* The name 'diazin' has been suggested by Dr. Armstrong for compounds of the type $R'-N=N-R'$, hitherto known as 'azo-compounds,' thus:

Diphenyl-diazin				
(Azobenzene.)				$C^6H^4.N = N.C^6H^4$
Phenyl-naphthyl-diazin	.	.	.	$C^6H^4.N = N.C^{10}H^7$
Dinaphthyl-diazin				
(Azonaphthalene.)	.	.	.	$C^{10}H^7.N = N.C^{10}H^7$

It has the advantage of indicating the relation of these compounds to the hydrazines, $R'.N.N.N'.N'$ (p. 1048). The prefix 'azo' is more appropriately applied to compounds in which a nitrogen-atom simply replaces 3 atoms of hydrogen, e.g. Azomethane (Hydrogen Cyanide or Methylene-nitril), CHN ; Azo-ethane (Methyl Cyanide or Ethenyl-nitril), C^2H^3N ; Azo-toluene (Phenyl Cyanide or Benzonitril), C^7H^5N .

$C^{12}H^9N^2SO^4K$, prepared as above, or by boiling a concentrated aqueous solution of the acid with potassium chloride, forms thin, yellow, highly lustrous rhombic or six-sided plates, mostly imperfectly developed and easily soluble in hot water. The *acid barium salt*, $(C^{12}H^9N^2SO^4)^2Ba + 5H^2O$, obtained by the action of barium chloride on a hot aqueous solution of the acid, crystallises in reddish-yellow microscopic plates only slightly soluble in water, even at the boiling heat. The *normal barium salt*, $C^{12}H^9N^2SO^4Ba$, is obtained by adding barium chloride to a hot strongly ammoniacal solution of the acid, as an orange-coloured precipitate composed of small nodules, and very slightly soluble in water even at the boiling heat.

- ii. [4' - 3] *Hydroxydiphenyldiazinsulphonic acid*, $C^6H^4(OH)N=N.C^6H^4(SO^3H)$, or SO^3H

, is formed by the action of the metamidobenzenesulphonic acid prepared from metadiazobenzenesulphonic acid, on an alkaline solution of phenol. It is insoluble in ether, dissolves readily in water and alcohol, and to nearly the same amount whether hot or cold, and crystallises from the aqueous solution by spontaneous evaporation in long narrow pentagonal laminae having a violet shimmer. By tin and hydrochloric acid, it is reduced to metamidobenzenesulphonic acid and paramidophenol. The *acid potassium salt*, $C^{12}H^9N^2SO^4K$, crystallises in long needles, and is somewhat more soluble in water than the corresponding salt of the preceding compound.

iii. [3 : 4] *Hydroxydiphenyldiazinsulphonic acid*, $C^6H^5.N=N.C^6H^3(SO^3H)(OH)$, is obtained by the action of diazobenzene nitrate on an equivalent quantity of orthophenolsulphonic acid in alkaline solution. The free acid dissolves easily in water and in alcohol, but is nearly insoluble in ether. From a cold concentrated aqueous solution, it separates, on addition of strong hydrochloric acid, in thin, rhombic, yellowish-red, shining laminae, which change on stirring into microscopic needles. By slow evaporation of its aqueous solution it is obtained in large cherry-red rhombic tables or prisms. With tin and hydrochloric acid, it yields aniline, and the amidophenolsulphonic acid described by Post (vii. 922).

- iv. [2' : 4' - 4] *Nitrohydroxydiphenyldiazinsulphonic acid*,

$C^6H^3(OH)(NO^2)N=N.C^6H^4(SO^3H)$, formed from paradiazobenzenesulphonic acid and orthonitrophenol, is slightly soluble in alcohol, and crystallises therefrom either in slender yellow needles or in well-defined rhombic or hexagonal laminae. It dissolves with moderate facility in hot water, the solution solidifying on cooling to a crystalline pulp. The dry compound detonates strongly when heated.

v. *Dihydroxydiphenyldiazin-p-sulphonic acid*, $C^6H^3(OH)^2N=N.C^6H^4(SO^4H)$, is formed by the action of paradiazobenzenesulphonic acid on a solution of resorcinol in potash, and separates on addition of acetic acid, in the form of a crystalline acid potassium salt. The free acid separated from this salt by strong hydrochloric acid is nearly insoluble in ether, very slightly soluble in alcohol and in cold water, more freely in hot water, and crystallises in acute rhombic laminae, often elongated into needle-shaped crystals, steel-blue by reflected, ruby-red by transmitted light. It is decomposed by boiling with nitric acid, and when treated with tin and hydrochloric acid, yields sulphanilic acid and amidoresorcinol. It appears to be identical with the dye-stuff called tropæolin O, which Witt obtained by the action of sulphuric acid on resorcinol-diazobenzene. The *acid potassium salt*, $C^{12}H^9N^2SO^5K$, crystallises in reddish-yellow rhombic or six-sided laminae, sparingly soluble in cold, easily in hot water. Hydrochloric acid precipitates it from its aqueous solution at first without alteration, but a large excess of the strong acid decomposes it. The *acid barium salt*, $(C^{12}H^9N^2SO^5)^2Ba$, crystallises with $4H^2O$.

vi. The corresponding *meta*-compound, $[N=N : SO^3H = 1 : 3]$, crystallises in yellowish-red slender needles which, like the last compound, are insoluble in ether, but slightly soluble in water. With tin and hydrochloric acid it yields metamidobenzenesulphonic acid and amidoresorcinol. The *acid potassium salt* forms hygroscopic needles, sparingly soluble in cold, easily in hot water.

- vii. *Methyldihydroxyphenyldiazin-p-sulphonic acid*,

$C^6H^2(CH^3)(OH)^2N=N.C^6H^4(SO^3H)$, prepared from orcinol in the same manner as the preceding compounds from resorcinol, forms small yellowish-red needles, sparingly soluble in hot, very sparingly soluble in cold water. The *acid potassium salt* has the composition $C^{13}H^{11}N^2SO^5K + 2H^2O$.

- viii. *Salicylodiphenyldiazin-p-sulphonic acid*, $C^6H^3(CO^2H)(OH)N=N.C^6H^4(SO^4H)$

crystallises in fine golden-yellow needles, insoluble in ether, sparingly soluble in water, more freely in alcohol. The *acid barium salt*, $(C^{13}H^9N^2SO^2)^2Ba$, obtained by the action of barium chloride on a hot solution of the freed acid, forms a light yellow precipitate, somewhat gummy at first, but converted by boiling into irregular six-sided laminæ having a strong lustre; very slightly soluble in cold, more freely in hot water.

ix. *Dihydroxyphenylarylldiazinsulphonic acid*, $C^6H^3(OH)^2N=N.C^6H^3(SO^3H)$, forms yellowish-red slender needles, sparingly soluble in hot, still less soluble in cold water, more easily in alcohol, insoluble in ether.

x. *Hydroxyl- α -Naphthylphenyldiazin-p-sulphonic acid*, $\alpha-C^{10}H^6(OH)N=N.C^6H^4(SO^3H)$, is formed from α -naphthol and paradiazobenzene-sulphonic acid, and occurs in commerce as *Poirrier's orange*, No. I. The corresponding β -naphthol compound is *Poirrier's orange*, No. II.

xi. *Hydroxyl- α -Naphthylphenyldiazin-m-sulphonic acid*, $\alpha-C^{10}H^6(OH)N=N.C^6H^4(SO^3H)$, is separated from its orange-coloured aqueous solution by hydrochloric acid in very small blackish-green laminæ, which when pulverised appear gold-green by reflected, violet by transmitted light. It is insoluble in ether, dissolves sparingly in cold water and cold alcohol, more easily in these solvents on warming.

xii. *Hydroxyl- β -Naphthylphenyldiazin-m-sulphonic acid*, $\beta-C^{10}H^6(OH)N=N.C^6H^4(SO^3H)$, separates on mixing the two solutions as a brown oil, which after some time solidifies in needles. It is slightly soluble in ether, moderately soluble in water and in alcohol. Its powder is gold-green by reflected, red by transmitted light. The *acid barium salt*, $(C^6H^{11}N^2SO^2)^2Ba + 5H_2O$, obtained by treating a hot solution of the acid with barium chloride, crystallises in yellowish-red scales having a golden lustre, and sparingly soluble in boiling water.

xiii. *Phenylhydroxyl- α -Naphthylldiazinsulphonic acid*, $C^6H^3N=N.\alpha-C^{10}H^5(SO^3H)(OH)$.—The *sodium salt* of this acid is obtained by mixing a solution of sodium- α -naphthylsulphonate with aniline and potassium nitrite:

By dissolving the product in ammonia, precipitating with hydrochloric acid, and repeatedly crystallising it from a hot mixture of alcohol and hydrochloric acid, the free acid is obtained in slender brown-red needles moderately soluble in water, more readily in alcohol, insoluble in ether. It dissolves in alkalis with brown-red colour, changing to deep violet on acidulation. The *sodium salt* is moderately soluble in hot water, less soluble in hot alcohol, insoluble in ether; it is a dye-stuff producing a fine orange-colour inclining to red. At a high temperature it decomposes with strong intumescence. The *silver salt*, $C^6H^{11}N^2SO^2Ag$ (at 100°), crystallises in fine brick-red needles. The *barium salt*, $(C^{10}H^{11}N^2SO^2)^2Ba$, and the *calcium salt*, are also crystalline precipitates (A. W. Hofmann, *Ber.* x. 1378).

xiv. The corresponding β -naphthyl-compound, obtained by the action of diazobenzene nitrate on an alkaline solution of β -naphtholsulphonic acid, crystallises in red-brown needles having a gold-green surface-shimmer, moderately soluble in water and in alcohol. The *acid barium salt*, $(C^{10}H^{11}N^2SO^2)^2Ba$, separates on mixing a hot dilute aqueous solution of the acid with barium chloride, in very small nodular groups of yellowish-red microscopic laminæ, which are but very sparingly soluble even in hot water.

xv. *Phenyl-hydroxyl- β -Naphthylldiazindisulphonic acid*,

is obtained, on mixing the barium salt of Poirrier's orange II. (*supra*) with the exact quantity of sulphuric acid required to decompose it, and evaporating the filtrate, as a yellowish-red crystalline mass, soluble in all proportions in water and in alcohol. Its *acid barium salt*, $C^{10}H^{10}N^2SO^4Ba + 7\frac{1}{2}H_2O$, crystallises in deep orange-red microscopic needles, which dissolve sparingly in hot and very sparingly in cold water.

xvi. *β -Hydroxyldinaphthylldiazinsulphonic acid*, $\beta-C^{10}H^6(OH)N=NC^{10}H^6(SO^3H)$, is produced, as first shown by Caro, by the action of diazonaphthionic acid on β -naphthol. It dissolves very readily in alcohol with blood-red colour, and separates from the boiling-hot solution on addition of hydrochloric acid, in small red-brown needles yielding a blood-red powder, sparingly soluble in cold, more readily in hot water,

almost insoluble in ether; it is tasteless, and decomposes when heated in a test-tube, leaving a very difficultly combustible cinder. The *acid barium salt*, $(C^8H^7N^2SO^4)^2Ba$, is obtained on mixing a moderately strong aqueous solution of the free acid with barium chloride, as a brown-red precipitate composed of microscopic needles.

xvii. *Hydroxydicarboxylphenyl- α -Naphthyl diazinsulphonic acid*,

formed by the action of diazosulphobenzoic acid on an alkaline solution of α -hydroxy-naphthoic acid, crystallises in microscopic needles or laminae having a brown colour with bronze surface-shimmer, sparingly soluble in hot, very sparingly in cold water.

xviii. *Dibromodihydroxyphenylnaphthyl diazinsulphonic acid*,

is formed by the action of diazodibromobenzenesulphonic acid on dihydroxynaphthalene. It dissolves with moderate facility in boiling water, forming a yellow solution, from which it is precipitated by hydrochloric acid in violet-brown microscopic needles (Griess).

SULPHOPHENOLIC ACIDS. Syn. with PHENOLSULPHONIC ACIDS (pp. 1538-1540).

SULPHOPHLOGRUCIC ACID. Syn. with PHLOGRUCOLSULPHONIC ACID (p. 1572).

SULPHOPIMELIC ACID, $C^7H^{12}O^7 = C^7H^{11}SO^3H$, is produced, together with oxalic acid, by the action of nitric acid of sp. gr. 1.25, at a gentle heat on sulphocamphylic acid (p. 1354).

It forms colourless crystals, very soluble in cold water (Kachler, *Liebig's Annalen*, clxix. 178).

SULPHOPROPIONIC ACID, $C^3H^5SO^3$ (A. Kurbatow, *Ber.* vi. 563). The α -modification of this acid, $CH^3.CH(SO^3H).CO^2H$, is formed:—(1). By boiling α -chloropropionyl chloride, $CH^3.CHCl.COCl$, with an aqueous solution of normal ammonium sulphite, in the manner described by Hemilian (p. 1857). (2). By the action of sulphuric hydroxychloride ($1\frac{1}{2}$ pt.) on propionic acid (1 pt.), the mixture being warmed to complete the action, the product then diluted with water, the unaltered propionic acid distilled off, the residue saturated with lead oxide, and the lead salt decomposed by hydrogen sulphide. The acid thus obtained is purified by repeated conversion into lead salt and separation therefrom. The free acid forms a syrup easily soluble in water and in alcohol. The *barium salt*, $C^3H^4BaSO^3 + 2H^2O$, crystallises in colourless shining scales, sparingly soluble in alcohol, more freely in water (7.4 pts. in 100 water). The *calcium salt*, $C^3H^4CaSO^3 + 2H^2O$, is thrown down by alcohol from the aqueous solution as a flocculent precipitate.

The *normal sodium salt* crystallises in deliquescent needles, and the acid salt forms prisms with 3 mol. of water. The *normal potassium salt* is very soluble, and does not crystallise well, and the less soluble acid salt forms needles. The *normal copper* and *silver salts* separate on evaporation in crusts, consisting of microscopic needles. The *zinc salt* is a gummy mass, in which crystals form on standing in the air. The *lead salt* forms glistening crystals.

Sulphophenylpropionic acid, $C^8H^{10}SO^3$, is obtained by reducing the brominated acid with sodium-amalgam. Its *acid barium salt*, $(C^8H^9SO^3)^2Ba + 5H^2O$, forms small tabular triclinic crystals exhibiting the combination ∞P^{∞} (predominant) $\infty P^{\infty}.0P$. Axial angles, $\alpha = 87^\circ 26'$; $\beta = 108^\circ 58'$; $\gamma = 78^\circ 6'$.

The crude sodium salt fused with potassium hydroxide yields *meta*-hydroxybenzoic acid; consequently the acid is *meta*-sulphophenylpropionic acid, $C^8S^1O^3H.H.C^2H^4(CO^2H).H^3$, and its bromo-derivative is *parabromo-meta*-sulphophenylpropionic acid, $C^8S^1O^3H.H.C^2H^4(CO^2H).Br.H^3$.

Bromosulphophenylpropionic acid, $C^8H^2Br^2SO^3 = C^8H^2Br^2SO^3H.CH^2.CH^2.COOH$ (Göring, *Chem. Centr.* 1877. 793, 808). This acid is prepared by adding parabromophenylpropionic acid (p. 1566), in small portions (not exceeding 15 grams), to a threefold quantity of fuming sulphuric acid, care being taken that the temperature of the mixture does not rise above 60° . On diluting the mass with water after twelve hours, a small quantity of bromocinnamic acid separates out; and the filtrate, after due concentration, yields a crystalline deposit of bromosulphophenylpropionic acid, which, when freed from adhering sulphuric acid, crystallises in rhombic plates permanent in the air, having the composition $C^8H^2Br^2SO^3 + 2\frac{1}{2}H^2O$, and gradually giving off about 2 mol. water over sulphuric acid. The

crystals, according to measurements by Haushofer (*Zeitschr. Kryst.* ii. 91)—who likewise examined the forms of the following salts—are orthorhombic, having the axial ratio $a : b : c = 0.7881 : 1 : 1.3013$, and exhibiting the combination $0P.3P.P$, tabular according to $0P$, indistinctly cleavable parallel to $0P$. The normal *barium salt* forms a soft mass of felted microscopic needles, only slightly soluble in water even at the boiling heat. The amount of water of crystallisation in this salt (1 or 2 mol.) has not been exactly determined, and the same is true with regard to the following salts. The *acid barium salt*, $(C^6H^5BrSO^3)^2Ba + 8H^2O$, forms triclinic crystals, which quickly effloresce. $a : b : c = 0.4941 : 1 : 0.5046$; $\alpha = 68^\circ 36'$; $\beta = 98^\circ 22'$; $\gamma = 83^\circ 38'$. Observed faces, ∞P_∞ , ∞P_∞ , $0P'$, P_∞ ; P_∞ , ∞P , $\infty P'$. Angle $\infty P_\infty : 0P = 78^\circ 25'$; $\infty P_\infty : 0P = 67^\circ 13'$; $\infty P_\infty : \infty P_\infty = 79^\circ 45'$; $\infty P_\infty : P_\infty = 76^\circ 55'$; $0P : P_\infty = 21^\circ 18'$. The brachypinacoid, ∞P_∞ , is vertically striated. No cleavage. The *normal calcium salt*, $C^6H^5BrSO^3Ca + 3H^2O$, forms hard crusts made up of microscopic needles. The *acid calcium salt*, $(C^6H^5BrSO^3)^2Ca + 8H^2O$, is monoclinic. $a : b : c = 0.9774 : 1 : 0.7962$; $\beta = 86^\circ 45'$. Observed faces, ∞P_∞ , P_∞ , ∞P , ∞P_∞ , ∞P_4 . Tabular according to ∞P_∞ , which is mostly vertically striated. Angle $\infty P_\infty : \infty P = 44^\circ 18'$; $\infty P_\infty : P_\infty = 87^\circ 27'$; $P_\infty : P_\infty = 70^\circ 0'$.

SULPHOSALICYLIC ACID, $C^6H^4(OH)(SO^3H)CO^2H$. The two potassium salts of this acid, $C^6H^4K^2SO^6 + 1\frac{1}{2}$ and $2H^2O$, described by Ira Remsen (vii. 1125), yield when fused with potash, as sole products, salicylic acid and phenol (*Sill. Am. J.* [3], vi. 284).

SULPHOTOLUIC ACID, $SO^3H.C^6H^4.CO^2H$. See **TOLUIC ACIDS**.

SULPHOTOLUIDE, $(C^6H^7)^2SO^2$. See **SULPHONES** (p. 1855).

SULPHO-UREA. Syn. with **THIOCARBAMIDE** (p. 395).

SULPHO-URETHANE, $NH^2.CS.SC^6H^5$. Syn. with **ETHYL THIOCARBAMATE** (p. 386).

SULPHUR. *Influence of Gypsum on the Extraction of Sulphur by Distillation*. According to Sestini (*Gazz. chim. ital.* 1874, 29), the saying of the miners in the Romagna, 'that gypsum destroys sulphur,' finds its explanation in the fact that gypsum and sulphur, at the temperature at which the latter distils, act on one another so as to form sulphur dioxide and calcium sulphide, according to the equation $CaSO^4 + 2S = 2SO^2 + CaS$. At the melting point of sulphur this reaction takes place to a slight extent only, and by itself would not occasion any considerable loss of sulphur; but the loss is increased by the circumstance that the expulsion and volatilisation of the crystallisation-water of the gypsum absorbs a quantity of heat which must be supplied by the burning sulphur. When sulphur is distilled under similar conditions over gypsum and over calcium carbonate, the latter gives rise to the formation of a much larger quantity of calcium sulphide than the former.

Physical Properties.—Crystals of sulphur from a mine in Sicily have been found by O. Silvestri (*Gazz.* 1873, 578) to agree exactly in crystalline form and other physical characters with artificially crystallised rhombic sulphur. Sp. gr. = 2.00630 at 26° . Melting point $124-125^\circ$. Solidifying point $96-99.5^\circ$. Specific heat = 0.1776.

On the Expansion-coefficient of Fused Sulphur, as determined by Pisati, see **HEAT** (p. 936).

Gernez (*Compt. rend.* lxxix. 219) finds that it is possible to obtain at pleasure, from the same solution and at the same temperature, either the octohedral or the prismatic modification of sulphur, by dropping into a supersaturated solution of sulphur in benzene or toluene, an octohedral or a prismatic sulphur-crystal; or the two modifications may be obtained simultaneously by dropping in the crystals of the two kinds together.

Further experiments have shown that the octohedral and prismatic modifications may also be produced simultaneously from melted sulphur. Fused sulphur left to cool in a vessel in which it is protected from the dust of the air is easily obtained in the state of superfusion, and may then be made to solidify by contact with a cold body, especially with a fragment of a prismatic sulphur-crystal, or by rubbing two bodies together within the fused mass. The crystals formed under these conditions are always prismatic. If, on the other hand, a fragment of an octohedral sulphur crystal be dropped into the superfused mass, the octohedral modification will be formed, and the solidification will proceed much more slowly. The best way of making this experiment is to melt the sulphur in a U-tube, then leave it to cool, and drop a crystal of octohedral sulphur into one arm of the tube. An octohedral crystal is then immediately seen to form at the surface of the liquid, and to grow downwards till it reaches the lower layers, the solidification being accompanied by a contraction

of volume, evidenced by the sinking of the level of liquid in the other arm by about a seventh of its original height. When one arm of the tube has thus been filled with octohedral crystals, if the surface of the liquid in the other arm be touched with a prismatic sulphur-crystal, this arm of the tube will in a few seconds be completely filled with prismatic crystals of sulphur. The two kinds of crystal are transparent, and at first undistinguishable in appearance; but, on leaving the tube at rest for awhile, the prismatic crystals in contact with the octohedrons become opaque and paler, whilst the octohedral crystals retain their colour and transparency (Gernez, *Compt. rend.* lxxxiii. 217).

According to Barilari (*Gazz.* 1878, 178), the crystals of sulphur which separate from an alcoholic solution of ammonium sulphide at ordinary temperatures are monoclinic.

According to W. R. Hodgkinson (*Chem. News*, xxxiv. 68), the *plastic* modification of sulphur may be obtained in the wet way by passing hydrogen sulphide into a solution of iodine.

On the Isomorphism of Sulphur and Selenium, see Rammelsberg (*Ber.* vii. 669; *Jahresb. f. Chem.* 1874, 206).

Solubility in Acetic Acid.—According to L. Liebermann (*Ber.* x. 866), acetic acid can dissolve a considerable quantity of sulphur. On diluting the solution with water, a precipitate of sulphur-milk is formed; and when it is evaporated under the air-pump, the sulphur remains in the form of long slender prisms.

Direct Oxidation.—According to Pollacci (*Gazz. chim. ital.* 1875, 237), sulphur is directly oxidised by the oxygen of the air. He finds that sulphur, when moistened with water or merely exposed to moist air, is converted after some time into sulphuric acid. Moist flowers of sulphur form in a given time a larger quantity of sulphuric acid than sulphur which has been melted and pulverised, probably because they expose a larger surface to water and air. The crystals of gypsum and sulphur which form in the clefts of San Filippo in Tuscany are often found to be soaked in free sulphuric acid. In the bath-rooms of Aix in Savoy, the limestone walls and the iron plates on the doors and windows are gradually converted into sulphates, and the linen curtains are very quickly destroyed by the action of the free sulphuric acid. All these effects are attributed by Pollacci to the oxidation of hydrogen sulphide.

Relative Affinity of Sulphur and Oxygen for Metals.—O. Schumann (*Liebigs Annalen*, clxxxvii. 286) has endeavoured to determine the relative affinities of sulphur and oxygen for metals from a comparison of the results of experiments on the action: (1) of hydrogen on sulphates; (2) of superheated steam on sulphides; and (3) of hydrogen sulphide on oxides. The substances experimented on were heated in tubes of glass or porcelain, while a current of pure hydrogen, or of steam, or hydrogen sulphide, was passed over them, and the products of the action were then analysed. The results are given in the following table, which shows, also, those previously obtained by other investigators:—

Metal	Action of Hydrogen on the Sulphate	Action of Steam on the Sulphide	Action of Hydrogen sulphide on the Oxide.
Ia.

In group Ia, the experiments are incomplete, owing to the want of vessels which are not attacked by the fused sulphides. There can be little doubt, however, that the sulphides would be converted into sulphates by the action of superheated steam; and since the oxides also yield sulphides with hydrogen sulphide, it follows that the metals of this group have a greater affinity for sulphur than for oxygen.

In group Ib, copper and silver behave exactly alike, and the affinities of sulphur and oxygen for these metals are about equal.

In group IIa, where the metals are arranged in the order of their atomic weights, the affinity for sulphur is seen to increase from magnesium to barium. Magnesium exhibits a greater affinity for oxygen; with calcium, the affinities for sulphur and for oxygen are about equal; whilst strontium and barium display a decidedly greater affinity for sulphur.

In group IIb, the affinities of the metals for sulphur and for oxygen are about

equal. The action of hydrogen on the sulphates shows that the affinities of the metals for both metalloids decrease in the order of the atomic weights, zinc yielding oxysulphide and cadmium yielding sulphide, whilst mercury yields only metal.

In group IV, the affinity of the metals is slightly greater for sulphur than for oxygen.

In group VII, manganese and iron exhibit equal affinities for sulphur and for oxygen. Nickel and cobalt show a somewhat greater affinity for sulphur.

The table exhibits a periodic rise and fall in the affinities of the metals for sulphur. In the first group the affinity decreases from potassium to silver. In the second group, it is almost *nil* with magnesium, increases from thence to barium, and decreases to mercury. In the third group, aluminium shows a minimum of affinity for sulphur. In the fourth and fifth groups the affinity for sulphur increases up to arsenic, and then decreases to bismuth. In the sixth group, it is once more at a minimum with chromium, and from thence increases throughout the seventh group.

The general conclusion from these experiments appears to be that the strength of affinity for sulphur in comparison with that for oxygen is greatest in metals of highest atomic volume.

SULPHUR BROMIDES (Hannay, *Chem. Soc. J.* xxvi. 823; xxxiii. 284).

When flowers of sulphur are treated with bromine, about 0.08 per cent. remains undissolved; this portion appears to belong to the prismatic modification, as it remains undissolved also when the flowers of sulphur are treated with carbon sulphide. Pulverised rolled sulphur, on the other hand, is completely dissolved. The vapour which surmounts the mixture of sulphur and bromine exhibits, even at 0°, the characteristic absorption-spectrum of bromine, but on addition of a larger quantity of sulphur this spectrum gradually disappears.

The following are the temperatures at which the spectrum ceases to be visible in a column 0.5 meter long of the vapour standing over different mixtures of sulphur and bromine:

For	S ² Br	S ² Br ²	S ² Br	S ² Br ²	SBr	S ² Br ²	SBr ²
Temp.	42°	33°	25°	13°	3°	-7	still visible at -18°

In the distillation of a considerable quantity, the mixture begins to boil at 72°, and the boiling point rises continuously up to that of sulphur, affording therefore no evidence of the formation of a definite compound.

The specific gravities of various mixtures of bromine and sulphur are as follows:

S ² Br	S ² Br	SBr	SBr ²	SBr ²	SBr ²
2.293	2.625	2.628	2.620	2.880	2.905

The greatest contraction therefore takes place with the proportion S : Br². On exposure to low temperatures, the mixtures become viscid, but do not solidify even at temperatures at which bromine freezes.

When the fuming liquid S²Br², formed on bringing bromine and sulphur together in the ratio 80 : 32, is exposed to the air in a thin layer, it deposits free sulphur in fine crystals soluble in carbon sulphide, as is also the amorphous sulphur which separates from the liquid on addition of a large quantity of water. Ordinary phosphorus dissolves in the sulphur bromide, with evolution of heat, forming a solution which explodes when an attempt is made to distil it. Amorphous phosphorus does not act on the sulphur bromide. Potassium and sodium in thin plates take fire in contact with it; aluminium powder remains bright in it; antimony powder unites with the bromine without incandescence; arsenic dissolves in it to a colourless fetid liquid. When a small quantity of arsenic is dissolved in SBr², and the liquid is cooled to -18°, dark-red crystals are formed, having the composition AsS²Br² or possibly AsSBr, SBr².

From these results, Hannay concludes that when bromine and sulphur are brought together in any proportions whatever, the action between them does not take place in multiple proportions, but is rather an action on the entire mass. If, however, the body SBr² comes in contact at a comparatively low temperature with another with which it can unite, combination between them then takes place in multiple proportions.

The properties of sulphur sulphodibromide, S²Br², have also been investigated by Muir (*Chem. Soc. J.* xxviii. 845). When sulphur and bromine are brought together in the proportion required to produce this compound, they unite, with only slight evolution of heat, which, however, may be increased by agitation. The sulphodibromide begins to distil at 60°, the thermometer then rising slowly to 190°, and by the time it rises to 220°, nearly half of the liquid will have passed over, the residue in the retort being then nearly solid. On rectifying the latter distillate, and collecting apart that which passed over between 190° and 200°, a liquid was obtained consisting

of nearly pure sulphur sulphodibromide, S^2Br^2 (anal. 70.39 p. c. Br; calc. 71.43). When an excess of bromine was added to the sulphodibromide, and carbon dioxide was passed for some time through the liquid at 15° , 50° , and 90° , the residue always exhibited the composition S^2Br^2 . When sulphur was treated with a quantity of bromine larger than that required to form the compound SBr^2 , the whole then placed in a freezing mixture and carbon dioxide passed through it for a considerable time, no definite compound was obtained.

According to Hannay (*Chem. News*, xxxviii. 240), sulphur bromide [$? \text{S}^2\text{Br}^2$] undergoes complete dissociation at 15° , and the retention of bromine at higher temperatures is due to the passage of the sulphur into the plastic state.

SULPHUR CHLORIDES and OXYCHLORIDES. See viii. 1129–1133.

Sulphuric Hydroxychloride, or Chlorhydrate, $\text{SO}^2(\text{OH})\text{Cl}$. This compound may be conveniently prepared by the action of hydrogen chloride on crystallised pyrosulphuric acid, $\text{S}^2\text{O}^4\text{H}^2$:

The acid liquefied by heat is saturated with dry hydrogen chloride, and the hydroxychloride, the formation of which is attended with considerable rise of temperature, is distilled off; it passes over in nearly theoretical quantity as a liquid boiling between 149° and 151° (corr. 150.7° – 152.7°) (Beckurts a. Otto, *Ber.* xi. 2058).

Sulphuric Chloride, SO^2Cl^2 . Williamson observed that the hydroxychloride is resolved by distillation into sulphuric acid and sulphuric chloride, SO^2Cl^2 , and Behrend (*J. pr. Chem.* [2], xv. 23) has founded on this observation a method of preparing the latter compound. He finds that the decomposition takes place readily in a sealed tube at 200° – 210° ; and that on distilling the contents of the tube, purifying the portion which goes over up to 110° by a second distillation on the water-bath, and pouring the whole of this second distillate into a tap-funnel filled with lumps of ice, the ice-cold water instantly decomposes the remaining sulphuric hydroxychloride and the sulphuric anhydride formed in the reaction, whereas the sulphuric chloride is scarcely attacked by it, and sinks to the bottom as a heavy oil. It may be dried with calcium chloride, or better in the exsiccator over phosphoric anhydride, and redistilled at the heat of the water-bath, whereupon it passes over as a colourless, mobile, extremely pungent-smelling liquid, which fumes slightly in the air, boils constantly at 70.5° , has a density of 1.661 at 21° , and vapour-density = 4.751 (calc. 4.677). The yield is about 40 per cent.

According to Beckurts a. Otto (*loc. cit.*), the decomposition of sulphuric hydroxychloride, in the manner above mentioned, is by no means complete, a considerable portion remaining unaltered even after heating for a long time at 170° – 180° . Moreover, chlorine and sulphurous anhydride are amongst the products of the decomposition, and the conversion of the sulphuric hydroxychloride into the chloride appears to take place in such a manner that the hydroxychloride is first resolved into free chlorine and dithionic acid, which latter splits up into sulphurous anhydride and sulphuric acid, according to the equations:

and the chlorine and sulphurous anhydride then unite to form sulphuric chloride.

Action of Sulphuric Chloride on Alcohols.—The products of this reaction are alcoholic sulphuric chlorides, $\text{Cl}.\text{SO}^2.\text{OR}$, analogous to sulphuric hydroxychloride. To prepare them, the alcohol is added by drops to the sulphuric chloride contained in a cooled vessel, and the product is purified by pouring into ice-cold water and drying it over phosphoric anhydride. In this manner have been prepared: *Sulphuric methoxychloride*, $\text{Cl}.\text{SO}^2.\text{OCH}^3$, which is easily decomposed by water; and *sulphuric butoxychloride*, $\text{Cl}.\text{SO}^2.\text{OC}^4\text{H}^9$, a pungent-smelling liquid, which is converted gradually at ordinary temperatures, with explosive violence at 80° , into a dark-brown glutinous substance. Benzyl alcohol did not yield a pure sulphochloride (Behrend, *Ber.* ix. 1334).

Sulphuric ethoxychloride, $\text{Cl}.\text{SO}^2.\text{OC}^2\text{H}^5$, is formed, together with other products, by the action of sulphuric anhydride on ethyl chloride, also by that of phosphorus pentachloride on potassium ethylsulphate. After drying by means of anhydrous cupric sulphate (calcium chloride decomposes it), it distils almost completely at 80° – 96° under a pressure of 13.5 mm. When ammonia is passed into a solution of this compound in anhydrous ether, a white crystalline mass is formed, which is insoluble in absolute alcohol, and appears by analysis to be a mixture of sal-ammoniac and

sulphuric ethyloxamide, $\text{NH}_2\text{SO}_2\text{OC}_2\text{H}_5$, which could not be separated. With *phenol*, sulphuric ethoxychloride yields two sulphonic acids which have not yet been investigated (T. v. Purgold, *Ber.* vi. 502). With *methyl alcohol*, sulphuric ethoxychloride forms methyl-ethyl sulphate, $(\text{CH}_3)(\text{C}_2\text{H}_5)\text{SO}_4$, a neutral, faintly yellowish liquid, which is also formed by the action of ethyl alcohol on sulphuric ethoxychloride (Behrend).

Sulphur-selenium Oxytetrachloride, $\text{SO}^*\text{SeCl}^4 = \text{ClSO}^*\text{O}.\text{SeCl}^3$, which Rose obtained by the action of sulphuric anhydride on selenium tetrachloride (v. 223), is also produced from the latter: (1). By the action of sulphuric hydroxychloride, $\text{SO}^*\text{Cl}(\text{OH})$. The resulting solution, which has a yellowish to red-brown colour while warm, solidifies on cooling to a crystalline cake, made up of small slender white needles, mostly grouped in radial bundles. (2). By the action of pyrosulphuric acid:

(3). By heating selenium tetrachloride with sulphuric acid:

(4). By heating selenium tetrachloride with pyrosulphuric chloride:

(5). From sulphuryl chloride and selenium oxychloride. At ordinary temperatures these bodies do not act on one another, but mix to a greenish-yellow liquid, which after some time deposits small cubic crystals of selenium chloride; but if the mixture be heated for some hours at 170° – 180° , it solidifies to a crystalline mass of sulphur-selenium oxytetrachloride:

(6). Together with sulphuric acid by heating sulphuryl chloride with selenious anhydride.

Sulphur-selenium oxytetrachloride resembles sulphur oxytetrachloride (vii. 1132) in external appearance, deliquesces with equal rapidity in moist air, but does not decompose spontaneously when excluded from the air, and is not decomposed by heat. It melts at 165° , boils at 183° , is but very slightly attacked by strong sulphuric acid. Its vapour-density at 209° is 3.362, instead of the calculated value 10.426; it therefore undergoes dissociation when heated, probably according to the equation:

(F. Clausnitzer, *Ber.* xi. 2007).

Sulphur-titanium Oxytetrachloride, $\text{SO}^*\text{TiCl}^4 = \text{ClSO}^*\text{O}.\text{TiCl}^3$, is formed, with evolution of hydrogen chloride, when sulphuric hydroxychloride is added by drops to titanium tetrachloride, and remains, on heating the product at 100° , as a yellow amorphous powder, which deliquesces partially in moist air, but may be kept unaltered for a long time apart from the air (Clausnitzer, *loc. cit.*)

SULPHUR, OXIDES and OXYGEN-ACIDS OF. On the Thermic Relations of these Compounds and their Salts, see HEAT (pp. 954–959; 962; 982–989; 996–997).

Hyposulphurous acid, SO^*H^2 .—On the Reaction of this Acid with Aërated Water see OXYGEN (p. 1470).

Sesquioxide, S^2O^3 (R. Weber, *Pogg. Ann.* clvi. 531). The blue substance produced by the action of sulphur on sulphuric oxide (SO^2), or on strongly fuming oil of vitriol, is insoluble in pure sulphuric oxide, and may be isolated by the following method. Well-dried flowers of sulphur are gradually added to sulphuric oxide freed by careful rectification from sulphuric acid, fresh quantities being added only when the previous portions have entered into combination. The sulphur, at the moment of contact with the sulphuric oxide, liquefies to dark-blue drops which do not mix with the oxide, but sink in it and immediately solidify. The operation may be conveniently performed in a test-tube covered with the lid of a small porcelain crucible to protect the contents from the moisture of the air. It is advisable to incline the tube after each addition of sulphur, so that the drops of the resulting compound may come in contact with its surface; they then spread out on the glass, and harden to a thin crust which does not enclose so much of the anhydride as the solidified drops surrounded by the liquid. The tube should be cooled by immersion in water at 12° –

15°, to prevent decomposition by rise of temperature. After about a gram of sulphur has been added, the excess of sulphuric oxide—which is perfectly colourless if the process has been well conducted—is poured off, the last portions of it expelled by very careful evaporation at a temperature not above blood-heat, and the layer of blue substance adhering to the tube is removed with a sharp-edged glass rod. The compound thus prepared forms bluish-green very friable crusts having a structure like that of malachite, and made up of nodular groups of crystals recognisable only with a magnifying glass. It is liquid at the moment of formation, but soon solidifies, and cannot be remelted without decomposition. It decomposes, after a short time, even at ordinary temperatures, and much more quickly when heated, giving off sulphur dioxide, and leaving, if moisture has been excluded, perfectly dry sulphur having a very light yellow colour in consequence of its finely divided state. At low temperatures the decomposition goes on slowly enough to admit of the weighings required for analysis. In moist air the compound quickly absorbs water, and deliquesces to a clear brown liquid, which, on further absorption of moisture, becomes turbid from separation of sulphur. The compound, when dropped into cold water, decomposes instantly with violent hissing, yielding sulphuric and sulphurous acids, together with thiosulphuric acid or a polythionic acid resembling it, and free sulphur, mostly of soft tenacious consistence. With *anhydrous alcohol* or *ether* the blue compound decomposes, with separation of sulphur. Its analysis gave on the average 57·12 per cent. sulphur, agreeing closely with the formula S^2O^3 , which requires 57·14 per cent.

Sulphur sesquioxide dissolves with deep blue colour in a mixture of sulphuric oxide and acid, even if this mixture contains but a small proportion of the latter. Such solutions, if kept in sealed tubes and in a cool place, retain their blue colour for several weeks. Gradually, however, this colour becomes paler, and the solutions acquire a green, afterwards a brown tint, and ultimately a colour like that of common oil of vitriol, sulphurous oxide being at the same time evolved, and sulphur deposited if the quantity of sulphuric oxide present is not very large. Addition of sulphuric acid or of sulphur causes the change of colour to take place immediately. The brown solutions are much more stable than the blue. In an acid containing only 1 mol. SO^3 to 5 mols. SO^2H^2 , the sesquioxide dissolves at once with brown colour. Ordinary sulphuric acid decomposes it immediately, with separation of sulphur.

A corresponding *sulphur-selenium compound*, $SeSO^3$, is produced by direct combination of selenium with sulphuric oxide. The selenium softens, and is converted into a deep green tarry mass which gradually solidifies; and after decanting the excess of sulphuric oxide, and removing the last portions of it by careful evaporation, the selenium-compound may be scraped out with a sharp-edged glass rod. It has a dingy-green colour in the compact state, yellow in powder. It is much more stable than sulphur sesquioxide, not being decomposed even by gentle heating. At a higher temperature it is resolved, without previous fusion, into sulphur dioxide, selenium dioxide, and selenium. On throwing it into water, a violent reaction takes place, selenium being separated as a coherent mass, and sulphuric, sulphurous, and selenious acids produced. The compound dissolves with deep green colour in sulphuric oxide mixed with sulphuric acid; also without decomposition in strong sulphuric acid, (SO^2H^2), and, on adding a small quantity of water to the solution, it turns brown before completely decomposing. The compound also dissolves with brown colour in sulphuric acid of sp. gr. 1·806 (Weber).

Dioxide, Sulphurous Oxide, or Anhydride, SO^2 . Melsens (*Compt. rend.* lxxvi. 92) prepares this compound, as formerly suggested by Dumas, by the action of sulphur on sulphuric acid. If a glass vessel is used for the purpose, fragments of pumice must be immersed in the acid to ensure the production of a regular current of the gas. With cast-iron vessels it is easy to prepare in this way large quantities of sulphur dioxide.

Pierre (*ibid.* 214) determines the boiling point of the liquid dioxide by placing it in a test-tube of thin glass closed with a cork having two borings, through one of which a thermometer is inserted, while the other affords an escape for the vapours. At ordinary temperatures the sulphurous oxide begins to boil violently, but the boiling soon slackens in consequence of the cold produced by the evaporation; then again becomes violent, once more slackens, and so on. During this fluctuating ebullition, the boiling point scarcely varies by 0·2°. If the tube be wrapped in flannel to prevent the deposition of a film of water on the glass, the limit will be still further narrowed. The boiling point thus determined is about -8° .

Sulphites. *Normal Ammonium Sulphite*, $(NH^4)^2SO^3$, is produced by the decomposition of the residues of Lamings masses from gas works, which are used for the preparation of ammonium sulphate. These residues, when left to themselves, become heated, sometimes even to redness, and give off white vapours which may be

condensed in a glass vessel held over the heap, the deposit being found to consist of ammonium sulphite. The masses originally contain—in addition to sulphate of ammonium—considerable quantities of thiocyanate, and the sulphite appears to be formed from this latter salt by oxidation and assumption of water:

(E. Scheitz, *Arch. Pharm.* [3], v. 332).

Sodium-hydrogen Sulphite, SO^3NaH .—This salt is recommended by Th. Schuchardt (*Dingl. pol. J.* cxix. 154) as an antichlor, instead of the thiosulphate. The latter deposits sulphur on the tissues in a very finely divided state, and this sulphur becomes oxidised to sulphuric acid, which gradually destroys the fibre. This inconvenience may be obviated by the use of normal sodium sulphite; but the acid sulphite is preferable, as it acts more strongly and is relatively cheaper.

Sulphite of Palladium and Sodium, $\text{PdSO}^3, 3\text{Na}^2\text{SO}^3 + 2\text{H}^2\text{O}$, is formed on mixing a solution of palladium dichloride with sulphurous acid, and gradually adding caustic soda, whereupon a nearly white precipitate is formed, which gradually becomes crystalline, and dissolves in an excess either of sulphurous acid or of soda. When dry, it forms a pale-yellow crystalline powder, which, when heated, first assumes a deeper yellow colour, then decomposes and turns black. Potash and ammonia do not precipitate a solution of palladious chloride mixed with sulphurous acid (Wöhler, *Liebig's Annalen*, clxxiv. 199).

Sulphites of Iridium and Sodium (Seubert, *Ber.* xi. 1761).—In the process of separating iridium from rhodium by means of sodium sulphite, a sodium-iridium sulphite is obtained in the form of a more or less bulky whitish-yellow precipitate. In one of the flasks used for the precipitation, whitish-yellow satiny scales were deposited, having the composition $\text{IrSO}^3, 3\text{Na}^2\text{SO}^3 + 10\text{H}^2\text{O}$, and separable for the most part by levigation from the amorphous precipitate formed at the same time. In another flask the precipitate consisted chiefly of broad white needles having the composition $\text{IrH}^2(\text{SO}^3)^2, 3\text{Na}^2\text{SO}^3 + 4\text{H}^2\text{O}$. A third salt separated on the sides of the vessel in stellate groups of very slender needles consisting of $\text{IrH}^2(\text{SO}^3)^2, 3\text{Na}^2\text{SO}^3 + 10\text{H}^2\text{O}$. All these salts are but slightly soluble in cold water, more abundantly, but not without decomposition, in hot water. They have an acid reaction, and dissolve in acids, with evolution of sulphur dioxide; oxidising bodies change the light colour of their solutions to green, afterwards to blue. With alkalis and alkaline chlorides they yield white precipitates containing the whole of the iridium, and a similar reaction is produced by silver nitrate. When heated, they acquire a darker colour, and give off sulphur dioxide; and at a red heat they leave a skeleton of black iridium and sodium sulphate.

When ammonium chloridate is treated with sulphurous acid, a moss-green powder is obtained, the aqueous solution of which, when strongly concentrated, deposits brown needles of the sesquichloride of iridium and ammonium, $\text{Ir}^2\text{Cl}_2, 6\text{NH}^4\text{Cl} + 3\text{H}^2\text{O}$, described by Claus; afterwards, when strongly cooled, beautiful orange-red shining crystals of the salt $\text{IrCl}^2, \text{SO}^3\text{H}^2, 4\text{NH}^4\text{Cl}$, which is extremely soluble, but not deliquescent, and has an acid reaction. This compound is an acid capable of decomposing alkaline carbonates, and forming with the alkalis very unstable salts, which lose their power of crystallisation even at the heat of the water-bath, and are separated from their solutions by alcohol in the form of dark-red oils, solidifying, when treated with absolute alcohol, to dark masses. The *potassium salt* has the composition $\text{IrCl}^2, \text{SO}^3\text{K}^2, 2\text{NH}^4\text{Cl} + 4\text{H}^2\text{O}$; the *ammonium salt* is $\text{IrCl}^2, \text{SO}^3(\text{NH}^4)^2, 2\text{NH}^4\text{Cl} + 4\text{H}^2\text{O}$.

On the compounds of Sulphites with *Pyrroacemates*, see PYRORACEMIC ACID (p. 1718).

Sulphur Trioxide, Sulphuric Oxide, or Anhydride, SO^3 . *Formation*.—According to Scheurer-Kestner (*Compt. rend.* lxxx. 1230), the white fumes given off in the combustion of pyrites, consist not of sulphuric acid vapours, but of the anhydride, since they are formed even when the pyrites is perfectly dry. The anhydride is in fact produced by the direct combination of sulphur dioxide with oxygen in presence of red-hot ferric oxide (oxidised pyrites), as Scheurer-Kestner has shown by passing air mixed with sulphur dioxide through a red-hot platinum-tube containing burnt pyrites (*comp.* Wöhler, *Liebig's Annalen*, lxxxi. 255).

Winkler (*Dingl. pol. J.* ccxviii. 128, *Chem. Soc. J.* xxix. 784) has made experiments on the formation of sulphur trioxide by the direct combination of oxygen and sulphur dioxide, platinised asbestos being used as a contact-agent. With a layer of asbestos 30 cm. long and 12 mm. thick, containing 8.5 per cent. platinum, and heated to redness, 100 pts. by weight of sulphur dioxide yielded the following results:—

(a). Mixture of pure SO_2 and pure oxygen	73.3 pts. SO^2
(b). Mixture of pure SO_2 and air	47.4 „
(c). Mixture of air and 4 to 5 vols. per cent. SO_2 obtained by burning sulphur in a current of air	11.5 „

The action of the platinised asbestos (and of other contact-substances) diminishes therefore in proportion as the sulphur dioxide is diluted with indifferent gases.

A mixture of pure sulphur dioxide and oxygen in the required proportions may be obtained from sulphuric acid, which at high temperatures is resolved into SO_2 , oxygen and water.

The apparatus used by Winkler consisted of a wrought-iron tube coated inside and out with a mixture of Chamotte clay and water-glass, this mixture being burnt in, and the tube filled with fragments of porcelain. It was then heated to bright redness in a charcoal fire, and sulphuric acid of 66° was continually dropped into it through a twice-bent funnel-tube. The escaping gases were dried by passing over lumps of pumice drenched with sulphuric acid, and then passed into a long glass tube, horizontal at first, then bent downwards, and having its horizontal part loosely filled with platinised asbestos (containing 8.5 per cent. platinum), whilst the vertical arm dipped into a receiver filled with strong sulphuric acid destined to receive the anhydride formed by the reaction. This receiver was connected with a second, also containing strong sulphuric acid, and the latter with a third containing a solution of sodium carbonate. With this apparatus, 195 grams of sulphuric acid of 66° (= 146.2 g. SO^2) yielded 107.8 g. SO^2 , 22.6 g. SO^2 , 5.6 g. oxygen and 45.8 g. water, while 13.2 g. sulphuric acid remained undecomposed. Consequently 73.7 per cent. of the anhydride contained in the total quantity of sulphuric acid employed, or 78.4 per cent. of the anhydride contained in the sulphuric acid actually decomposed, was obtained in the form of fuming sulphuric or pyrosulphuric acid.

For preparation on the large scale, sulphuric acid of 66° is made to flow in a thin stream into earthenware retorts heated to bright redness, and the products of decomposition are passed, first through a cooling apparatus to condense the water, then through towers filled with coke moistened with strong sulphuric acid, to complete the drying, and finally into tubes of glazed earthenware filled with platinised asbestos, and heated to low redness. From 50 to 103 kg. asbestos, containing 8 kg. platinum, are sufficient for a work of considerable size. The resulting sulphur trioxide is collected in tubes of glazed earthenware, or brought in contact with a shower of sulphuric acid of 66° . The unabsorbed mixture of sulphur dioxide and oxygen is passed into lead chambers.

This process has been patented by Squire a. Messel (see further *Dingl. pol. J.* cccxiii. 409).

Properties.—The variation in the melting point of sulphur trioxide according to its mode of solidification, which was attributed by Marignac (v. 569) and Schultze-Sellack (vii. 1135) to the existence of different modifications, has been shown by R. Weber (*Pogg. Ann.* clxx. 313) to be due to imperfect purification. Weber has prepared the pure trioxide by repeated distillation, finally in a sealed bent tube. It is at ordinary temperatures a very mobile perfectly colourless liquid, which when slowly cooled solidifies in long transparent crystals resembling those of saltpetre, and quite different from the opaque asbestos-like needles of ordinary sulphuric anhydride; it melts at 14.8° , and boils at 46.2° (bar. 761.6 mm.) Sp. gr. 1.940 at 16° . It may be kept for years without giving any indication of change in its molecular state. By absorption of a small quantity of moisture it is converted into a snow-white, opaque, infusible body, which, if present even in small quantity, diffuses itself through the liquid in flocks, which may easily be made to adhere together in the upper part of a glass tube. This hydrated compound, the proportion of water in which must be very small, is a constituent of the ordinary anhydride, and gives rise to its peculiar properties. Besides this hydrate containing the minimum of water, the cautious addition of ordinary sulphuric acid to the ordinary anhydride gives rise to a liquid product, from which at 8° to 10° spicular crystals separate, having the composition $\text{H}_2\text{S}^2\text{O}^{13}$ or $\text{H}^2\text{O}, 4\text{SO}^2$. In preparing this last hydrate, an excess of common sulphuric acid must be avoided, as even a small quantity of it prevents the separation of these crystals and determines the formation of pyrosulphuric acid, $\text{S}^2\text{O}^2\text{H}^2$, or $\text{H}^2\text{O}, 2\text{SO}^2$.

With reference to these observations of Weber, Marignac (*N. Arch. ph. nat.* lviii. 228) publishes the following results of some new experiments on preparations made twenty-four years ago.

When sulphuric oxide which had been kept in sealed glass tubes was slowly heated in a water-bath, it began to melt on the first day at about 100° ; on the second day it began to become transparent between 50° and 60° ; between 60° and 65° a

partial fusion took place; at 80° it was still only partly fused, and the fusion was not complete till the heat was raised to 95°. In an experiment made on the following day the oxide began to be transparent at 35°–40°, at 70° the greater part was melted, and at 80° the fusion was complete. The experiment was repeated on the fourth day, the temperature being kept for twenty-four hours between 45° and 50°. After that time three-fourths of the substance was found to be melted, the rest forming a gelatinous mass floating in a liquid. From these observations, Marignac thinks it may be inferred that, even admitting the probability of Weber's supposition as to the solid modification owing its existence to the presence of a hydrated compound, still the gradual alteration of the melting point after repeated fusion can be due only to an isomeric alteration, or to an alteration of the mode of combination of the hydrated compound with the anhydrous oxide. He observes that he formerly examined both the liquid compound and that which fuses only at a higher temperature, and found them both to have the composition SO_3 , so that the amount of water in the solid modification must at all events be extremely small.

With *ethyl chloride*, sulphuric oxide yields sulphuric ethoxychloride, $\text{ClSO}_2\text{OC}_2\text{H}_5$, together with the two isomeric compounds, chlorisethionic acid, $\text{C}_2\text{H}_4\text{ClSO}_2\text{OH}$, and isethionic chloride, $\text{C}_2\text{H}_4(\text{OH})\text{SO}_2\text{Cl}$ (see *ETHYL CHLORIDE*, p. 746).

Sulphuric Acid, $\text{SO}_3\text{H}_2 = \text{SO}_2(\text{OH})_2$. *Manufacture*.—H. A. Smith (*Phil. Mag.* [4], xli. 121) infers from observations of his own that the best dimensions for the lead chambers are 150 feet long, 20 to 30 broad, and 10 to 12 high. The temperature in the chamber should be kept as nearly as possible at 200° F. (93·33° C.), this temperature being produced and kept up by the vapours which enter the chamber. In starting the operation, the floor of the chamber should be covered with sulphuric acid, not with water.

H. Sprengel has contrived an apparatus by means of which water-spray instead of vapour is introduced into the leaden chambers. A jet of steam is blown through a platinum tuyere into a jet of water, whereby the latter is finely divided. 20 kg. of steam are sufficient to convert 80 kg. of water into spray. By thus dispensing with the evaporation of the water, a considerable saving of fuel is effected. The nitric acid may also be introduced into the chambers in a very similar manner, the Glover tower being thereby reduced to a mere condensing apparatus, and the loss of nitric acid ascribed to it thereby avoided (*Pharm. J. Trans.* [3], vi. 324; *Chem. News*, xxxii. 150).

On Apparatus for the Manufacture of Sulphuric acid, contrived by de Homptinne, see Bode (*Dingl. pol. J.* cxxvii. 300; cxxiv. 1137; *Jahresb. f. Chem.* 1875, 1053; 1877, 1137). On the roasting of Pyrites, see McCulloch (*Chem. News*, xxvii. 124, 135).

On the Estimation of the Loss of Sulphurous acid in the Lead-chamber process, see Mactear (*Chem. News*, xxxvi. 49).

On the Recovery of Nitrogen Oxides in the Manufacture of Sulphuric acid, and the Function of the Glover Tower, see Vorster (*Dingl. pol. J.* cxxiii. 411, 506; *Jahresb. f. Chem.* 1874, 1104; *Chem. Soc. J.* xxvii. 829, 924; and Lunge, *Ber.* x. 1432; *Dingl. pol. J.* 225; *Jahresb.* 1877, 1139; *Chem. Soc. J.* xxxii. 944).

Purification from Arsenic.—H. A. Smith (*Amer. Chemist*, 1873, 413) observes that the process of heating the sulphuric acid with common salt, or passing hydrochloric acid gas through it, never effects a complete removal of the arsenic. Better results are obtained with hydrogen sulphide, the best mode of proceeding being to mix the sulphuric acid with a sufficient quantity of iron sulphide, or of sodium sulphide in case the introduction of iron into the acid should be objectionable. The metallic sulphide is added to the acid in a leaden pan containing a layer of coke, which serves as a filter, and covered with a perforated lid, through which the excess of hydrogen sulphide can escape.

W. Thorn (*Dingl. pol. J.* cxxvii. 495) observes that in many sulphuric acid works, the removal of the arsenic is effected by sodium thiosulphate. Chamber-acid of 50° B. is heated to 70°–80°, and a quantity of thiosulphate equivalent to the arsenic present is added either in concentrated solution or in the form of powder. After the mixture has been sufficiently stirred, the arsenic separates on the surface in flocks of arsenious sulphide. The purified acid is withdrawn from under the flocks; the leaden vessel is again charged with chamber-acid, and after several repetitions of the operation, the arsenious sulphide is collected. The crude sulphuric acid contained 0·098 per cent. arsenic, the purified acid 0·004 per cent., together with 0·3 to 0·4 per cent. sodium sulphate.

With regard to this process, R. Wagner remarks (*ibid.* cxxviii. 321) that if the contamination of the acid with sodium sulphate is not objectionable, sulphide of sodium

is preferable to the thiosulphate; if, on the other hand, such contamination must be avoided, he recommends barium thiosulphate as the purifying agent, the reaction taking place as follows:

19·8 pts. arsenious oxide require 85·5 pts. $\text{BaS}^2\text{O}^3 + \text{H}^2\text{O}$.

With regard to the distribution of the arsenic occurring in pyrites in sulphuric acid and the products of the soda-manufacture prepared therewith, C. Hjelt shows (*Dingl.* cxxvi. 174) that the amount of arsenic in pyrites is very variable, Spanish pyrites containing 0·12 per cent., Westphalian 0·3, and Norwegian only traces of arsenic. He found also that in a sulphuric acid made from Spanish pyrites the average amount of arsenic, reckoned on pure hydrogen sulphate, H^2SO^4 , was:

	Arsenic p. c.	Present as arsenic acid p. c.
In chamber-acid.	0·202	0·040
In acid from the Glover tower	0·331	0·041
In acid from the Gay-Lussac tower . . .	0·344	0·132

He also directs attention to the fact that the loss of nitric acid in sulphuric acid works is due, at least in part, to the arsenic in the acid—that is to say in the pyrites—inasmuch as, in the Gay-Lussac tower, part of the nitrous acid is reduced by the arsenic in the sulphuric acid to nitrogen dioxide. In accordance with this view, it is found that the larger the proportion of arsenic in the pyrites used, the greater is the loss of nitric acid. In well-conducted alkali-works, the arsenic of the sulphuric acid never goes into the sodium sulphate, but is all found in the hydrochloric acid produced at the same time, none of it, however, passing into the bleaching-powder. In the burnt residues of Spanish pyrites, Hjelt found only 0·19 per cent. arsenic.

A description of the apparatus used at the Freiberg works for purifying sulphuric acid from arsenic is given by F. Bode (*Dingl.* ccxiii. 25).

Concentration.—Apparatus for the Concentration of Sulphuric acid is described by F. Bode (*Dingl.* cxi. 26; ccxiii. 204; ccxvi. 326; *Jahresb. f. Chem.* 1874, 1107; 1875, 1053).

Estimation.—The following method for the quantitative analysis of a mixture of sulphates of alkalis and alkaline earths (magnesia and lime) is described by Jean a. Pellet (*Bull. Soc. Chim.* [2], xxvii. 203). To determine the sulphuric acid in combination with the alkalis, the mixture of salts, dissolved, if necessary, with addition of hydrochloric acid, and carefully neutralised, is mixed with excess of barium hydrate, then with water containing carbonic acid, heated till the carbonic acid is expelled, and the weighed filtrate is titrated with sulphuric acid. The *calcium sulphate* is precipitated by alcohol from a measured volume of the solution, decomposed by boiling with a titrated solution of sodium carbonate, and the excess of the latter is determined by back titration. *Magnesium sulphate* is also decomposed by sodium carbonate and estimated in like manner by titration. To determine the total amount of sulphuric acid, free and combined, the sulphates are boiled with solution of sodium carbonate, and the liquid is filtered, neutralised with standard sulphuric acid, and treated with baryta as above. This method may be applied to the estimation of sulphates in pyrites.

To determine the amount of free sulphuric acid in vinegar, J. C. Thresh (*Pharm. J. Trans.* [3], vi. 1) adds a known quantity of barium chloride, evaporates and incinerates the whole, and calculates the free sulphuric acid from the loss of hydrochloric acid thence ensuing.

According to A. Hilger (*Arch. Pharm.* [3], vi. 510), the detection of free sulphuric acid in vinegar is best effected by means of sugar, which, if sulphuric acid is present, is blackened when the liquid is evaporated to dryness.

On the Methods of Estimating Sulphuric acid in Water, see Tiemann (*Ber.* vi. 918; *Jahresb. f. Chem.* 1873, 903).

Hydrates.—According to Pierre a. Puchot (*Ann. Chim. Phys.* [5], ii. 164), the 'dihydrate,' $\text{SO}^3\cdot 2\text{H}^2\text{O}$ or $\text{SO}^4\text{H}^2\cdot \text{H}^2\text{O}$, melts and solidifies at 7·5°, but afterwards exhibits superfusion. 3 pts. of the crystallised hydrate and 8 pts. of snow produced a fall of temperature to $-26\cdot 25^\circ$, whereas with an equal quantity of liquid acid, the temperature fell only to $-19\cdot 5^\circ$. On cooling a sulphuric acid intermediate between $\text{SO}^3\cdot \text{H}^2\text{O}$ and $\text{SO}^3\cdot 2\text{H}^2\text{O}$ (63°B.), part of it crystallised, and the liquid decanted therefrom exhibited a higher concentration. A more dilute acid did not crystallise at -8° to -10° , even when small crystals of the dihydrate were thrown into it.

METALLIC SULPHATES. The action of dry hydrogen chloride on these salts has been examined by C. Hensgen (*Ber.* ix. 1671, 1674; x. 259). *Potassium sulphate* is not attacked by the dry gas either at ordinary or at lower temperatures; at 100° the crystals become corroded at certain points; at 360°, the water into which the gas passes is found to contain a weighable quantity of sulphuric acid; and at a dull red heat, the salt is converted almost quantitatively into potassium chloride and free sulphuric acid. *Anhydrous sodium sulphate* is likewise completely decomposed by hydrogen chloride at high temperatures; crystallised Glauber's salt, $\text{Na}_2\text{SO}_4 + 10\text{H}_2\text{O}$, on the other hand, is completely converted at ordinary temperatures, and even at -17° , though less quickly, into sodium chloride. The Glauber's salt first melts in its water of crystallisation, with considerable reduction of temperature (-17°), but the temperature quickly rises, and remains during the decomposition at 53° – 55° ; and the resulting sodium chloride separates in the form of a fine-grained powder. *Anhydrous lithium sulphate*, Li_2SO_4 , behaves like the anhydrous sulphates of the other alkali-metals; the hydrate, $\text{Li}_2\text{SO}_4 + \text{H}_2\text{O}$, decomposes completely, even at ordinary temperatures, melting in its water of crystallisation, and taking up hydrogen chloride with considerable evolution of heat. The sulphates of calcium, strontium, and barium are likewise completely decomposed by HCl at a dull-red heat, as formerly shown by Bonssingault. *Magnesium sulphate*, MgSO_4 , is not attacked by dry hydrogen chloride at any temperature below commencing redness, but with the hydrated salt, $\text{MgSO}_4 + 7\text{H}_2\text{O}$, the action begins at ordinary temperatures. The crystals melt to a clear liquid, which after a while deposits a crystalline powder, soon in such quantity that the whole solidifies to a stiff crystalline pulp. The composition of these crystals (disregarding a small amount of chlorine) is most nearly expressed by the formula $\text{MgSO}_4 + 6\text{H}_2\text{O}$. The absorption of hydrogen chloride (12.52 p. c.) by the salt $\text{MgSO}_4 + 7\text{H}_2\text{O}$ was probably due to the water of crystallisation, and not to decomposition of the salt into magnesium chloride and sulphuric acid. *Dehydrated cupric sulphate*, CuSO_4 , is strongly attacked by dry hydrogen chloride, of which it takes up 2 mol., at the same time becoming hot, acquiring a dark brown colour, losing its pulverulent consistence, and caking together to a damp mass which gives up all its hydrogen chloride when exposed to the air or when heated. Hydrated cupric sulphate, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, is completely decomposed by dry hydrogen chloride, according to the equation $\text{CuSO}_4 + 2\text{HCl} = \text{CuCl}_2 + \text{H}_2\text{SO}_4$, the chloride separating in green needles having the composition $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$.

Ethylsulphates are not decomposed by dry hydrogen chloride at ordinary temperatures. The *potassium salt* remains quite unaltered; the *barium salt* absorbs the gas, with rise of temperature, the gas abstracting the water of crystallisation and dissolving therein. Between 65° and 85° , however, both these salts are decomposed, with evolution of ethyl chloride and formation of potassium disulphate in the one case, and of barium sulphate and sulphuric acid in the other (H. Köhler, *Ber.* xi. 1929).

Conversion of Sulphates into Carbonates, &c.—Alkaline sulphates may be converted into carbonates by dissolving them in carbonic acid water, and mixing them with $1\frac{1}{2}$ time their weight of barium carbonate rubbed to a thick paste with a little water, agitating the mixture strongly for some time, and finally heating it to the boiling point: the filtered liquid will then be found to contain nothing but carbonates. To convert an alkaline sulphate into the corresponding tartrate, oxalate, &c., it is heated in a porcelain basin with barium carbonate and water, and the requisite quantity of tartaric or oxalic acid is gradually added (L. Smith, *Amer. Chem.* 1873, iii. 241).

Aluminium sulphate.—The presence of free sulphuric acid in this salt may be quickly detected by stirring up the pulverised salt in alcohol. The salt is insoluble in this liquid, but free sulphuric acid dissolves in it, and may be recognised by its acid reaction, or estimated by titration. Pure aluminium sulphate gives with decoction of logwood a blue-violet coloration, but the presence of free sulphuric acid gives rise to a brown colour.

Ammonium sulphate.—The normal salt, $(\text{NH}_4)_2\text{SO}_4$, is formed in the combustion of coal-gas, and collects as a sublimate of short anhydrous prisms on the shades placed over the burners (Priwoznik, *Dingl.* ccciii. 223).

Several acid salts are formed by the action of heat on the normal salt. $(\text{NH}_4)\text{HSO}_4$ is produced when the normal salt is heated till the thick pasty mass ceases to give off ammonia. $(\text{NH}_4)^2\text{H}^+(\text{SO}_4)^3$ is formed when the preceding salt is more strongly heated, the heat being continued till the intumescence has subsided. By keeping the temperature somewhat lower, a third salt is obtained, having the composition $(\text{NH}_4)^3\text{H}^+(\text{SO}_4)^3$ (P. Schweitzer, *Amer. Chem.* vii. 42). These acid ammonium sulphates have also been examined by S. W. Johnson and R. H. Chittenden (*Sill. Am. J.* [3], xv. 131), whose analyses agree with those of Schweitzer so far as regards the amounts of sulphuric

acid, but differ considerably therefrom in the proportions of ammonia and water. They also show that Schweitzer's bisulphate still retained a portion of the normal sulphate, and hence conclude that it was a mixture of 1 mol. ammonium pyrosulphate, $(\text{NH}_4)_2\text{S}_2\text{O}_7$, 1 mol. normal sulphate, $(\text{NH}_4)_2\text{SO}_4$, and 3 mols. bisulphate, $(\text{NH}_4)\text{HSO}_4$. In like manner, they show that the so-called trisulphate, $(\text{NH}_4)_3\text{H}(\text{SO}_4)_3$, may be regarded as a mixture of 1 mol. pyrosulphate and 2 mol. bisulphate.

Barium Sulphate, BaSO_4 , may be obtained in crystals, partly grouped, by heating a dilute solution of the chloride with a slight excess of sulphuric acid at 245° (Scheerer a. Drechsel, *J. pr. Chem.* [2], vii. 68. When a solution of barium sulphate (14 pts.) in 100 pts. strong sulphuric acid (sp. gr. 1.843) was heated at 100° , a considerable number of needle-shaped crystals separated out. At 160° – 180° these crystals disappeared, and prismatic crystals began to separate, their quantity becoming greater the nearer the temperature of the liquid approached to the boiling point of the acid. At the latter temperature, 10 pts. of the acid still held in solution from 8.5–9 pts. of barium sulphate. On the other hand, the needles which separated at 100° were insoluble in the cold acid (T. Graside, *Chem. News*, xxxi. 245).

According to G. Brügelmann (*Zeitschr. anal. Chem.* x. 22), the process recommended by Fresenius (vii. 1128) for purifying the barium sulphate obtained in quantitative analyses does not always answer its purpose. Good results are, however, obtained when the ignited sulphate is triturated with 3 or 4 drops of strong hydrochloric acid and a few drops of water, then boiled with water and filtered, the process being repeated five times in the same manner.

Calcium Sulphate.—According to Pollacci (*Gazz. chim. ital.* 1874, 177, 245), gypsum, $\text{CaSO}_4 + 2\text{H}_2\text{O}$, is formed in a mixture of calcium carbonate and sulphur moistened with water, and the action is assisted by the organic matters in vegetable soil. In the hottest days of summer, 20–25 grams of material is sufficient to yield a small quantity of gypsum in three hours. According to Perognatelli a. Pelloggio (*Ber.* vii. 1462), sodium thiosulphate is formed at the same time. The carbonates of barium, strontium, and magnesium are converted into sulphates under like conditions, the action being slowest in the case of the magnesium salt. Pollacci attributes the transformation to a direct oxidation of sulphur: $\text{S}^2 + 3\text{O}^2 + 2\text{H}^2\text{O} = 2\text{SO}^2\text{H}^2$. In those cases in which calcium carbonate is said to be converted into gypsum under the influence of hydrogen sulphide, this compound does not appear to be directly oxidised, but to be decomposed by the oxygen of the air, with separation of sulphur, which then undergoes oxidation.

According to Cossa (*Gazz.* 1873, 135), 1000 pts. water dissolve 2.119 pts. gypsum at 16.5° , and 2.352 pts. at 22° . A saturated solution of gypsum acts on rocks containing alkaline silicates (gneiss, trachite, granite, felspar, basalt) much more readily than pure water, taking up in a given time a much larger quantity of soluble constituents. According to Asselin (*Compt. rend.* lxxvi. 884), 100 pts. of glycerol dissolve 0.957 pt. of gypsum at ordinary temperatures, and a continually larger quantity as the temperature rises.

Double Salts of Calcium Sulphate.—The following are described by R. Fassbender (*Ber.* ix. 1358; xi. 1968). The salt $\text{CaSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot \text{H}_2\text{O}$, first observed by Phillips, H. Rose, and others, and obtained by Struve (*Bull. Soc. Chim.* [2], xii. 348) on treating gypsum with a solution of potassium nitrate, chloride, or iodide, is also readily formed by dissolving potassium sulphate in a saturated solution of gypsum, the separation of the salt in slender silky needles beginning almost immediately, and going on for several months. The same double salt is obtained by treating solid gypsum with solution of potassium sulphate, and by dissolving potassium sulphate in a solution of potassium nitrate or chloride saturated with gypsum, a portion of the potassium nitrate or chloride, however, adhering to the product with great obstinacy (Fassbender); also, according to Ditte (*Compt. rend.* lxxxiv. 86), on adding sulphuric acid to a mixture of the two component sulphates, and boiling the liquid. The calcium sulphate then collects at the bottom in the form of a white powder, but in the course of twenty-four hours the whole solidifies to well-defined transparent flattened prismatic crystals of the double salt. These crystals lose their lustre and become anhydrous when heated, and are completely decomposed by water. When, on the other hand, calcium sulphate, either anhydrous or hydrated, is added to a saturated solution of potassium sulphate, the double salt, $\text{Ca}^2\text{K}^2(\text{SO}_4)_2 + 3\text{H}_2\text{O}$, separates almost instantly in spangles or small needles having a nacreous lustre. This salt is decomposed by cold water, which gradually abstracts all the potassium sulphate.

A Calcium-ammonium Sulphate, $\text{Ca}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$, which, according to Popp (*Liebig's Annalen*, 8 Suppl. 1), is obtained on evaporating the water of the Tuscan lagunes, may also be produced artificially by dissolving 285 grams of ammonium sulphate in 800 c.c. water, saturating the solution with gypsum, evaporating to 600–

500 c.c., and filtering at 40–50. This degree of concentration appears to be essential, inasmuch as the salt is resolved into its constituents by water (Fassbender). Ditte prepares this salt, like the corresponding potassium salt, by adding sulphuric acid to a mixture of the sulphates of calcium and ammonium, and boiling the liquid. It crystallises in needles which have a very strong lustre, and are instantly decomposed by water. The sulphates of sodium and lithium do not appear to unite under similar circumstances with calcium sulphate.

A *Calcium-potassium-ammonium Sulphate*, $\text{CaSO}_4 \cdot (\text{KNH}_4)\text{SO}_4 \cdot \text{H}_2\text{O}$, is obtained by adding potassium sulphate to a solution of ammonium sulphate saturated with gypsum; by digesting calcium-potassium sulphate with solution of ammonium sulphate; or by digesting gypsum with solutions of potassium and ammonium sulphates. Analogous sodium salts do not appear to exist; moreover, the above-mentioned double salts are decomposed by saturated solutions of sodium sulphate or other sodium salts, with separation of gypsum.

If, in a saline solution saturated with calcium sulphate, the solubility of that salt be diminished by the introduction of another salt, the calcium sulphate will be precipitated as gypsum or as anhydrite, according as the solution is at ordinary temperature or at the boiling heat. This reaction is best shown by adding magnesium sulphate to a solution saturated with common salt and gypsum (Fassbender).

Calcium-rubidium Sulphate, $\text{Ca}^2\text{Rb}^2(\text{SO}_4)^3 + 3\text{H}_2\text{O}$, prepared like the corresponding potassium salt, crystallises in stellate groups of translucent needles, which are decomposed by water (Ditte).

A number of remarkable double salts of calcium sulphate have been found by J. B. Hannay amongst the crystalline precipitates deposited in tubes through which have been successively passed solutions of K^2SO_4 , Na^2SO_4 , CaSO_4 , MgSO_4 and K^2CrO_4 , the last in excess. The greater number of the layers thus formed consisted of $\text{CaK}^2(\text{SO}_4)^2 \cdot \text{H}_2\text{O}$, but there were also found two double salts of potassium chromate, consisting respectively of $\text{CaK}^2(\text{SO}_4)(\text{CrO}_4) \cdot \text{H}_2\text{O}$ and $\text{CaK}^2(\text{SO}_4)(\text{CrO}_4)^2$. These two salts, scarcely distinguishable from one another in external appearance, form flat prisms of undeterminable form, but having a brilliant aspect like that of lead iodide; they are resolved by water into potassium chromate and pure calcium sulphate. Associated with the latter of these two salts was found a mass having a darken colour and no determinate crystalline structure, but appearing under the microscope to be made up of small felted needles, and having the composition $\text{CaSO}_4 \cdot \text{Na}^2\text{SO}_4 \cdot \text{K}^2\text{CrO}_4$. In another tube through which large quantities of the salt $\text{CaNa}^2(\text{SO}_4)^2$ had passed, a deposit was formed resembling the salt above described, but differing from it by containing water of crystallisation: its composition was $\text{CaSO}_4 \cdot \text{Na}^2\text{SO}_4 \cdot \text{K}^2\text{CrO}_4 + \text{H}_2\text{O}$. Hannay also describes a compound of calcium sulphate with hydrogen chloride. When a solution of calcium sulphate in hydrochloric acid is evaporated in a flask having its neck drawn out, and the residual gas is displaced by air without cooling the flask, a residue is left the composition of which agrees best with the formula $2\text{CaSO}_4 \cdot \text{HCl} + 3\text{H}_2\text{O}$, which is that of the normal salt $2\text{CaSO}_4 + 4\text{H}_2\text{O}$, having $1\text{H}_2\text{O}$ replaced by 1HCl (*Chem. Soc. J.* xxxii. 399).

Cerium Sulphates. See CERIUM (p. 421).

Chromic Sulphate, $\text{Cr}^2(\text{SO}_4)^3$.—Etard (*Compt. rend.* lxxxiv. 1089) prepares this salt by passing ether-vapour into a solution of 100 pts. chromic acid, 150 sulphuric acid, and 225 water, whereby, after some time, a dense crystalline mass is formed, which, after washing with ether and drying, consists of small lamellae, having a beautiful violet colour, permanent in the air, and having, when air-dried, the composition $\text{Cr}^2(\text{SO}_4)^3 + 18\text{H}_2\text{O}$. Schrötter, on the other hand, obtained the salt with $15\text{H}_2\text{O}$ (v. 588). When dried at 100° it gives off $12\text{H}_2\text{O}$, and is converted into a crystallised deliquescent salt belonging to the green modification. Hence it appears that the difference between the green and violet modifications of chromic salts is due to the different amounts of water which they contain, and that the passage from the violet to the green modification on heating must be attributed to an abstraction of water, which may take place even within the solution, and thereby depends upon a true dissociation. In confirmation of this view, Etard has treated the violet sulphate with dehydrating agents, such as strong nitric acid, sulphuric acid, and phosphorus trichloride, and finds that a conversion of the violet into the green modification takes place in every instance. He remarks that the complete conversion of a chromic salt into the green modification can be ascertained only by observation with artificial light, inasmuch as many chromic solutions appear green in sunlight, although they still contain considerable quantities of violet salt (Etard).

According to Lecoq de Boisbaudran (*Compt. rend.* lxxix. 1491), blue solutions of chrome-alum prepared in the cold gradually assume a green colour, and the green solutions prepared at higher temperatures gradually turn blue, these changes taking

place either in open or in closed vessels, in dilute or in strong solutions, and independently of contact with crystals. The first change is attended with dehydration of the blue salt and gradual increase of the volume of the solution; the second with hydration and gradual diminution of volume. The rate of conversion of the green into the blue salt diminishes rapidly with the time elapsed after cooling, an increase of volume being still perceptible after a month, and the state of equilibrium does not appear to be attained till after the lapse of eight years.

The double salt, $\text{Cr}^2(\text{KSO}_4)_6$, is obtained in yellowish-green felted needles by adding small quantities of chromic chloride to melting potassium bisulphate; and the corresponding sodium salt is obtained in like manner, though less easily, as a crystalline sandy powder (Etard).

On Double Sulphates of Chromium, see also p. 458.

Copper Sulphates.—A hydrate, having the composition $\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$, is obtained as an amorphous powder when the ordinary pentahydrate is heated at 25° – 30° in dry air. It is especially characterised by remaining quite unaltered in a vacuum, whereas the pentahydrate left in a vacuum at the same temperature gives off 4 mol. water (Magnier de la Source, *Compt. rend.* lxxxiii. 899). Another hydrate, formed in the preparation of the copper salt of benzenesulphonic acid, crystallises in large, thin, blue laminae, containing a small quantity of the benzenesulphonate (Ozier, *Ber.* ix. 83).

On the Dissociation of Cupric Sulphate, see p. 1013; on its reaction with HCl, see p. 1872.

Didymium Sulphate, $\text{Di}^2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$. See DIDYMIUM (pp. 425, 644).

Iron Sulphates.—*Ferrous and Ferric Sulphates* are formed, together with free sulphuric acid and hydrogen sulphide, when iron pyrites is heated with water at 120° in a sealed tube (C. A. Burghardt, *Chem. News*, xxxvii. 49).

Double Sulphates of Iron and Allied Metals (Etard, *Compt. rend.* lxxxvi. 1399; lxxxvii. 602). 1. *Ferrico-aluminic salts.*—When 2 mols. ferrous sulphate and 1 mol. aluminium chloride are dissolved in the smallest possible quantity of hot water, the ferrous salt oxidised with nitric acid, a large excess of strong sulphuric acid added, and the liquid heated to about 220° , a crystalline precipitate separates composed of microscopic hexagonal plates, which when freed by decantation from excess of sulphuric acid, washed with glacial acetic acid, and dried at 120° , exhibit the composition $\text{Fe}^2(\text{SO}_4)_3 \cdot \text{Al}^3(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4$. This salt, when heated to redness, gives off sulphuric acid, and leaves a white crystalline salt, insoluble in water, and having the composition $\text{Fe}^2(\text{SO}_4)_3 \cdot \text{Al}^3(\text{SO}_4)_3$.

2. *Ferrico-chromic Salts.*—The salt $\text{Fe}^2(\text{SO}_4)_3 \cdot \text{Cr}^2(\text{SO}_4)_3 \cdot \text{H}_2\text{SO}_4$ is obtained in like manner, with molecular proportions of ferrous sulphate and chromic acid, as a yellowish crystalline precipitate insoluble in water. When strongly heated, it likewise gives off sulphuric acid, leaving the insoluble and very stable salt, $\text{Fe}^2(\text{SO}_4)_3 \cdot \text{Cr}^2(\text{SO}_4)_3$.

Alumino-chromic Sulphate, $\text{Al}^3\text{Cr}^2(\text{SO}_4)_6 \cdot \text{H}_2\text{SO}_4$, is obtained in a similar manner, as a light-green crystalline precipitate, which when heated gives off H_2SO_4 , leaving $\text{Al}^3\text{Cr}^2(\text{SO}_4)_6$.

Manganico-aluminic Sulphate, $\text{Mn}^2(\text{SO}_4)_3 \cdot 2\text{Al}^3(\text{SO}_4)_3$, is formed when a mixture of manganous sulphate and aluminium sulphate is treated as above, and a mixture of sulphuric and nitric acids in equal volumes is added by small portions to the liquid previously heated to 250° . At this temperature the manganous sulphate is raised to a higher state of oxidation, nitrous fumes are evolved, the originally colourless solution turns violet, and the double salt separates as a fine blue precipitate insoluble in water.

Manganese-iron Sulphates.—The salt $\text{Fe}^2(\text{SO}_4)_3 \cdot 2\text{MnSO}_4 \cdot 3\text{H}_2\text{SO}_4$ is prepared in a similar manner, using ferrous sulphate instead of aluminium sulphate, and separates at about 160° , as a light-yellow well-crystallised salt, which is soluble in water, and when heated gives off $2\text{H}_2\text{SO}_4$, and is converted into $\text{Fe}^2(\text{SO}_4)_3 \cdot 2\text{MnSO}_4 \cdot \text{H}_2\text{SO}_4$, which has a darker yellow colour and is insoluble in cold water. In these two salts the manganese is not raised to a higher stage of oxidation, but if the oxidising mixture of nitric and sulphuric acid be poured into the strongly heated solution without previously separating the yellow precipitate, the salt $\text{Fe}^2(\text{SO}_4)_3 \cdot \text{Mn}^2(\text{SO}_4)_3$, gradually separates in the form of a deep green crystalline precipitate insoluble in water.

Manganese-chromium Sulphates.—If in the process last described the iron salt be replaced by chromic acid, the salt $\text{Mn}^2(\text{SO}_4)_3 \cdot \text{Cr}^2(\text{SO}_4)_3$ is obtained in the form of a green precipitate, and if the solution, after being heated with sulphuric acid, be left to cool before a precipitate is deposited from it, brown tabular crystals are obtained, consisting of the salt $\text{Mn}^2(\text{SO}_4)_3 \cdot \text{Cr}^2(\text{SO}_4)_3 \cdot 2\text{H}_2\text{SO}_4$, which dissolves with decomposition in water, and when heated in the air is reduced to a green powder, $\text{Cr}^2(\text{SO}_4)_3 \cdot 3\text{MnSO}_4$, and a white basic salt.

A rose-coloured acid ferroso-ferric sulphate, $\text{Fe}^2(\text{SO}_4)_3 \cdot \text{FeSO}_4 \cdot 2\text{H}_2\text{SO}_4$, is sometimes

found at the bottom of the platinum vessels used for the concentration of sulphuric acid, and may be easily prepared by dissolving ferrous and ferric sulphates (1 mol. of each) in the smallest possible quantity of water, adding a large excess of strong sulphuric acid, and heating the liquid to 200°, avoiding as much as possible the contact of air or other oxidising agents. The liquid on cooling deposits the double sulphate in small six-sided plates having a peach-blossom colour. In a similar manner the following salts may be obtained:

$\text{Cr}^2(\text{SO}^4)^3, \text{NiSO}^4, 2\text{SO}^4\text{H}^2 + 3\text{H}^2\text{O}$:	:	greenish-yellow.
$\text{Cr}^2(\text{SO}^4)^3, 2\text{FeSO}^4, \text{SO}^4\text{H}^2 + 2\text{H}^2\text{O}$:	:	brownish-green.
$\text{Cr}^2(\text{SO}^4)^3, 2\text{CuSO}^4, \text{SO}^4\text{H}^2$:	:	greenish, asbestos-like needles, having a silky lustre.
$\text{Fe}^2(\text{SO}^4)^3, \text{NiSO}^4, 2\text{SO}^4\text{H}^2$:	:	yellow, crystalline.
$\text{Fe}^2(\text{SO}^4)^3, 2\text{MnSO}^4, \text{SO}^4\text{H}^2$:	:	light-yellow, well-crystallised laminæ.
$\text{Al}^2(\text{SO}^4)^3, 2\text{FeSO}^4, \text{SO}^4\text{H}^2$:	:	white six-sided laminæ.
$\text{Al}^2(\text{SO}^4)^3, 2\text{NiSO}^4, \text{SO}^4\text{H}^2$:	:	yellowish, crystalline mass.

All these salts are insoluble in water, and are gradually decomposed thereby. Corresponding manganese salts may also be obtained, but they are difficult to purify.

Double sulphates of diatomic metals (magnesium group) of the general formula $(\text{M}'\text{SO}^4, \text{R}'\text{SO}^4)^2, \text{H}^2\text{SO}^4$ may be prepared by similar processes: the following have been obtained:

$(\text{NiSO}^4, \text{ZnSO}^4)^2, \text{SO}^4\text{H}^2$:	:	yellowish.
$(\text{FeSO}^4, \text{ZnSO}^4)^2, \text{SO}^4\text{H}^2$:	:	rose-coloured.
$(\text{CuSO}^4, \text{ZnSO}^4)^2, \text{SO}^4\text{H}^2$:	:	"
$(\text{CuSO}^4, \text{CoSO}^4), \text{SO}^4\text{H}^2$:	:	"
$(\text{FeSO}^4, \text{CoSO}^4)^2, \text{SO}^4\text{H}^2$:	:	"
$(\text{CuSO}^4, \text{NiSO}^4)^2, \text{SO}^4\text{H}^2$:	:	"

The sulphates of iron and copper yield in like manner a red crystalline double salt, $\text{CuSO}^4, \text{FeSO}^4 + 2\text{H}^2\text{O}$, which does not give up its water of crystallisation till somewhat strongly heated, and is not oxidised even by fuming nitric acid. In the same manner have been obtained the salts $\text{CuSO}^4, \text{MnSO}^4 + \text{H}^2\text{O}$ and $\text{CuSO}^4, \text{NiSO}^4 + 3\text{H}^2\text{O}$. By similar treatment of the simple salts instead of the mixtures, the mono- and di-hydrated salts are easily obtained in crystalline form, e.g. $\text{CoSO}^4 + \text{H}^2\text{O}$, $\text{NiSO}^4 + 2\text{H}^2\text{O}$, $\text{ZnSO}^4 + \text{H}^2\text{O}$, $\text{CuSO}^4 + \text{H}^2\text{O}$. By dissolving the simple salts in strong sulphuric acid and boiling the solutions, the anhydrous salts are obtained in crystalline form, e.g. CoSO^4 , in hexagonal prisms with pyramidal summits at each end, and having the aspect and reddish colour of some kinds of quartz; also NiSO^4 in lemon-yellow crystals of similar aspect, and CuSO^4 in fine white prisms (Etard).

Lead Sulphate, PbSO^4 .—On the crystalline form of Hungarian lead sulphate, see Krenner (*Zeitschr. Kryst. i.* 321; *Jahresb. f. Chem.* 1877, 1295).

Solubility.—J. Kolb (*Dingl. pol. J.* clix. 268) has determined the solubility of this salt in sulphuric acid of different strengths and at ordinary temperatures, with the following results:

100 pts. acid of sp. gr. 1.841	dissolve	0.039 pt. PbSO^4
" " " 1.793	"	0.011 "
" " " 1.540	"	0.003 "

The solubility is increased by the presence of nitric acid, but not by that of sulphurous acid.

In *Acetates*. According to H. C. Dibbitts (*Zeitschr. anal. Chem.* 1874, 137), 100 pts. of water containing a drop of acetic acid, and

2.05 pts. sodium acetate	dissolve	0.054 pt. PbSO^4
8.2 " "	"	0.900 "
41.0 " "	"	11.200 "

The quantity of lead sulphate dissolved appears to be but little influenced by temperature. The solution is immediately precipitated by sulphuric acid and by lead acetate. On mixing the solution with 7 vols. alcohol of 92 per cent. a precipitate is formed consisting of anhydrous sodium sulphate and lead sulphate, in one instance 89.4 per cent. Na^2SO^4 and 10.6 PbSO^4 , in another 96.0 Na^2SO^4 and 4.0 PbSO^4 . Lead sulphate also dissolves in the acetates of manganese, zinc, nickel, and copper, but not in acetate of mercury or silver. Barium acetate and lead sulphate decompose one another partially at ordinary temperatures, producing lead acetate and barium sulphate; the converse reaction does not take place.

Reactions.—Lead sulphate, treated with excess of *potassium iodide*, is readily con-

verted into lead iodide, or the double iodide of lead and potassium. When lead sulphate (1 mol.) and *sodium chloride* (1 mol.) in solution are brought together in presence of lead oxide, about half of the material is converted into lead chloride and sodium sulphate. The quantity of lead oxide may be varied to a considerable extent without perceptible effect on the intensity of the reaction. After several repetitions of the treatment with sodium chloride, at each of which a similar action takes place, there finally remains a mixture containing, together with a small quantity of unaltered lead sulphate, a double salt of lead chloride and carbonate easily decomposed by water (F. Matthey, *Arch. Pharm.* [3], xiii. 233).

Lithium Sulphate.—An acid lithium sulphate, $\text{LiHSO}_4 \cdot \text{H}_2\text{SO}_4$, is obtained in deliquescent crystals melting at 120° , by dissolving the normal salt in pure hydrogen sulphate, H_2SO_4 (Nordhausen acid from which the anhydride had been distilled off) (Lescœur, *Bull. Soc. Chim.* [2], xxiv. 516).

Magnesium Sulphate.—On the dehydration of magnesium sulphate, $\text{MgSO}_4 \cdot \text{H}_2\text{O}$, by heating in a current of air, see Hannay (p. 1014). On its decomposition by dry hydrogen chloride, Hensgen (p. 1872).

To detect the presence of alkali-sulphates in commercial magnesium sulphate, E. Biltz (*Zeitschr. anal. Chem.* x. 258) triturates 2 grams of the salt with 2 g. dry calcium hydrate prepared from burnt marble; then adds water in sufficient quantity to convert the mixture into a granular powder; drenches the mass with 5 g. of a mixture of equal parts alcohol of 90 degrees and water; and, after agitation, leaves it at rest for an hour, and lastly adds 10 g. absolute alcohol. If alkali salts are present (from $\frac{1}{2}$ per cent. upwards), turmeric paper in contact with the mixture immediately turns brown.

Manganese Sulphates. See MANGANESE (p. 1266). On Double Manganese Sulphates, p. 1875.

Mercuric Sulphate.—The compound $\text{HgSO}_4 \cdot 2\text{HCl}$, or more probably $\text{HgCl}_2 \cdot \text{H}_2\text{SO}_4$, is formed by the action of gaseous hydrogen chloride or of strong hydrochloric acid on mercuric sulphate. It is fusible, and sublimes in white needles. The corresponding *bromine-compound*, formed in like manner, sublimes in white shining laminae. Both these compounds dissolve in water without decomposition (A. Ditte, *Compt. rend.* lxxxvii. 794).

Nickel Sulphates, Double (p. 1876).

Philippium Sulphate. See YTTRIUM METALS.

Potassium Sulphates.—In preparing the normal sulphate K_2SO_4 from kieserite, $2\text{MgSO}_4 \cdot \text{H}_2\text{O}$, and potassium chloride, G. Borsche proposes first to prepare the double sulphate of magnesium and potassium, and then convert this salt by means of potassium chloride into potassium sulphate and magnesium-potassium chloride. The reaction is somewhat retarded by the presence of the magnesium chloride, but this inconvenience may be avoided by treating a mixture of 5 to 8 mols. potassium chloride and 4 mols. magnesium sulphate with successive small quantities of cold or moderately warm water, not sufficient in all to dissolve the salt completely. The residue then consists of pure potassium sulphate. The greater part of the magnesium chloride remains in the first mother-liquors, and the later mother-liquors, which contain less magnesium, may be used to decompose fresh quantities of kieserite, whereby the yield of potassium sulphate is increased, and chloride of potassium is saved. For evaporation there is always obtained a determinate quantity of mother-liquor of constant composition, which deposits carnallite, $\text{KCl} \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O}$, available for the preparation of potassium chloride.

F. Bränjes has patented a process for preparing potassium sulphate from kainite and from kieserite, $\text{KCl} \cdot \text{MgSO}_4 \cdot 3\text{H}_2\text{O}$, which consists in dissolving 1.5 to 2 mols. potassium chloride and 1 mol. kieserite or kainite (in the latter case with addition of 1 mol. KCl) in 460–600 pts. water, and precipitating with alcohol. The whole of the magnesium then remains dissolved as chloride, and any potassium chloride that may remain in excess is partially precipitated with the sulphate. On evaporating the mother-liquor to 30°B , an additional quantity of pure potassium chloride separates out, followed, on further concentration to 36°B , by carnallite. An excess of potassium chloride is necessary in this process, so that the precipitated sulphate may be rendered loosely coherent by the admixture with the chloride, and the washing thereby facilitated (*Jahresb. f. Chem.* 1878. 1127).

J. Ogier (*Compt. rend.* lxxxii. 1055), in preparing the potassium salt of benzene-sulphonic acid, has obtained a new form of normal potassium sulphate, differing from the ordinary form by containing a smaller amount of crystallisation-water. It crystallises in large transparent plates, having the composition $\text{K}_2\text{SO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$, and gives off its water in a vacuum or when heated to 150° . 100 pts. of water at 15° dissolve

9.82 pts. of this salt. The same salt is obtained by crystallisation of a mixture of potassium sulphate and benzenesulphonate containing an excess of the latter.

An *acid potassium sulphate*, $K^2O, 4SO^3 + 6H^2O$, or perhaps $K^2H^4(SO^4)^2 + 3H^2O$, is obtained by dissolving the normal salt in hot strong sulphuric acid, and separates on cooling in large nacreous deliquescent crystals which melt at 61° , and give off water at 235° (H. Lesceur, *Compt. rend.* lxxviii. 1044).

Sodium Sulphate, Na^2SO^4 .—On the solubility of this salt in glass, see Ebell (*Dingl. pol. J.* ccxxv. 168; *Jahresb. f. Chem.* 1877, 1165).

On the analysis of crude sodium sulphate (*Ball-soda*), see Tate, Tinniswood, and Simmonds (*Chem. News*, xxix. 144, 164, 185, 205, 216, 239).

Sodio-ferrous Sulphate, $Na^2Fe(SO^4)^2 + 4H^2O$, may be prepared by dissolving crystallised ferrous sulphate, in its own weight of hot water, with addition of 2 per cent. dilute sulphuric acid, and adding an equivalent quantity of crystallised sodium sulphate (100 pts. to 88.8 ferrous sulphate), then heating the solution to the boiling point, and evaporating it with gentle ebullition and constant stirring. The double salt which separates out is drained, washed with a little cold water, and dried, first in the air of a warm room, and finally at 100° , at which temperature it does not give off its water of crystallisation (Biltz, *Zeitschr. anal. Chem.* 1874, 174).

Strontium Sulphate, $SrSO^4$, dissolves in strong sulphuric acid (sp. gr. 1.843) at 70° in the proportion of 14 pts. to 100, the solution at a higher temperature depositing tabular rhombic crystals, which at a still higher temperature are replaced by cubic and octohedral crystals (Garside, *Chem. News*, xxxi. 245).

On Sulphates of Terbium and Ytterbium, see YTTRIUM METALS.

On Vanadium Sulphates, see VANADIUM.

Zinc Sulphate, $ZnSO^4$.—Commercial zinc-vitriol may easily be purified from iron or manganese by adding to the boiling concentrated aqueous solution, first a small quantity of levigated zinc-white, and then a solution of zinc permanganate, till a reddish colour begins to appear (*Jahresb. f. Chem.* 1876, 1103). Zinc sulphate is completely reduced by hydrogen-potassium sulphide to white sulphide of zinc (J. Myers, *Ber.* 1873, 440).

On Double Salts of Zinc Sulphate, see p. 1876.

SULPHURIC ETHERS (Maria Mazurowska, *Ber.* viii. 332; *J. pr. Chem.* [2], xiii. 158). *Normal Ethyl Sulphate*, $SO^2 \begin{smallmatrix} OC^2H^5 \\ OC^2H^5 \end{smallmatrix}$, is obtained by the action of sulphuric hydroxychloride on ethyl alcohol:

It is a faintly yellowish, inodorous, perfectly neutral liquid, soluble in alcohol, nearly insoluble in ether, converted by water into ethylsulphuric acid. Treated with potash it yields a potassium salt, $SO^2(OC^2H^5)(OK)$, which is converted by potassium hydrosulphide into potassium sulphate and mercaptan:

The constitution $SO^2(OC^2H^5)^2$ has hitherto been assigned to the ether which Wetherill obtained in 1847 by the action of sulphuric anhydride on anhydrous ethyl alcohol (v. 624). Mazurowska, however, finds that the potassium salt of this ether does not yield mercaptan when treated with potassium hydrosulphide. She represents the ether by the formula $SO^2 \begin{smallmatrix} C^2H^4.OH \\ OC^2H^5 \end{smallmatrix}$ or $C^2H^4 \begin{smallmatrix} OH \\ SO^2.OC^2H^5 \end{smallmatrix}$, and its potassium salt by the formula $C^2H^4(OH).SO^2.OK$.

The normal ethers of methyl, propyl, butyl, and amyl are prepared in like manner by the action of sulphuric hydroxychloride on the corresponding alcohols. The *phenyl-ether*, $C^{12}H^{10}SO^4$, similarly prepared, is a thick oily liquid, which is decomposed by water yielding paraphenolsulphonic acid, $C^6H^4(OH)(SO^3H)$. By heating *nitrophenol* with sulphuric hydroxychloride, decomposing the product with water, and saturating with barium carbonate, a barium salt is obtained having the composition $(C^6H^4NO^2SO^4)Ba + 2H^2O$.

Thymyl Sulphate, $SO^2(OC^{10}H^{13})^2$, has not been obtained pure, but by decomposing the product of the action of sulphuric hydroxychloride on thymol with water, and saturating with baryta-water, a barium salt is obtained having the composition $(C^{10}H^{13}SO^4)^2Ba$.

Pyrosulphuric or Disulphuric Acid, $S^2O^7H^2 = 2SO^4H^2 - H^2O$. On the formation and reactions of this acid, see vii. 1149.

Thiosulphuric Acid, $H^2S^2O^3 = SO^2(OH)(SH)$ or $HO.SO.O.SH$. This acid has been found in the urine of a typhus patient (A. Strumpell, *Zeitschr. anal. Chem.* xvi. 134).

Estimation.—An indirect method of analysing a mixture of sulphites and thiosulphates is described by J. Grossmann (*Chem. News*, xxxvii. 224). Denoting by x the quantity of iodine equivalent to the thiosulphate, by y the quantity equivalent to the sulphite, by A the total quantity of iodine used, and by B the quantity of sulphuric acid yielded by the whole after complete oxidation, then

$$x = \frac{2I}{3Na_2SO_4} \cdot B - \frac{1}{2}A; \quad y = \frac{1}{4}A - \frac{2I}{3Na_2SO_4} \cdot B$$

from which the quantities of thiosulphate x and sulphite y may be calculated by means of known coefficients.

According to Polacci (*Ber.* x. 174), thiosulphates may be separated from carbonates by gently heating the mixture with acid potassium tartrate, the carbonate alone being thereby decomposed.

Certain double thiosulphates, *e.g.* the lead-potassium, silver-potassium, and mercury-sodium salts, are resolved when boiled with water into sulphides and trithionates, thus: $2AgK_2S_2O_3 = Ag_2S + K_2S_2O_6$. The reaction, however, soon reaches a limit, and to ensure its continuation, the metallic sulphide must be separated by filtration and the boiling renewed (*W. Spring, Ber.* vii. 1157).

Ammonium thiosulphate, $(NH_4)_2S_2O_3$, is formed: 1. By combining sulphuric anhydride with ammonia and treating the resulting ammonium sulphonate with hydrogen sulphide: $SO_3 \cdot 2NH_3 + H_2S = (NH_4)_2S_2O_3$.—2. Together with small quantities of ammonium polysulphide and ammonium trithionate, when normal ammonium sulphate is heated with phosphorus pentasulphide, the thiosulphate and polysulphide subliming while the trithionate remains behind. The formation of the trithionate is probably due to a decomposition of the ammonium thiosulphate, analogous to that of the double thiosulphates above mentioned: $2(NH_4)_2S_2O_3 = (NH_4)_2S + (NH_4)_2S_3O_6$ (*Spring*).

Sodium thiosulphate, $Na_2S_2O_3$.—According to A. v. Trentinaglia (*Wien. Akad. Ber.* 1875, [2 Abth.], lxxii. 669), this salt melts at 48.09° ; and its specific heat is, for the solid state, 0.4447; for the liquid state, 0.569; latent heat of fusion 37.6 for 1 gram at 9.86° . According to T. A. Edison (*Amer. Chem.* vii. 127), it dissolves in considerable quantity in oil of turpentine, from which it almost completely removes the odour.

The specific gravities of the thiosulphates of barium, strontium, and calcium have been determined by T. L. Richardson (*Sill. Am. J.* [3], xiv. 281) with the following results:

$BaS_2O_3 \cdot H_2O$ precipitated	$\left\{ \begin{array}{l} 3.4461 \text{ at } 16^\circ \\ 3.4486 \text{ at } 18^\circ \end{array} \right.$
$SrS_2O_3 \cdot 6H_2O$, in good crystals	$\left\{ \begin{array}{l} 2.1566 \text{ and } 2.1991 \text{ at } 17^\circ \\ 1.8715 \text{ at } 13.5^\circ \end{array} \right.$
$CaS_2O_3 \cdot 6H_2O$, in fine crystals	$\left\{ \begin{array}{l} 1.8728 \text{ at } 16^\circ \end{array} \right.$

Bismuth thiosulphate, $Bi_2(S_2O_3)_3$.—The double thiosulphates of bismuth and the alkali-metals, formed by mixing a slightly acid solution of a bismuth salt with sodium thiosulphate, are distinguished by their perfect solubility in water. The solutions, however, when left to themselves, change in course of time, and more quickly as they are more concentrated, sulphates being formed, together with a precipitate of bismuth sulphide. The sodium-bismuth salt dissolves also in all proportions in alcohol, whereas sodium thiosulphate is nearly insoluble in that liquid. When an alcoholic solution of potassium chloride is added to an alcoholic solution of this double salt, a copious light yellow precipitate is formed, having the composition $Bi_2(S_2O_3)_3 \cdot 3K_2S_2O_3 \cdot 2H_2O$. As no similar precipitate is formed by the chlorides of sodium, lithium, ammonium, calcium, magnesium, aluminium, manganese, iron, &c., or indeed by any metallic chlorides except those of barium, strontium, and the metals which are precipitated by hydrogen sulphide, this reaction is remarkably well adapted for the analytical separation of potassium from other metals. Further, it takes place in solutions of the nitrates as well as in those of the chlorides, but not at all, or less completely, when sulphates are present (*A. Carnot, Compt. rend.* lxxxiii. 338).

Compound of Sodio-cuprous Thiosulphate with Cuprio Sulphide.—The yellow salt, to which Lenz a. Siewert assigned the formula $Na_2S_2O_3 \cdot Cu_2S_2O_3 \cdot CuS + 4H_2O$ (*Pogg. Ann.* lvi. 528), is found by Kessel (*Ber.* x. 1677, 2000; xi. 1581) to vary in composition according to temperature. When prepared at $+10^\circ$, it has a composition agreeing very nearly with Siewert's formula (atomic ratio $Na : Cu : S = 2 : 3 : 5$), but when it is prepared at -10° , the ratio is nearly $Na : Cu : S = 4 : 1 : 4$. It may be obtained with the composition given by Siewert, except as regards the amount of water, by taking care to keep the temperature down to 0° by throwing in snow during the

separation of the salt. The proportion in which the sodium thiosulphate and cupric sulphate act on one another to produce this salt are not those given by Siewert, viz. $5\text{Na}_2\text{S}_2\text{O}_3 : 3\text{CuSO}_4$, but $2\text{Na}_2\text{S}_2\text{O}_3 : \text{CuSO}_4$. That the formation of this double salt is preceded by that of another containing a larger proportion of sodium thiosulphate is inferred by Kessel from the sudden yellow coloration which takes place after the addition of a certain quantity of cupric sulphate, also from the fact that the colourless mixture gives no precipitate with soda-ley, but that after the addition of a quantity of cupric sulphate sufficient to produce the yellow coloration, soda-ley immediately produces a precipitate of cuprous oxide. Kessel has also determined the quantity of free sulphuric acid produced in the reaction, by estimating the quantity of sulphur separated from the sodium thiosulphate by the action of this free acid, and finds that 1 mol. H^2SO_4 is formed to every 2 mols. CuSO_4 , agreeing exactly with the first phase of the reaction:

The yellow salt is decomposed by cold strong hydrochloric acid, forming a white mass which contains neither sulphur nor copper chloride, is permanent when dry, but in contact with water or moist air, turns first blue and afterwards brown, with separation of copper sulphide and evolution of sulphur dioxide. It dissolves in ammonia, forming a colourless solution which slowly turns blue in contact with the air, and gives with alkalis a precipitate of cuprous oxide. By dilute mineral acids the white salt is partly dissolved, partly decomposed, with separation of copper sulphide. After deduction of admixed sodium chloride, the white salt exhibits the atomic ratio $\text{Na} : \text{Cu} : \text{S} = 3 : 1 : 3$, so that in its formation from the yellow salt, not only copper, but also sulphur, must have been eliminated.

When Siewert's yellow salt is boiled with water, it is converted into copper sulphide, sulphurous acid, and sodium sulphate, a little free sulphuric acid being probably also formed at the same time. The same decomposition is also unaccountably produced in the double salt separated at lower temperatures, which undoubtedly contains more than 1 mol. $\text{Na}_2\text{S}_2\text{O}_3$ to 1 mol. $\text{Cu}^2\text{S}_2\text{O}_3$. The white salt is also decomposed by boiling in the same manner. The supposition of Renesse (*Maandblad voor natuurwetenschap*, 3 Jahrgang, 1872-1873), that a mixture of copper and sulphur is thereby produced is inadmissible. The precipitate contains free sulphur only when the copper solution has been boiled with a large excess of sodium thiosulphate, and in this case the sulphur results from the decomposition of the sodium thiosulphate due to the action of the free sulphuric acid formed in the process.

When the yellow salt dried over sulphuric acid is drenched with hydrochloric acid, it is not converted into the white salt, but dissolves in the acid with dark brown colour, this difference of behaviour of the dried and undried salts being probably due to the different amounts of water which they contain. Alcohol precipitates from the brown solution a chocolate-coloured powder, which is resolved by heat into copper sulphide, sulphur dioxide, sulphur, and sodium sulphate, and dissolves without decomposition in water, and in dilute hydrochloric acid, but when boiled with the latter, gives off sulphur dioxide and yields a precipitate of copper sulphide. Its dilute aqueous solution is not precipitated by ammonium sulphide or by soda-ley, but the concentrated solution gives with sodium hydrate a precipitate of cuprous oxide and copper sulphide. Zinc immersed in the hydrochloric acid solution eliminates hydrogen sulphide. Ammonia does not act upon it in the cold, but throws down copper sulphide at the boiling heat, the liquid at the same time turning blue. The composition of the chocolate-coloured salt is $\text{Cu}_2\text{Na}_2(\text{S}_2\text{O}_3)_2 \cdot 2\text{CuS}$.

Chloropurpureocobalt thiosulphate, $(\text{Co}^2, 10\text{NH}^3)\text{Cl}^4, 2\text{S}_2\text{O}_3$, prepared by pouring a lukewarm solution of the corresponding nitrate into sodium thiosulphate, forms brownish-red orthorhombic crystals ∞P . $\text{P} \infty$ with sharply defined faces (Jørgensen, *J. pr. Chem.* [2], xviii. 209).

Trimethylsulphine thiosulphate, $[(\text{CH}^3)_3\text{S}]^2\text{S}_2\text{O}_3$. See SULPHINES (p. 1850).

Ethyl-thiosulphuric acid, $\text{C}^2\text{H}^5\text{S}_2\text{O}_3 = \text{SO}^2(\text{SC}^2\text{H}^5)(\text{OH})$ (H. Bunte, *Ber.* vii. 646).—The sodium salt of this acid is formed by heating 1 mol. ethyl bromide for a few hours in a reflux apparatus with 1 mol. sodium thiosulphate. On evaporating to dryness at a gentle heat, and exhausting the saline mass with a little boiling alcohol, a solution is obtained which solidifies on cooling to a pulp of thin, silky, six-sided laminae, having, when recrystallised from alcohol, the composition $\text{C}^2\text{H}^5\text{S}_2\text{O}_3\text{Na}$. The neutral aqueous solution of the salt is but slightly decomposed by heating on a boiling water-bath, but on adding a small quantity of hydrochloric acid, decomposition sets in rapidly, the odour of mercaptan becomes perceptible, and sulphuric acid may be detected in the liquid:

The dry sodium salt, when heated for some time at 100° , is converted into dithionate, and on distilling it in a sulphuric acid bath, sulphur dioxide is given off, and a distillate of ethyl disulphide is obtained:

and

The solution of the sodium salt yields sparingly soluble precipitates with silver nitrate, lead nitrate, and mercuric chloride. The precipitate formed with the last-mentioned reagent is quickly converted on heating into the compound $\text{C}^2\text{H}^5\text{S} \cdot \text{Hg} \cdot \text{Cl}$, while sulphuric acid remains in solution:

The sodium salt is readily oxidised by nitric acid, yielding sulphuric and ethylsulphonic acids.

Sulphuric Peroxide, S^2O^7 . *Persulphuric acid* (Berthelot, *Ann. Chim. Phys.* [5], xiv. 345, 354; *Compt. rend.* lxxxvi. 20, 71). This oxide is formed by the action of an electric current of high tension on a mixture of equal volumes of dry sulphurous oxide and oxygen; strong sulphuric acid, under similar circumstances, does not unite either with oxygen or with ozone. The same oxide is obtained in the electrolysis of strong solutions of sulphuric acid, a circumstance which has given rise to its being confounded sometimes with hydrogen dioxide, sometimes with the imaginary substance called *antozone*. It is also formed when a solution of hydrogen dioxide is cautiously mixed with sulphuric acid containing not more than 1 mol. H^2O (not weaker than H^2SO^4), probably also in various other processes in which strong sulphuric acid is mixed with alkaline or metallic peroxides. Lastly, it may be produced directly from sulphuric oxide and oxygen; but in this case, as well as in its formation from sulphurous oxide, a large excess of oxygen is required to furnish good results.

Sulphuric peroxide, when pure, forms broad transparent flexible needles often a centimeter long, and bearing a strong resemblance to sulphuric oxide; frequently, however, it is obtained in liquid drops which solidify to indistinctly crystallised nodules. It has a considerable vapour-tension, exceeding at 10° several centimeters. At temperatures near the freezing point, it may be kept unaltered for several days, but after a while it decomposes. In aqueous solution this decomposition takes place very quickly; the solution in strong sulphuric acid is more permanent, but even in this a gradual evolution of oxygen takes place. When heated it decomposes immediately into sulphuric oxide and oxygen. In contact with the air it gives off white vapours, and gradually deliquesces to hydrogen sulphate. With baryta-water it partly decomposes, with evolution of oxygen and separation of barium sulphate, while another portion forms soluble barium persulphate, which, however, is quickly resolved into oxygen and *barium persulphate*, so that it cannot be obtained pure. The peroxide is converted by sulphurous acid into sulphuric acid, but its solution in a large quantity of strong sulphuric acid, yields, after treatment with sulphurous acid, a considerable quantity of dithionic acid.

Polythionic Acids. Michaelis (*Liebig's Annalen*, clxx. 31) represents these acids by the following constitutional formulæ, based on those of sulphurous acid, $\text{SO}(\text{OH})^2$, and thiosulphuric acid, $\text{S}(\text{OH}) \cdot \text{O} \cdot \text{S}(\text{OH})$, or—which he regards as more probable— $\text{SO}(\text{OH}) \cdot \text{O} \cdot \text{SH}$:

Sulphurous acid . . .	$\text{SO}(\text{OH})(\text{OH})$	Thiosulphuric acid . . .	$\text{SO}(\text{OH}) \cdot \text{O} \cdot \text{SH}$
Dithionic acid . . .	$\text{SO}(\text{OH}) \cdot \text{O} >$	Tetrathionic acid . . .	$\text{SO}(\text{OH}) \cdot \text{O} \cdot \text{S} >$
	$\text{SO}(\text{OH}) \cdot \text{O} >$		$\text{SO}(\text{OH}) \cdot \text{O} \cdot \text{S} >$
Trithionic acid . . .	$\text{SO}(\text{OH}) \cdot \text{O} > \text{S}$	Pentathionic acid . . .	$\text{SO}(\text{OH}) \cdot \text{O} \cdot \text{S} > \text{S}$
	$\text{SO}(\text{OH}) \cdot \text{O} > \text{S}$		$\text{SO}(\text{OH}) \cdot \text{O} \cdot \text{S} > \text{S}$

Spring (*Ber.* vi. 1108) finds that the action of SCl^2 on potassium sulphite gives rise to trithionate and chloride of potassium, whence he assigns to trithionic acid the formula $\text{HO} \cdot \text{O} \cdot \text{SO} \cdot \text{S} \cdot \text{SO} \cdot \text{O} \cdot \text{OH}$:

When S^2Cl^2 is added by small portions to barium thiosulphate made up into a paste with a small quantity of water, sulphur separates in the first instance; and if the mass be immediately thrown on a filter, the liquid which runs through allowed to drop into sulphuric acid, and the free sulphuric acid removed by the exact quantity of barium hydrate required to combine with it, a clear liquid is obtained, exhibiting all the

reactions of pentathionic acid: hence Spring assigns to this acid the formula $\text{HO.O.SO.S.S.S.O.OH}$.

Dithionic Acid, $\text{H}_2\text{S}_2\text{O}_6$. Several salts of this acid have been examined by H. Baker (*Chem. News*, xxxvi. 203). The *sodium salt*, $\text{Na}_2\text{S}_2\text{O}_6 + 2\text{H}_2\text{O}$, has a density of 2.175 at 11° , and forms rhombic crystals having the axial ratio $a : b : c = 0.9922 : 1 : 0.9581$, and the faces ∞P , P , P , P_2 , ∞P ; prismatic from predominance of ∞P . The *silver salt*, $\text{Ag}_2\text{S}_2\text{O}_6 + 2\text{H}_2\text{O}$, forms rhombic crystals isomorphous with those of the sodium salt. $a : b : c = 0.9884 : 1 : 0.5811$. Observed faces P , P , ∞P , P_2 , ∞P , ∞P ; habit short prismatic. The *silver-sodium salt*, $(\text{AgNa})\text{S}_2\text{O}_6 + 2\text{H}_2\text{O}$, is rhombic, with the axial ratio $0.9813 : 1 : 0.5856$, and the faces P , P , ∞P , ∞P , ∞P , ∞P . The dome is so strongly developed that the crystals appear horizontally prismatic (Baker). The *barium salt*, $\text{BaS}_2\text{O}_6 + 2\text{H}_2\text{O}$, has a density of 4.536 at 13.5° . Its saturated solution boils at 102° , and 1 pt. of the salt dissolves in 0.994 pts. water at this temperature; according to an older statement by Heeren (*Ann. Phys. Chem.*, vii. 172), 1 pt. of the salt dissolves in 1.1 pt. of boiling water. The *calcium salt*, $\text{CaS}_2\text{O}_6 + 4\text{H}_2\text{O}$, has a density of 2.176 at 11° . From the corrosion-figures of these two salts, Baumhauer (*Zeitschr. Kryst. i.* 54) infers that they crystallise in rhombohedral-hemihedral forms, and not in tetartohedral forms, as might be supposed from their optical rotatory power. The *magnesium salt*, $\text{MgS}_2\text{O}_6 + 6\text{H}_2\text{O}$, crystallises in oblique prisms dissolving in 0.692 pt. water at 17° . The *nickel salt*, $\text{NiS}_2\text{O}_6 + 6\text{H}_2\text{O}$, dissolves in 0.897 pt. water at 12° .

Hypovanadic dithionate is prepared by precipitating a solution of the barium salt with the requisite quantity of hypovanadic sulphate, and evaporating the blue filtrate in a vacuum. It then separates in crystals, which, however, always retain a small quantity of the sulphate (E. J. Bevan, *Chem. News*, xxxviii. 294).

Chloropurplecobalt dithionate, $(\text{Co} \cdot 10\text{NH}_3)\text{Cl}_2\text{S}_2\text{O}_6$, obtained by pouring a lukewarm solution of the corresponding nitrate into sodium dithionate, crystallises in shining rectangular prisms (Jørgensen, *J. pr. Chem.* [2], xviii. 209).

Aniline dithionate, $(\text{C}_6\text{H}_7\text{N})^2\text{H}_2\text{S}_2\text{O}_6$, is obtained in fine long needles by decomposing aniline sulphate with barium dithionate. It is a moderately stable compound, dissolving without decomposition in water and in alcohol. 100 pts. water at 16° dissolve 7.89 pts. of this salt (Bevan).

Trithionic Acid, $\text{H}_2\text{S}_3\text{O}_6$. On the formation of the ammonium salt of this acid by heating ammonium sulphate with phosphorus pentasulphide, see p. 1879. It is also formed when sulphur sulphodichloride, S_2Cl_2 , is added by drops to a solution of normal potassium sulphite. The *potassium salt*, $\text{K}_2\text{S}_3\text{O}_6$, prepared by the action of sulphurous acid on a saturated solution of potassium thiosulphate, crystallises in orthorhombic needles. $a : b : c = 0.3586 : 1 : 0.4204$. Observed faces ∞P , ∞P_2 , ∞P , ∞P , P . An attempt to prepare the sodium salt by a similar process yielded nothing but crystals of the thiosulphate (Baker, *loc. cit.*) When a concentrated solution of potassium trithionate and sulphite is heated with solution of cupric sulphate, the liquid becomes colourless, and on cooling deposits a double salt, $\text{Cu}_2\text{S}_3\text{O}_6 \cdot \text{K}_2\text{S}_3\text{O}_6 + \text{H}_2\text{O}$, in white needles having a silky lustre (Spring, *Ber.* vi. 1108). *Thallium trithionate*, $\text{Tl}_2\text{S}_3\text{O}_6$, separates, on evaporating a solution of thallium carbonate in trithionic acid, in colourless needle-shaped crystals isomorphous with the potassium salt. It decomposes slowly at ordinary temperatures, quickly when heated, and is therefore difficult to obtain free from sulphate.

Tetrathionic Acid, $\text{H}_2\text{S}_4\text{O}_6$. According to Spring (*Bull. Belg.* [2], xlv. No. 5, May, 1878), the production of this acid from sulphurous oxide and hydrogen sulphide is due to the formation of thiosulphuric acid by the action of sulphurous acid upon sulphur, and its subsequent oxidation by the excess of sulphurous oxide present, as represented by the equations:

The correctness of these equations is shown by the fact that tetrathionic acid may be obtained by the action of sulphurous acid on flowers of sulphur, and that the hypsulphurous acid, which should be formed according to the second equation, may be actually detected by its strong reducing action on solution of indigo.

Pentathionic Acid, $\text{H}_2\text{S}_5\text{O}_6$. The existence of this acid, which, according to Wackenroder, is produced by passing hydrogen sulphide in excess into a saturated aqueous solution of sulphurous acid (v. 642), has been called in question by M. W. Spring (*Bull. Acad. Belg.* [2], No. 5, Mai, 1878), who states, as the result of his own experiments, that the acid solution thus produced contains, not pentathionic acid, but

a mixture of tetrathionic and hyposulphurous acids; that it is not decomposed by alkaline hydrates (as stated by Wackenroder, who cites this decomposition, with precipitation of sulphur, as a test for distinguishing pentathionic from tetrathionic acid), but that, on addition of the alkali, a tetrathionate is formed, without precipitation of sulphur. Stingl & Morawski, on the other hand (*J. pr. Chem.* [2], **xx**, 76), find, both by qualitative and quantitative experiments, that Wackenroder's solution contains an acid richer in sulphur than tetrathionic acid; and the same conclusion results from the recent experiments of Takamatsu & Watson Smith (*Chem. Soc. J.* **xxxvii**, 592), who also point out that the acid contained in Wackenroder's solution is clearly distinguished from tetrathionic and all the other polythionic acids by the fact that it is decomposed, with separation of sulphur, by alkaline and earthy hydrates, by alkaline carbonates, and gradually even by earthy carbonates, its salts being indeed very unstable, though the acid itself is stable. The sulphur thus precipitated is redissolved by the alkali on boiling, and even on standing for some time at ordinary temperatures. The action of alkalis on pentathionic acid in aqueous solution may be represented by the equation:

In an ether-alcoholic solution a different reaction takes place, resulting in the formation of tetrathionic acid:

In this case, also, sulphur is separated, but in smaller quantity, and it is immediately taken up by the alcohol: hence the mistake made by Spring, who treated a mixture of Wackenroder's solution with alcohol and ether, and then added a solution of caustic soda, and finding that no sulphur was precipitated, and that the solution contained tetrathionic acid, concluded that the latter acid was the immediate product of Wackenroder's reaction; whereas it now appears from the experiments of Takamatsu & Smith that the addition of the alkali does really give rise to a separation of sulphur, but that the sulphur is immediately dissolved by the ether-alcohol. When a small quantity of the Wackenroder solution was treated in a test-tube with strong alcohol, then with ether, and a few drops of caustic soda-solution were added to the resulting clear liquid, an immediate turbidity was produced in the upper alkaline layer, which was formed for an instant, evidently in consequence of separation of sulphur, but as this alkaline layer sank through the liquid and mixed with the subnatant ether-alcoholic solution, the precipitate quickly disappeared. On adding more caustic soda, a further precipitate was formed, but this also quickly disappeared on agitation.

Tetrathionic and pentathionic acids may be prepared synthetically by acting upon lead thiosulphate with a solution of iodine in hydriodic acid, a moderately strong solution giving rise to tetrathionic, and a solution as strong as can be obtained producing pentathionic acid. The formation of the latter is represented by the equation:

Reactions of the Polythionic acids.—The following table (p. 1884) exhibits a comparative view of the reactions of these acids with various tests.

SUPERPHOSPHATES. See PHOSPHATES (p. 1596).

SYENITE. This rock from Biella has been analysed by A. Cossa (*Jahrb. f. Min.* 1876, 874) with the following result:

SiO^2	P^2O^5	TiO^2	Al^2O^3	Fe^2O^3	FeO	CaO	MgO	K^2O	Na^2O
59·37	0·58	0·26	17·92	6·77	2·02	4·16	1·83	6·68	1·24 = 100·83
Also 0·38 loss by ignition, water, and CO^2 .									

From these analytical data, and from the specific gravity of the rock (2·710), compared with that of orthoclase crystals (2·573), and that of hornblende crystals (3·157), Cossa calculates 76·5 per cent. orthoclase, and 23·5 per cent. hornblende, as constituents of the rock. Kennigott, however (*Jahrbuch*, 1877, 169), objects to this conclusion.

Syenite granites.—(1). From Ravenswood in Queensland, in which plagioclase, quartz, mica, and hornblende were perceptible (Daintree, *Geol. Soc. Qu. J.* **xxviii**, 271).—2 and 3. Syenite-granites from Minnesota, including porphyritic mixtures of quartz, orthoclase, oligoclase, and small quantities of hornblende, biotite, apatite, and magnetic or titaniferous iron ore. The hornblendes appear to enclose an augitic nucleus. 3. From Sauk Rapids, medium to coarse-grained; 3. From Watab, porphyritic (Streng & Kloos, *Jahrb. f. Min.* 1877, 225).

Distinguishing Reactions of the Polythionic Acids.

Reagents	Dithionic acid, $\text{H}_2\text{S}_2\text{O}_6$	Tritithionic acid, $\text{H}_2\text{S}_3\text{O}_6$	Tetrathionic acid, $\text{H}_2\text{S}_4\text{O}_6$	Pentathionic acid, $\text{H}_2\text{S}_5\text{O}_6$
Caustic potash.	No precipitate.	No precipitate.	No precipitate.	Immediate precipitate of sulphur, redissolving gradually on standing, if not in much excess and coagulated.
Dilute hydrochloric acid.	No action.	Evolution of SO_2 , and precipitate of S.	No action.	No action.
Mercurous nitrate.	No precipitate.	Immediate black precipitate, becoming white on standing.	Yellow precipitate, gradually darkening.	At first yellow precipitate, turning white with excess of reagent on standing.
Silver nitrate.	No precipitate.	Yellow precipitate, soon becoming black.	Yellow precipitate, soon turning black, and also on adding ammonia.	Yellow precipitate, gradually darkening; black on adding ammonia.
Ammoniacal silver nitrate.	—	No brown coloration, even on standing. On warming, Ag_2S formed.	No dark or brown coloration, even on standing, <i>unless warmed</i> .	Almost immediate brown coloration, becoming black on warming.
Mercuric cyanide.	No precipitate.	—	At first yellow precipitate; turns black on warming, with evolution of HCN .	At first yellow precipitate, gradually turning on heating, with evolution of HCN .
Mercuric chloride.	No precipitate.	Yellow precipitate, becoming white with excess of reagent.	On warming, white precipitate.	On warming, whitish yellow precipitate.
Potassium sulphhydrate solution.	—	—	White precipitate of sulphur.	White precipitate of sulphur.
Dilute solution of potassium permanganate.	One drop, immediate brown precipitate.	One drop, immediate brown precipitate, even in presence of dilute SO_2H_2 .	Decolorised, without addition of dilute sulphuric acid.	Decolorised, without addition of dilute sulphuric acid.

On *Syenite-porphyrries* from South Norway, see Liebis (Jahrb. f. Min. 1878, 412; Chem. Soc. J. xxxvi. 362).

SYEPOORITE. See JEXPOORITE (p. 1142).

SYLVANITE. See TELLURIUM MINERALS.

SYLVESTRENE, C¹⁰H¹⁶. A terpene occurring, together with australene, in Swedish wood-tar from *Pinus sylvestris*. It is a colourless liquid, boiling between 173° and 175°, having a specific gravity of 0.8612 at 16°, and a rotation-coefficient of +19.5° for sodium light. The *dihydrochloride*, obtained by passing hydrogen-chloride into an ethereal solution of sylvestrene, crystallises in broad, flat, shining needles, or in bar-shaped crystals melting at 72°–73°; it is somewhat strongly attacked by water at 100°, and completely decomposed by alcoholic potash with formation of potassium chloride. The last reaction also yields an oil which has an odour of pelargonium, and is likewise produced by treating the dihydrochloride with aniline; it appears to be a terpinol-like substance, 4C¹⁰H¹⁶ + H²O, and is reconverted by hydrogen chloride into the dihydrochloride (Atterberg, Ber. x. 1202).

SYLVIN. Fibrous sylvin from Kalusz has been found by Niedzwiedzki (Min. Mitth. 1877, 95) to contain 60 to 80 per cent. KCl, together with NaCl. Nodules of anhydrite 3 to 4 cm. in diameter were imbedded in it.

SYMPLOCOS. Lotur-bark, from *Symplocos racemosa*, a tree indigenous in India, contains three alkaloïds, loturine, colloturine, and loturidine. *Loturine* may be easily obtained in crystals from its solution in acetone, ether, or alcohol, and is characterised by the intense blue-violet fluorescence of its solutions in dilute acids. *Colloturine* crystallises in long shining prisms, terminated at both ends by pyramids, and sublimates at 234°. Its solutions in dilute acids likewise exhibit a blue-violet fluorescence. *Loturidine* is amorphous; its solutions in dilute acids exhibit a blue-violet fluorescence, which becomes especially conspicuous when the solution is strongly diluted.

SYNANTHRENE. A constituent of crude anthracene, probably having the formula C¹⁴H¹⁰. It forms a dibromo-derivative, C¹⁴H⁸Br², which crystallises in light yellow microscopic needles, sublimes undecomposed, melts at 175°, is more soluble than dibromanthracene in benzene and tar-oils, moderately soluble in hot alcohol. By boiling with alcoholic potash it is gradually converted into a viscid resin, which is precipitable by water, but does not yield any crystalline constituent (Zeidler, Wien. Akad. Ber. [2 Abth.], lxxvi. 231).

SYNANTHROSE. On the occurrence of this kind of sugar in rye, see p. 1768.

SZABOITE. A mineral occurring, together with tridymite and pseudobrookite, in clefts and cavities of the andesite of the Aranyer Berg in Transylvania. Crystal triclinic, exhibiting the faces $\{P\}$; $2/P'$, ∞ ; $0P$. Colour hair-brown to hyacinth-red. Analysis gave 52.35 per cent. SiO², 44.70 Fe²O³, and 3.12 CaO, with 0.4 loss on ignition, leading to the formula Fe²²Ca²Si³²O¹⁰³ = 11Fe²Si²O⁹ + 2CaSiO³ (A. Koch, Jahrb. f. Min. 1878, 652; Zeitschr. Kryst. iii. 307).

SZMIKITE. A reddish-white to rose-red mineral, occurring in stalactitic nodules in an abandoned mine at Felsobanya, and agreeing, according to the analyses of Schrauf (A.) and Dietrich (B.), with the formula MnSO⁴ + H²O (C.) Sp. gr. = 3.15.

	SO ³	MnO	H ² O
(A.)	47.43	41.78	10.92 = 100.13
(B.)	47.11	41.61	11.19 = 99.91
(C.)	47.34	42.01	10.65 = 100

(J. v. Schröckinger, Jahrb. f. Min. 1877, 729).

T.

TACAMAHACIN. A crystallised body contained in the yellow resin of the Tacamahac or Balsam poplar. It is insoluble in ether, aqueous alcohol, ammonia, and potash, slightly soluble in hot absolute alcohol, not altered by nitric acid, but dissolved with violet coloration by sulphuric acid (Batka, *Arch. Pharm.* [3], vi. 111).

TACHYLITE. The following analyses of this mineral from the basalt of the Rossberg are given by T. Petersen (*Jahrb. f. Min.* 1873, 385). A. Fresh; sp. gr. 2.524. B. Decomposed.

	SiO ²	TiO ²	Al ² O ³	Fe ² O ³ , FeO	MgO	CaO	Na ² O	K ² O	H ² O
A.	66.42	0.31	13.07	3.66	1.30	1.19	6.09	7.36	0.73 = 100.13
B.	62.43		17.12	1.82	0.68	0.30	6.19	7.95	2.81 = 99.30

TAGETES. The flowers of the common marigold (*Tagetes patula*), and other species of the same genus, contain a crystallisable substance, quercetagetin, having the composition $C^{27}H^{22}O^{13} + 4H^2O$ (p. 1732).

TALC. Pseudomorphs of talc after pectolite, occurring in the calcite-veins of the 'Trapp' of Bergen Hill, Hoboken, New Jersey, have been described and analysed by A. R. Leeds (*Sill. Am. J.* [3], vi. 23).

SiO ²	Al ² O ³	MgO	FeO	MnO	CaO	H ² O	Sp. gr.
60.54	1.06	26.46	0.70	0.55	1.19	9.52 = 100.02	2.565
60.57	0.98	26.67	0.74	0.76	1.65	9.07 = 100.44	

TANNINS. *Ordinary tannin*, or the *tannin of nut-galls*, $C^{34}H^{28}O^{22}$, appears, from the experiments of H. Schiff, to be most probably a glucoside of digallic acid, $C^{14}H^{10}O^9$ (p. 646); see also *Liebig's Annalen*, clxxv. 165. P. Freda (*Gazz. chim. ital.* 1878, 9) has endeavoured to settle the question as to whether this tannin is a glucoside, by means of fermentation experiments. For this purpose he used: 1. A solution of commercial tannic acid mixed with a few drops of acetic acid; 2. A solution neutralised with potash, and then slightly acidulated with acetic acid; 3. Solutions prepared in like manner, and mixed with various quantities of glucose; 4. A solution of tannic acid which had been boiled for some time with sulphuric acid, then neutralised with marble, filtered, evaporated to dryness, and redissolved in water. These solutions were treated with fresh beer-yeast, and left to ferment under the usual conditions. In 1 and 2 no fermentation took place; in 3 and 4 brisk fermentation. Parallel experiments with amygdalin and salicin yielded the same result. From these results Freda infers that gallotannic acid is really a glucoside, and not merely a mixture of tannic acid and glucose, since such a mixture would have fermented in contact with the yeast as the added glucose did. Schiff (*Gazz.* 1878, 87) does not regard Freda's experiments as conclusive, but nevertheless adheres to his opinion that the unaltered tannin of nut-galls is a very easily decomposable glucoside of digallic acid.

Artificial Formation (?)—When citric acid is gently heated with phosphorus oxychloride, a violent action takes place, and the residue left after the excess of the oxychloride has been partly distilled off, yields to ether a coloured flocculent substance, which, after repeated solution in water and precipitation with hydrochloric acid (the colouring matter going down with it), gives by analysis 53.5 per cent. C. and 2.9 H, [the formula $C^{34}H^{28}O^{22}$ requires 51.8 C. and 3.6 H], and after drying dissolves slowly and abundantly in water, yielding a solution which exhibits all the reactions of tannic acid, except that it acts less strongly on iodide of starch (Schiff, *Liebig's Annalen*, clxxii. 359).

Estimation.—To estimate the amount of tannin in any given tanning material (galls, sumach, &c.), J. Löwenthal (*Zeitschr. anal. Chem.* xvi. 33; *Chem. Soc. J.* xxxi. 745) first titrates a measured volume of the extract with permanganate solution, using indigo as an indicator, so as to ascertain its permanganate value; then precipitates the tannin from another equal portion of the extract by means of a solution of gelatin saturated with common salt; and titrates the filtrate in the same manner: the difference of the two titrations determines the quantity of tannin in the solution.

On the estimation of Tannin in *Tea* by this method, see Estcourt (*Chem. News*, xxix. 109; *Chem. Soc. J.* xxvii. 712).

On an older method proposed by Löwenthal, see *J. pr. Chem.* lxxxi. 150; *Jahresb. f. Chem.* 1860, 680. Observations thereon, by J. M. Merrick (*Amer. Chem.* 1873, iii. 324; iv. 15, 202; *Jahresb. f. Chem.* 1873, 971).

Prud'homme (*Bull. Soc. Chim.* [2], xxi. 169) estimates tannin by oxidation with bleaching-powder, using aniline-green as indicator. The bleaching liquid is first standardised against the colouring matter, and afterwards against successive portions of a standard tannin solution, to which small quantities (say 10 c.c.) of the aniline colour have been added. On deducting the volume of chloride of lime corresponding with the known quantity of colouring matter, the remainder indicates the quantity of tannic acid present. Solutions of gallic and pyrogallic acids may be examined in a similar manner. To apply the method to the valuation of commercial tannins, a known weight of pure tannin is added to a known volume of methyl-green, and the solution made up to a certain volume; the precipitated lake is filtered off; and the residuary colouring matter estimated by the chloride of lime solution. A similar treatment applied to the same weight of the commercial tannin will show the ratio of quality existing between the two tannins.

E. Schmidt (*Bull. Soc. Chim.* [2], xxi. 256) estimates tannin volumetrically by a modification of a method proposed by Pribram (*ibid.* vii. 496; *Jahresb. f. Chem.* 1866, 821), which depends on the precipitation of the tannin by lead acetate. 50 grams of neutral lead acetate are dissolved in 400 g. alcohol, and the solution is made up to a litre with distilled water. A second solution is prepared by dissolving 1 g. tannin in 40 g. alcohol, and diluted with water to 100 c.c.; 10 c.c. of the tannin solution is then mixed with 20 c.c. water; the whole is heated to 60°; and the lead-liquor is poured into the hot solution as long as a precipitate is formed, a solution of potassium iodide being used to indicate excess of lead. To prepare the solution of the tanning material under examination, a weighed quantity of the coarsely pulverised bark is exhausted with water at 50°–60°; the filtrate is evaporated to dryness; the residual extract is dissolved in 40 g. alcohol of 92 per cent.; and the solution is diluted with water to 100 c.c. This treatment effects the separation of resinous and gummy constituents, the tannic acid then remaining contaminated only with soluble organic salts and extractive matters. As, however, some of these foreign matters are, under certain circumstances, likewise precipitated by lead acetate, Schmidt endeavours to estimate them approximately by treating equal quantities of the impure tannin solution, and a solution of pure tannin containing a somewhat smaller amount of tannic acid, under exactly similar conditions and in similar vessels, with animal charcoal, which absorbs part of the tannic acid, but not the foreign substances. Assuming, then, that equal quantities of tannic acid are absorbed in the two cases, the excess of lead acetate solution used to precipitate the impure tannin over that required for an equal quantity of the pure tannin solution will give approximately the amount of the foreign constituents.

Gerland (*Zeitschr. anal. Chem.* ii. 419) estimates tannin volumetrically by means of a solution of tartar-emetie containing 2.611 g. of the dried salt in a litre. This solution (1 c.c. of which corresponds to 0.005 g. tannic acid) produces in neutral or slightly acid solutions of tannic acid a precipitate of antimonious tannate, which quickly settles down on addition of sal-ammoniac. A slight modification of this method is proposed by Richards a. Palmer (*Sill. Am. J.* [3], xvi. 196, 361), which consists in titrating the tannin solution containing at least 0.1–0.3 g. tannic acid, with solution of tartar-emetie containing 6.73 g. of the dried salt $C^4H^4KSbO^7$ in the litre, the end of the reaction being indicated by ammonium sulphide, after the tannate has been separated by addition of ammonium acetate.

A. Gautier (*Zeitschr. anal. Chem.* xvii. 222) estimates tannic acid in wine by agitating 100–200 c.c. of the wine with 1–2 g. recently precipitated cupric carbonate, then adding an equal volume of alcohol, and leaving the mixture at rest for twelve to twenty hours. The tannic acid then separates in the form of an insoluble copper-compound, whilst the colouring matter of the wine (*ænotannin*) remains in solution, probably also in combination with copper.

For the estimation of tannin in the *must of the grape* and in *wine*, Pavesi a. Rotondi (*Gazz. chim. ital.* 1874, 192) adopt a modification of a method originally proposed by Fleck, which consists in precipitating the tannin with a solution of cupric acetate. A neutral solution of this salt, however, also precipitates gallic acid, but an ammoniacal solution of cupric acetate precipitates only the tannin, and has no action on any of the other constituents of the wine. The amount of tannin can be ascertained by estimating either the copper remaining in solution, or that contained in the precipitate. The process is simple and gives accurate results.

Carpene (*ibid.* 1875, 120) separates the tannin from the other constituents of wine by means of an ammoniacal solution of *zinc acetate* containing a large excess of ammonia, which forms with tannin a tannate of zinc quite insoluble in water, in

ammonia, and in an excess of the reagent itself, and no precipitate with alcohol, malic acid, tartaric acid, potassium bitartrate, calcium tartrate, glycerol, gelatin, albumin, or the ferrous and ferric salts of organic acids. With gallic acid, succinic acid, glucose, and aluminium salts, it forms precipitates soluble in excess of the reagent and in ammonia. Lastly, it forms a violet precipitate with a solution of encocyanin prepared according to Macagno's method. This, however, does not interfere with its use in the method of analysis under consideration.

On treating the wine with an excess of this reagent, a precipitate is formed consisting of zinc tannate mixed with a small quantity of colouring matter. The wine is heated nearly to boiling to agglomerate the flocculent precipitate, and the precipitate after cooling is washed on a filter with a small quantity of boiling water, which removes the adhering colouring matter. On dissolving the precipitate in dilute sulphuric acid, a solution is obtained containing all the tannin of the wine, and having a very faint red tint, due to minute traces of encocyanin, which compensate for the slight loss of tannin incurred in the manipulations. In this acid liquid the quantity of tannic acid is determined volumetrically with a millinormal solution of potassium permanganate, each cubic centimeter of which is equivalent to 0.00760 gram of tannic acid. The examples given of the application of this method to several wines show that it is capable of giving very exact results.

A method of estimating tannin by filtration through *skin*, which absorbs the tannin and allows the other soluble substances to pass through, was proposed by Hammer (*J. pr. Chem.* lxxxi. 159; *Jahresb. f. Chem.* 1860, 679), and has more recently been adopted with some modifications by Muntz a. Ramsbacher (*Dingl. pol. J.* ccxiv. 74; *Chem. Soc. J.* xxvii. 1183). According to R. Procter, however (*Chem. News*, xxxiii. 245), this method cannot give exact results, inasmuch as a solution containing only 1 per cent. tannin can pass through skin 2 or 3 mm. thick, and, moreover, skin in general is capable of fixing only a certain quantity of tannin.

Hop-tannin. The tannin of hops is amorphous; does not precipitate a solution of gelatin; is slightly soluble in cold water, easily in hot water; also in alcohol and ethyl acetate; insoluble in ethyl oxide. It is easily alterable; turns red, and gives off water at 100°, and then, like gallotannic acid, precipitates a solution of gelatin. Hop-tannin also resembles gallotannin in being converted, with elimination of water, into a phlobaphene having the composition $C^{50}H^{16}O^{25}$, when its aqueous solution is heated to 120°; this phlobaphene exists also ready formed in hop-cones, and may easily be prepared therefrom (C. Etti, *Dingl. pol. J.* ccxxviii. 254; *Chem. Soc. J.* xxxiv. 797).

Oak-tannins. The amount of tannin in oak-branches more than a year old remains nearly constant from March till the end of October; the buds contain a much larger proportion than the branches. In the young shoots the amount of tannin increases considerably from July onwards, but decreases in winter, probably in consequence of internal respiration. The proportion of tannin in the leaves is very considerable, and appears to be determined by the individuality of the tree, leaves of different trees exhibiting considerable diversity in their proportion of tannin. The tannin of the leaves is identical with that of the bark; the leaves also contain ellagic acid. The composition of oak-bark tannin may be represented by the formula $C^{20}H^{20}O^{11}$; that of oak-red by $C^{14}H^{10}O^6$; and the relations of the latter to ellagic acid and to gallotannic acid by the equations $C^{14}H^{10}O^6 + O^3 = C^{14}H^{10}O^9$ (gallotannic acid); $C^{14}H^{10}O^6 + O^4 = 2H^2O + C^{14}H^8O^8$ (ellagic acid) (J. Oser, *Wien. Akad. Ber.* [2 Abth.], lxxii. 165).

Strawberry-tannin, or Fragarianin. The root of the strawberry (*Fragaria vesca*) contains, according to Phipson, a tannic acid analogous to quinotannic acid, which he designates as *Fragarianin*. This tannin is resolved, by boiling with hydrochloric acid, into sugar and a red amorphous body called *Fragarin*, which is soluble in water, alcohol, and ether, and dissolves, with fine red colour, in potash-ley. Strong sulphuric acid dissolves fragarin; nitric acid converts it into a yellow nitro-compound different from picric acid; with potassium chlorate and hydrochloric acid it yields a yellow chlorinated product. When heated, it yields a small quantity of catechol, and when fused with potassium hydroxide, a small quantity of protocatechuic acid. Strawberry-root also contains bodies resembling quinovin and quinovic acid, together with a small quantity of ordinary tannin.

On *Divi-divi Tannin*, see ELLAGITANNIC ACID (p. 731).

On the presence of Tannin in various species of *Willow*, see Johanson (*Arch. Pharm.* [3], xii. 103; *Chem. Soc. J.* xxxvi. 160).

Sulphotannic Acid, $C^{12}H^{10}S^2O^{11}$ (vii. 1125). *Acetyl-derivatives.*—*Pentacetyl-sulphotannic acid*, $C^6H^2 \left\{ \begin{array}{l} (O.C^2H^3O)(C^2H^3O.O)^2 \\ SO^2.OH \\ SO^2 \end{array} \right. C^6H^2$, is obtained by gradually adding

sulphotannic acid to a mixture of equal volumes of glacial acetic acid and acetic anhydride, in which it dissolves at ordinary temperatures. The solution is heated for about two hours in a reflux apparatus; the excess of acid and anhydride distilled off; the residue mixed with a large quantity of ether; and the crystalline precipitate is washed with cold and dissolved in boiling alcohol. On cooling, the pentacetyl-compound separates in small orange-coloured crystals insoluble in water, but soluble in caustic alkalis.

When sulphotannic acid is added in like manner to pure acetic anhydride, a flocculo-crystalline precipitate is obtained, consisting of a *tetracetyl-derivative*, probably

TANTALUM. *Atomic Weight* 182. A nitride of tantalum, Ta^3N^5 , is produced by heating tantalum chloride, TaCl_5 , in a current of ammonia-gas at a temperature a little above the subliming point of sal-ammoniac. It is an amorphous, ochre-yellow mass, which, when heated to whiteness in a stream of perfectly dry ammonia-gas, gives off nitrogen, and is converted into a black amorphous mass of the mononitride TaN .

A *carbonitride*, $10\text{TaC}, \text{Ta}_3\text{N}$, is obtained, like the carbonitrides of niobium (p. 1393), by heating tantalum oxide, Ta_2O_5 , with sodium carbonate and charcoal at about the temperature of melting cast-iron. The product has a fine brass-yellow colour (A. Joly, *Compt. rend.* lxxxii. 1195).

Tantalates.—Tantalum acid forms with most bases four series of salts analogous in composition to the niobates described by Joly (p. 1393), viz.:

When tantalum acid is dissolved in a hot concentrated solution of ammonium fluoride, the salt $\text{TaOF}_3 \cdot 3\text{NH}_4\text{F}$ crystallises on cooling in regular octohedrons. The corresponding *potassium salt* has not been obtained pure (Joly, *Compt. rend.* lxxxi. 1266).

A tantalate occurring, together with beryl, columbite, samarskite, and garnet, in Yancey County, North Carolina, was found by G. Koenig (*Jahrb. f. Min.* 1876, 867) to contain:

Ta_2O^5	FeO	MnO	MgO
76.60	14.07	0.50	7.70 = 98.87

Koenig refers it to the species tantalite, but Kenngott shows (*ibid.* 1877, 168) that its composition does not agree with the formulæ of that species.

Tantalite occurring in lumps of the size of peas, and of sp. gr. 7.305–7.401, in the decomposed granite of Cousa County, Alabama, has been analysed J. L. Smith (*Sill. Am. J.* [2], xv. 203), with the following results:

Ta_2O^5	WO^3	ZnO	MnO	FeO	CuO
79.55	1.10	0.87	3.72	13.51	0.89 = 99.74

Smith regards the locality above mentioned as the first at which tantalite has been found in North America, and agrees with Kenngott in doubting the correctness of Koenig's view of the constitution of the mineral from North Carolina.

TAR. According to Liebermann a. Burg (*Ber.* xi. 723), the vapour of lignite-tar, when passed through a red-hot tube filled with porous substances, is converted, with copious evolution of gas (56–63 p. c.), into a mixture resembling coal-tar, and, like the latter, containing about 4 per cent. benzene and toluene, together with 0.9 per cent. crude anthracene. The largest quantity of gas was produced with empty tubes; the smallest with tubes filled with charcoal. When the oils thus obtained, or those produced from coal-tar itself, are passed through a red-hot tube, they experience a much smaller loss in weight, from 77–90 per cent. of the original quantity being recovered. Petroleum and vulcan oil similarly treated yield large quantities of gas and benzene, but no anthracene.

Salzmann a. Wiehelhaus (*Ber.* xi. 802) also find that when lignite-tar oil is decomposed by red-hot charcoal, 4 per cent. of an oil is obtained, which boils at 120° , and yields nitrobenzene. The same chemists find that the formation of benzene from lignite-tar is always attended with separation of carbon, and that abstraction of hydrogen, which may be effected by the admixture of oxygen with the oil-vapours as they pass over the red-hot charcoal, does not produce any essential alteration in the result of this decomposition.

Letny (*Ber.* xi. 1210) finds that when the vapours of hydrocarbons of the fatty series—especially the residues of Baku petroleum (b. p. 270°) are passed several times through a red-hot retort 7 feet long and 1 foot wide filled with charcoal, they yield a tar having a sp. gr. of 1.307. This tar yielded on distillation 2.3 per cent.

water, 4·6 benzene, 5·2 toluene and its homologues, together with 35·4 naphthalene and unaltered petroleum. Lastly, the residue boiling above 340° was found to contain -together with petroleum—considerable quantities of phenanthrene and anthracene. Still more complete is the decomposition when narrow tubes are employed. The distillation-products of natural asphalt and resinous shales are also decomposed in a similar manner under these conditions. Atterberg (*Ber.* xi. 1222), by subjecting pine-wood tar—the heavy tar-oil of Swedish wood-oil manufactories—to the action of red-hot coke in iron retorts, obtained, at commencing redness, the same products as those which are formed under these circumstances from lignite-tar and petroleum; they contained 0·3 per cent. anthracene, together with benzene, toluene, and phenol. When the coke was heated to bright redness, the product contained relatively more benzene and naphthalene, but less phenol.

TARTARIC ACID, $C^4H^6O^6$. The following process for the preparation of this acid is recommended by F. Dietrich (*Jahresb. f. Chem.* 1878, 1136). Tartar is subjected to the action of calcium carbonate in presence of water at a high temperature and under pressure, whereupon, as the carbonic acid cannot escape, the two salts act on one another so as to form potassium bicarbonate and calcium tartrate, which is decomposed in the usual way. The quantity of water is regulated so as to form a saturated solution of potassium bicarbonate.

On the Optical Rotatory Power of Tartaric Acid and its Salts, see LIGHT (pp. 1217–1219).

Solubility.—According to Bourgoin (*Ann. Chim. Phys.* [5], xiii. 400), 100 pts. by weight of alcohol and ether at 15° dissolve the following quantities of tartaric acid:

Ether	Absolute alcohol	Alcohol of 90°
0·400	25·604	41·135

Distinction between Tartaric and Citric Acids.—These two acids may be distinguished by their reaction with *potassium dichromate*, a cold saturated solution of this salt giving with tartaric acid a dark brown colour, with evolution of carbon dioxide, whereas on citric acid it acts but slowly, producing only a light brown colour. If 1 gram of powdered citric acid be added to 10 c.c. of the cold-saturated dichromate solution, the orange colour of the liquid remains unchanged after ten minutes if no tartaric acid is present; whereas 5 per cent. of that acid will produce a dark brown, and 1 per cent. a coffee-brown colour (Cailletet, *Chem. Centr.* 1879, 14).

According to A. H. Allen (*Zeitschr. anal. Chem.* 1877, 251), tartaric and citric acid may be separated in alcoholic solution by means of potassium acetate, also dissolved in alcohol, which throws down a precipitate of acid potassium tartrate.

Estimation.—To determine the amount of tartaric acid in crude tartar and similar substances, A. Scheurer-Kestner (*Compt. rend.* lxxxvi. 1024) dissolves the sample in hydrochloric acid, neutralises the filtrate with soda, and precipitates with calcium chloride. The washed precipitate is converted by ignition into carbonate, which is then titrated.

See also Warrington (*Chem. Soc. J.* xxviii. 959–981).

On the Estimation of Tartaric Acid and its separation from Citric Acid in Solutions, Fruit-Juices, and Insoluble Substances, see CITRIC ACID (p. 508 of this volume).

On the Conversion of Dextrotartaric Acid into Racemic and Inactive Tartaric or Mesotartaric Acid, see Jungfleisch (vii. 1147).

Tartrates. *Ferrous Tartrate*, $C^4H^4FeO^6$.—According to C. Méhu (*N. Jahrb. Pharm.* xl. 257), the directions usually given for the preparation of this salt do not give a pure product; but a perfectly stable salt may be obtained by boiling together equal weights of tartaric acid, water, and iron wire for some time, and thoroughly washing the resulting sandy powder with boiling water. The salt thus obtained is a white micro-crystalline powder, nearly insoluble in water even when boiling and saturated with sal-ammoniac, or strongly acidulated with tartaric, citric, or acetic acid; easily soluble in dilute mineral acids. The solutions are optically dextrogyrate.

Ammonio-ferric Tartrate is obtained by dissolving the ferrous salt in ammonia, whereby a thickish green solution is formed, which absorbs oxygen, becoming continually darker in colour and more viscid, but finally mobile and yellowish-red, and when exposed in thin layers to the air, dries up to garnet-red transparent laminae, easily soluble in water, insoluble in alcohol and ether. The salt when dried at 100° has the composition $C^8H^{18}Fe^2N^2O^{15} = C^8H^7(NH^2)^2(Fe^2)(OH)^3O^{12}$; when dried over sulphuric acid it contains in addition $3H^2O$. Its solution does not exhibit any colour-reactions with potassium ferrocyanide or thiocyanate, till it has been mixed with a mineral acid (Méhu, *loc. cit.*)

Telluric Tartrate, $Te(C^4H^6O^6)^2 \cdot 2C^4H^6O^6$. See TELLURIUM (p. 190').

Racemic Acid, $C^4H^4O^6$. According to Jungfleisch (*Compt. rend.* lxxxv. 805), the racemic acid which is formed in the manufacture of tartaric acid, owes its origin, not to the grapes, but to the action of alumina, ferric oxide, and other sesquioxides present in the liquors on the tartrates, these oxides, when not saturated with sulphuric or phosphoric acid, acting on the tartaric acid at the evaporating temperature of the liquors in such a manner as to convert it partly into racemic, partly into inactive tartaric acid. Direct experiment shows that tartaric acid, heated in closed vessels at 140° with a small quantity of aluminium tartrate, yields a considerable quantity of inactive tartaric acid.

The properties of the racemic acid which Strecker obtained (vi. 1079) by the action of hydrocyanic and hydrochloric acids on glyoxal have been compared by Fr. Gail (*Ber.* xi. 1644) with those of natural racemic acid. The crystals of the synthetically prepared acid agrees with those of the natural acid in form, but do not effloresce under certain circumstances. The dehydrated synthetic acid melts at 198° (the natural at 201°). On attempting to resolve the synthetical racemic acid, through the medium of its sodio-ammonium salt, into dextro- and lævo-tartaric acid, the solution at first deposited exclusively large monoclinic crystals, destitute of hemihedral faces, and yielding an *inactive* solution; and it was only from the mother-liquor of these that rhombic crystals of the two acids were obtained, containing $4H^4O$, and exhibiting hemihedral faces. Precisely the same phenomena were exhibited by ordinary racemic acid.

TARTRONIC ACID, $C^3H^4O^5 = COOH.CHOH.CO^2OH$. *Hydroxymalonic acid*. This acid is formed by treating dihydroxymalonic acid, $C^3H^4O^5$, with sodium-amalgam; also by the action of silver bromide on monobromomalonic acid, $CO^2H.CHBr.CO^2H$ (Petrieff, *Ber.* xi. 414). Demole (*ibid.* x. 1778) prepares it by gradually adding 20 g. dinitrotartaric acid to 60 c.c. alcohol of sp. gr. 0.925 in a porcelain basin heated over a water-bath. When the evolution of gas ceases, the liquid is left to cool, and the crystals which separate are pressed between bibulous paper. They are then dissolved in water; the solution is evaporated to dryness; and the residue is treated with ether to remove oxalic acid. The tartaric acid thus prepared melted at 150° – 151° , whereas that which Grimaux obtained (*Ber.* x. 903) by the action of baryta-water on dibromopyruvic acid is described by him as melting at 145° – 147° .

TAURINE, $C^2H^4NSO^3$. Strecker, by the action of heat on ammonium isethionate, obtained a body of this composition which he regarded as taurine (v. 699). This body has also been prepared and further examined by H. Seyberth (*Ber.* vii. 391). When ammonium isethionate, melting at 135° (Strecker gives 130° as the melting point), was heated for several days in an oil-bath at 210° – 230° , it remained quite unaltered; but on heating the mass to 230° – 240° decomposition set in. The viscid syrup obtained after about eight hours' heating was dissolved in water; the solution boiled with animal charcoal and evaporated; the residue crystallised from alcohol; and the nodules which separated were boiled with alcohol in which they were nearly insoluble, till they melted constantly at 190° – 193° . The body thus obtained gave off ammonia when boiled with potash, dissolved very easily in water, appearing indeed to be hygroscopic, and had the composition of taurine. Since, however, taurine does not melt, even at 240° , and reacts differently with potash-ley, the compound obtained as above must be regarded, not as identical with it, but as the true amide of isethionic acid.

Taurine is but slowly attacked by potassium permanganate, its sulphur being only incompletely oxidised (Guareschi, *Ber.* xi. 1383).

Metallic Derivatives of Taurine.—J. Lang (*Bull. Soc. Chim.* [2], xxv. 180), by treating solutions of taurine with the oxides or hydroxides of various metals, has obtained the following compounds:

A very stable mercury-compound, $(C^2H^4NSO^3)^2Hg.HgO$, is described by R. Engel (*Bull. Soc. Chim.* [2], xxiii. 532).

Methyltaurine, $C^2H^4NSO^3 = C^2H^4(NH.CH^3)SO^3H$ (E. Dittrich, *J. pr. Chem.* [2], xviii. 592). This compound is formed by heating silver chlorethyl-sulphate (10 pts.) with solution of methylamine (30 pts. saturated at 0°) or methylamine chlorethyl-sulphate (20 pts.) with methylamine solution (30 pts.) for five or six hours at 110° – 120° , the latter process giving the best yield. In either case the liquid is boiled with caustic baryta till the odour of methylamine is no longer perceptible, then freed from baryta, and evaporated to dryness; and the residue is several times exhausted with alcohol, and repeatedly crystallised from water.

Methyltaurine, thus obtained, crystallises in long triclinic prisms having a vitreous lustre, melting at 241° – 242° , nearly insoluble in alcohol and ether, easily soluble in water (7.5 times more readily than taurine), the solution having an acid reaction. It also dissolves in strong acids and in alkalis, but without combining with them, and is separated from the alkaline solutions by alcohol. It is decomposed by melting alkalis with separation of methylamine, and converted by nitrous acid into isethionic acid.

TAUROCARBAMIC ACID, or *Uramido-isethionic acid*, $C^3H^5N^2SO^4 = CH^2.NH.CO.NH^2$
 |
 $CH^2.SO^2OH$

(E. Salkowski, *Ber.* vi. 744, 1191). This acid may be formed synthetically by a process analogous to that by which Wislicenus obtained hydantoic acid (p. 1044). The mixed aqueous solution of taurine and potassium cyanate in molecular proportions is evaporated to a syrup, whereby on cooling a solid crystalline mass is obtained, consisting chiefly of potassium taurocarbamate, the aqueous solution of which, when shaken with absolute alcohol, becomes turbid and is converted in the course of a few minutes into a pulp of needle-shaped crystals. On mixing the aqueous solution of this potassium salt with an equivalent quantity of sulphuric acid and with alcohol, and leaving the alcoholic extract to evaporate, the free acid crystallises out, and may be freed from adhering potassium sulphate and accidental traces of taurine by recrystallisation from dilute alcohol. The yield is very nearly equal to the theoretical quantity. Taurocarbamic acid is also formed from taurine in the animal organism by addition of carbamic acid and elimination of water:

It passes out in the urine in the form of a salt, and may be obtained therefrom by exactly precipitating the liquid with basic lead acetate, filtering after twenty-four hours, removing the lead by hydrogen sulphide and evaporating, these processes being repeated several times if necessary. The strongly concentrated liquid is then precipitated with absolute alcohol, the precipitate dissolved in water, and decolorised with animal charcoal; and the precipitation with alcohol is several times repeated. The crude sodium salt thus obtained is mixed with sulphuric acid and alcohol, and on leaving the liquid to evaporate, at a rather low temperature, free taurocarbamic acid is obtained in the form of a strongly acid syrup. It may be freed from excess of sulphuric acid by baryta, from hydrochloric acid by silver carbonate, and from excess of silver by hydrogen sulphide, and separates gradually from the concentrated filtrate in granular masses, which may be purified by pressure and recrystallisation.

Taurocarbamic acid crystallises in shining, quadratic, anhydrous laminae, somewhat hygroscopic in moist air, easily soluble in water, sparingly in alcohol, insoluble in ether. The *barium salt* separates from hot alcohol in small, anhydrous, highly lustrous, rhombic, tabular crystals grouped in druses. The *silver salt* forms long radiating tufts of crystals.

Taurocarbamic acid heated for several hours at 130° – 140° with saturated *baryta-water*, is completely resolved into carbon dioxide, ammonia, and taurine, according to the equation:

without separation of even a trace of sulphuric acid.

TAUROCYAMINE, $C^3H^5N^3SO^3$, is formed by heating equivalent quantities of taurine and cyanamide with a quantity of water sufficient to dissolve them, for four or five hours at 110° – 112° , or by leaving the mixed solution to itself for some time, and separates in small white prisms melting at 224° – 226° , easily soluble in water, insoluble in alcohol and ether; it dissolves in strong acids, but does not combine with them (E. Dittrich, *J. pr. Chem.* [2], xviii. 63).

Methyltaurocyamine, $C^4H^{11}N^3SO^3 = C^3H^5NSO^3 + CN^2H^2$, formed in like manner from cyanamide and methyltaurine, crystallises in large prisms which have a vitreous lustre, give off their water at 110° , are insoluble in alcohol and ether, and only slightly soluble in cold water. It dissolves in strong acids, but does not form salts (Dittrich).

TEA. The composition of several kinds of tea has been examined by R. Weyrich (*Russ. Zeitschr. Pharm.* 1873, 322 and 353) with the following results. The cheaper sorts of yellow and green tea are richer in theine than the better sorts, but in black tea the contrary holds good. The differences in the total amount of ash, and in the portion soluble in water in the several kinds of tea are very small, and exhibit such irregularities that it is impossible to estimate the value of a tea by the amount of ash

contained in it. The same remark applies to the amount of potash. The proportion of phosphoric acid increases in general with the goodness of the tea, and may therefore be taken as a measure of its value. The estimations of the portion of tea which is soluble in water, and the determinations of nitrogen, showed great irregularities. Hence Weyrich considers, contrary to the view expressed by Zöller (vii. 1148), that the comparative value of unadulterated teas cannot be determined by chemical analysis.

Two samples of tea from Cachar: (1). from *Thea viridis*; (2), from a hybrid variety, have been analysed by Hodges (*Chem. News*, xxx. 114):

100 pts. of each gave the following results:

	(1).	(2).
Moisture	16.06	16.20
Organic matters	78.81	78.98
Mineral matters	5.13	4.82

The ash of each respectively consisted of—

Potash	35.200	37.010
Soda	4.328	14.435
Chlorine	3.513	2.620
Sulphuric acid	5.040	6.322
Phosphoric acid	18.030	9.180
Iron oxide	2.493	2.463
Manganous oxide	1.024	0.800
Lime	8.986	5.533
Magnesia	4.396	5.910
Sand and silica	0.500	1.300
Charcoal	2.900	1.830
Carbonic acid	13.590	12.600
	100.000	100.003

A. Winter Blyth (*Chem. News*, xxx. 212) found in genuine black tea from India:

Extractive	33.900 per cent.
Soluble ash	2.863
Insoluble ash	3.288
Tannin	11.500
Total ammonia	0.850

In a sample of Chinese tea which contained no theine, H. Weippen (*Arch. Pharm.* [3], v. 9) found cinnamic acid, probably derived from storax, which had been added to the tea for the sake of its odour.

An elaborate examination of Chinese tea has been made by Eder (*Dingl. pol. J.* cccxxi. 445, 526; *Chem. Soc. J.* xxxvi. 851–856).

Theine.—The quantity of this alkaloïd in tea is determined by Markownikoff (*Ber.* ix. 1312) as follows. 15 g. pulverised tea are drenched with 500 c.c. water and boiled, with addition of 15 g. calcined magnesia to every 5 g. tea. The precipitate is filtered off and washed, the filtrate evaporated to dryness with addition of a small quantity of magnesia; the theine extracted from the residue with benzene; the solvent evaporated; and the theine weighed.

The following quantities of theine have been found by Petrik (*Dingl. pol. J.* cccxviii. 220) in various kinds of tea.

Kaisow Congo	2.4 per cent. theine
" "	1.7 " "
" "	1.5 " "
Finest Gunpowder	1.4 " "
" Mayune Gunpowder	2.1 " "
" Souchong	2.12 " "
Tea-dust (10.8 per cent. ash)	1.46 " "

Tannin.—According to J. T. Clark (*Amer. Chem.* vii. 44), the proportion of tannin in tea varies from 5 to 19 per cent.

Paraguay tea from *Ilex paraguayensis* is, according to Byasson (p. 1496), destitute of tannin; according to Robins, on the contrary (*Pharm. J. Trans.* [3], viii. 1027), it contains, as an average of seven samples, 10 to 16 per cent. of that substance.

Mineral Constituents of Tea.—G. Wigner (*Pharm. J. Trans.* [3], iv. 909; vi. 261, 281, 402; *Chem. News*, xxxii. 166, 189, 235) has determined in several sorts of tea

the total amount of ash, the quantities soluble in water and in hydrochloric acid, and the amount of alkali reckoned as potash. The following are the results:

	Total ash	Ash soluble in water	Ash soluble in HCl	Silica	Alkalis reckoned as potash
Mean of 24 sorts ⁽¹⁾ .	5.66	3.01	2.21	0.44	1.62 p. c.
" 17 " ⁽²⁾ .	5.75	3.07	2.25	0.43	1.38 "
" 18 " ⁽³⁾ .	5.80	3.44	2.04	0.32	1.39 "
" 4 " ⁽⁴⁾ .	5.57	2.92	2.10	0.55	1.59 "
" 12 " ⁽⁵⁾ .	5.77	2.99	2.22	0.56	1.67 "
" 9 " ⁽⁶⁾ .	6.25	3.07	2.19	0.99	1.35 "

(¹) Taken from original chests. (²) Ordinary sorts from original chests. (³) Fine sorts from original chests. (⁴) Especially fine sorts. (⁵) From retail dealers. (⁶) Genuine Capers.

Similar determinations of the ash of ten sorts of tea have been made by A. I. Wilson (*Chem. News*, xxviii. 307):

	Total ash	Ash soluble in water	Ash soluble in HCl	Silicates	Ferric oxide
Moning . . .	6.00	3.15	2.03	0.82	0.05
" . . .	5.82	2.73	2.52	0.57	0.07
" . . .	5.90	2.76	2.36	0.78	0.07
" . . .	5.55	2.66	2.21	0.68	0.09
Kaisow . . .	5.43	3.33	1.88	0.22	0.05
Feechow Pekoe . . .	6.15	3.20	2.16	0.79	0.09
Assam Souchong . . .	5.15	2.90	2.05	0.20	0.03
Green Assam . . .	5.32	2.94	2.11	0.27	0.08
Fine green tea . . .	7.14	2.38	3.19	1.57	0.12
Mixed black tea . . .	5.68	2.86	2.33	0.49	0.04

Six kinds of tea examined by Wanklyn (*Chem. News*, xxviii. 186) gave, on the average, a quantity of ash equal to 5.92 per cent. of the dried tea, of which 3.55 pts. were soluble in water and 2.37 insoluble. As tea which has been exhausted with water contains a smaller proportion of soluble ash-constituents than fresh tea, Wanklyn recommends the determination of the total ash and of the amount of soluble constituents as a means of judging of the value of the tea.

The ash of black and of green tea was found by Wignor to contain:

	K ² O	Na ² O	SO ³	CO ²	SiO ²
Black	30.92	1.68	4.88	11.60	1.70
Green	28.42	2.08	5.66	6.43	7.50

The proportion of constituents soluble in water was in the black tea, 57.00 per cent.; in the green 52.85.

On the Detection of Adulterations in Tea, see A. H. Allen (*Chem. News*, xxviii. 210, 275, 303; xxix. 129, 140, 157, 189, 221; xxx. 2; *Chem. Soc. J.* xxvii. 191; xxviii. 786; *Jahresb. f. Chem.* 1873, 973; 1874, 1040).

On the Agricultural Chemistry of the Indian Tea-plantations, see J. Campbell-Brown (*Chem. Soc. J.* [1875]. xxviii. 1217-1228).

TEAK-WOOD. A white deposit in the wood of this tree (*Tectonia grandis*) has been analysed by G. Thoms (*Landw. Versuchs.-St.* xxii. 68, xxiii. 413), and found to consist of monocalcic orthophosphate, CaHPO⁴. The formation of this deposit leads to the idea that the wood itself must contain a considerable quantity of phosphoric acid, and analysis shows that this is really the case, the composition of the ash of the wood being as follows:

CaO	MgO	FeO	K ² O	Na ² O	SiO ²	SO ³	P ² O ⁵	CO ²	Cl
31.35	9.74	0.80	1.47	0.04	24.98	2.22	29.69	0.01	0.01 = 100.31

The percentages of carbon and hydrogen are higher than in most woods, and this, together with the richness in calcium phosphate and silica, may perhaps account for the great hardness of the wood.

TECHTOCHRY SIN, or *Methyl-chrysin*, $C^{16}H^{12}O^4 = C^{15}H^9(CH^3)O^4$. See CHRY-

TELLURIUM. *Preparation.*—1. H. Schnitzler (*Dingl. pol. J.* cxi. 484 and 492), by treating 6 pounds of tellurium ore with dilute hydrochloric acid, repeatedly heating it with aqua regia, concentrating the solution, treating it while warm with ferrous sulphate to precipitate gold, passing sulphur dioxide into it to throw down the tellurium, then extracting the silver chloride from the residues by aqueous ammonia, and reducing it with zinc, obtained 240 grams of tellurium, 10 telluriferous selenium, 128 gold, and 30 silver. The black pulverulent tellurium, gently heated in a covered porcelain crucible, sublimed almost without loss to a shining regulus.

2. Chemically pure tellurium may be prepared by reducing an alkaline solution of telluric acid (ammonium tellurate dissolved in caustic alkali or alkaline carbonate) with grape-sugar at the boiling heat. The compound thus reduced may be aggregated into a compact mass by heating it in a glass flask with a little dry saltpetre (F. Stolba, *Jahresb. f. Chem.* 1873, 214).

3. Crude tellurium may be purified by heating it in a glass tube through which a stream of hydrogen is passed. The greater part of the tellurium then sublimes in the free state, a small portion only being driven off as hydrogen telluride, and a residue of metallic tellurides is left, from which the rest of the tellurium may be obtained as chloride by heating it in dry chlorine (F. Becker, *Liebigs Annalen*, clxxx. 257).

4. Another method of purification is founded on the fact that tellurium and potassium, when brought together in water, form soluble potassium telluride, which in contact with oxygen is resolved into potassium hydroxide and metallic tellurium. The crude tellurium is melted, and a platinum wire is thrust into it, after which it is left to cool, and bound tightly round with a piece of linen or calico so as to form a bag. An electrolytic cell is then formed with a platinum plate, the tellurium together with the bag, and a dilute solution of potash, and an electric current is passed through it, the tellurium forming the hydrogen pole. Violet-brown potassium telluride is thereby formed, and sinks through the bag into the alkaline liquid, in which it is decomposed by the oxygen liberated at the other pole, the tellurium being separated in the reguline state.

Atomic Weight.—Berzelius, by oxidising tellurium with nitric acid, and weighing the resulting dioxide, obtained the number $\text{Te} = 127.956$; von Hauer, by the analysis of tellurium-potassium bromide, $2\text{KBr}\cdot\text{TeBr}_4$, obtained $\text{Te} = 127.74$. Dumas, from experiments not published in detail, deduced the number $\text{Te} = 129$ (see v. 712). The values thus found do not agree with that which should be assigned to tellurium in Mendeleeff's classification (vii. 462), according to which the atomic weight of tellurium should be between that of antimony 122, and that of iodine 126.53, tellurium thus taking its place in the same series as sulphur and selenium. To ascertain whether this is really the case, a very careful repetition of the experiments of Berzelius and of v. Hauer has been made by W. L. Wills (*Chem. Soc. J.* xxxv. 704), the result of which is to show that the atomic weight of tellurium is greater than that of iodine, and therefore that in Mendeleeff's system, tellurium must be placed after iodine.

The mean results of Will's experiments are as follows:

By oxidation of Tellurium with Nitric acid	.	.	Te = 127.80
Aqua regia	.	.	Te = 127.907
By analysis of Tellurium-potassium bromide	.	.	Te = 126.83

Estimation.—L. Kastner (*Zeitschr. anal. Chem.* 1875, 142) estimates tellurium by Stolba's method of reduction with grape- or invert-sugar. The tellurium is dissolved in the smallest possible quantity of aqua regia; the solution supersaturated with sodium carbonate and heated to boiling; the sugar-solution added; and the frothing liquid boiled for five or ten minutes, whereby the whole of the tellurium is thrown down. It is best to filter the solution while hot immediately after reduction, and add a little more sugar, which prevents the re-oxidation of the tellurium. The tellurium may then be weighed in the free state on a tared filter, or better in the form of tellurous oxide, by dissolving it in a mixture of nitric and sulphuric acids, and evaporating the solution in a porcelain crucible.

Tellurium-potassium Bromide, $\text{TeBr}_4 \cdot 2\text{KBr}$.—To prepare this salt, equivalent quantities of potassium bromide and tellurium are placed in a flask, and water is added till the potassium bromide dissolves; bromine is then run in, and the flask shaken till the tellurium disappears; and the resulting orange-yellow liquid, filtered from a small yellow deposit, is evaporated over the water-bath, the double salt then separating in crystals which may be purified by recrystallisation (Willis, *loc. cit.*) These crystals, according to H. Baker, are orthorhombic. $a : b : c = 1.0000 : 1.4901 : 3.6558$.

Observed forms, P, 0P, $\infty\tilde{P}\infty$. Type pyramidal, or $+\frac{P}{2}$, $-\frac{P}{2}$. Faces P perfectly smooth, and with a brilliant lustre; those of 0P and $\infty\tilde{P}\infty$ are uneven. At 120° the salt loses water and becomes orange-coloured, but remains quite constant in weight between 120° and 160°.

Oxides and Acids. The specific gravities of the following compounds have been determined by F. W. Clark (*Sill. Am. J.* [3], xiv. 281; xvi. 401):

Tellurous oxide, TeO^2	5.7559	at 12.5°	and 5.7841	at 14°
Telluric oxide, TeO^3	5.0704	„ 14.5°	„ 5.0794	„ 10.5°
„ „ another specimen	5.1118	„ 11°		
Telluric acid, H^2TeO^4	3.425	„ 18.8°	„ 3.458	„ 19.3°
			„ 3.410	„ 19.2°
„ „ (cryst.) $\text{H}^2\text{TeO}^4, 2\text{H}^2\text{O}$	2.999	„ 25.5°	„ 2.9649	„ 26.5°
Ammonium tellurate, $(\text{NH}^1)^2\text{TeO}^4$	3.024	„ 24.5°	„ 3.012	„ 25°

Barium Tellurate slightly heated gave 4.5486 at 10.5°, and 4.5305 at 10°; another specimen gave 4.4811 at 16°. The sp. gr. of the salt merely dried at 200° was nearly 4.2.

Thallium Tellurate, precipitated by mixing the solutions of ammonium tellurate and thallium nitrate, and dried at 100°, had a sp. gr. of 5.687 at 22°, and 5.712 at 20°; after heating to about 180°, with loss of 1.46 per cent. water, its sp. gr. was 6.742 at 16°, and 6.760 at 17.5°.

Tellurous Oxide is formed, with evolution of sulphurous oxide, when tellurium is heated in sulphuric acid, and if considerable quantities are operated on, separates on cooling in the crystalline form (A. Hilger, *Liebig's Annalen*, clxxi. 211).

Tellurous Acid, like selenious acid, is completely precipitated by a magnesian salt and ammonia, but the precipitate is amorphous, whereas that obtained with selenious acid is crystalline (Hilger a. von Gerichten, *Zeitschr. anal. Chem.* 1874, 132).

Telluric Acid, H^2TeO^4 , is best prepared by boiling a solution of tellurous acid in nitric acid with lead dioxide, precipitating the lead from the filtrate by sulphuric acid, evaporating on the water-bath, digesting the residue with alcohol and ether to remove excess of sulphuric acid, dissolving the residue then left in a small quantity of hot water, and recrystallising it in a vacuum (F. Becker, *Liebig's Annalen*, clxxx. 257).

On the reduction of Telluric Acid by *Grape-sugar*, see p. 1895.

A mercurous tellurate, Hg^2TeO^4 , called *Magnolite*, and a ferrous tellurate, FeTeO^4 , called *Ferrotellurate*, are described by F. A. Genth (*Zeitschr. Kryst.* ii. 7). Both occur in the upper veins of the Keystone Mine, Magnolia District, Colorado, the former in microcrystalline groups sometimes enclosing quicksilver, associated with brown hæmatite, psilomelane, and quartz as a product of decomposition of coloradoite; the latter containing a small quantity of nickel, and occurring as a crystalline coating on quartz.

Sulphides. The statement of Berzelius that hydrogen sulphide throws down TeS^2 from a solution of tellurous acid, and TeS^3 from telluric acid, requires, according to Becker (*Liebig's Annalen*, clxxx. 257), a certain amount of correction, his observations showing that the precipitates thus obtained give up nearly all their sulphur when treated with carbon sulphide, and consequently are not definite chemical compounds, but merely mixtures of tellurium and sulphur in approximately constant proportions. He, however, thinks it probable that sulphides of tellurium are formed in the first instance, since, on closely observing the change which takes place when hydrogen sulphide is passed into tellurous acid, each bubble of the gas is seen to produce a red precipitate which turns black only when it reaches the surface of the liquid.

Tellurium Minerals. 1. *Native Tellurium*.—Four varieties of native tellurium from Colorado have been analysed by F. A. Genth:

1. In crystals often enclosing quartz, or in plates between masses of ore consisting of calaverite, coloradoite, iron pyrites, and a mineral perhaps allied to roscoelite; sp. gr. = 6.275; from the Keystone Mountain, Lion, and Dunraven Mines, Magnolia District, Boulder County. 2. Tumefied mass looking as if it had been fused, and evidently consisting—in spite of apparent homogeneity—of a very intimate mixture of tellurium with quartz and silicates. Sp. gr. = 4.005; from the Mountain and Lion Mines; called by the finder *Lionite*. 3. Very small, shining, much distorted crystals in cavities of quartz: from Smuggler's Mine, Ballarat District, Boulder County. 4. Sample of tellurium occurring in very large masses (up to 12 kilo. in weight):

granular to cauliflower) in cavities, and oxidised on the surface to tellurous oxide: in the John-Jay Mine, Central District, Boulder County, at a depth of 9–10 meters.

	Te	Au	Ag	Hg	Cu	Pb	Fe	V ² O ⁵	X ⁽¹⁾
1.	96.91	0.60	0.07	trace	—	—	0.78 ⁽²⁾	0.49	1.15 ⁽³⁾ = 100 ⁽⁴⁾

(¹) Various. (²) FeO. (³) Al²O³.MgO.K²O. (⁴) After deduction of 8.90 per cent. quartz. (⁵) Consisting of 34.72 per cent. SiO², 6.16 Al²O³ and Fe²O³, 0.17 MgO, 0.48 CaO. (⁶) Consisting of 35.91 per cent. SiO², 6.14 Al²O³ and Fe²O³, 0.19 MgO, 0.26 CaO. (⁷) MgO. (⁸) After deduction of 28.04 per cent. quartz. (⁹) Estimated by difference. (¹⁰) After deduction of 65.24 per cent. quartz. (¹¹) After deduction of 14.08 per cent. quartz, including, however, 0.82 per cent. zinc.

2. *Metallic Tellurides*.—The following tellurides from California are described by H. J. Burkart (*Jahrb. f. Min.* 1873, 476) and by F. A. Genth (*J. pr. Chem.* 1874, [2], x. 355).

Bismuth Telluride, or *Tetradymite*, Bi²Te³.—The variety of this mineral which contains sulphur (v. 707) has been found in small quantities in some new localities, the most interesting of which is Uncle Sam's Mine, Highland District, Montana, where it is accompanied by gold and quartz; it is also found in dolomite. It is partly converted by oxidation into montanite (bismuth tellurate), and consequently evolves chlorine when heated with hydrochloric acid, the telluric acid contained in it being at the same time reduced to tellurous acid. Tetradymite occurs both in laminae, up to $\frac{3}{4}$ inch broad, and in scales. Colour blue-grey and iron-black, frequently variegated. *Analyses*: (1). Broad laminae. (2). Small scales from the dolomite:

Te	Bi	Au	Cu	Fe	Se	S	Quartz	Sp. gr.
34.90	60.49	0.21	trace	0.09	trace	4.26	0.05 = 100.00	7.332
34.41	59.24	—	0.47	—	0.14	5.16	0.58 = 100.00	7.542

It is remarkable that the tetradymite from Uncle Sam's Mine contains sulphur, while that from the gold-washings of Highland does not.

Montanite or *Bismuth Tellurate*, Bi²O³.TeO³ + H²O (or 2H²O).—This mineral, formed by oxidation of tetradymite, was first observed by Genth during the examination of the tetradymite of Highland in Montana; subsequently the so-called tetradymite from Davidson Co., North Carolina, which was in great part oxidised, and gave off chlorine when treated with hydrochloric acid, was found to be identical with it. The 'yellow bismuth oxide' from Whitehall in Virginia, analysed by Jackson (*Am. J. of Sci.* [2], x. 78), is also regarded by Genth as probably the same mineral.

Montanite is not crystallised, but exhibits here and there the scaly structure of the original tetradymite, and is in reality a pseudomorph after the latter, on which it forms a coating. It is earthy, soft, dull to waxy in lustre, yellowish to white, and opaque. Before the blowpipe it exhibits the reactions of bismuth and of tellurium, and gives off water when heated in a tube.

Genth's analyses lead to the following results:

	I	Oxygen	II	Oxygen	III	Oxygen
Ferric oxide . . .	0.56	—	1.26	—	0.32	—
Lead oxide . . .	0.39	—	—	—	—	—
Cupric oxide . . .	—	—	1.04	—	1.08	—
Bismuth oxide . . .	66.78	6.85	68.78	6.29	71.90	7.37
Tellurous oxide . . .	26.83	7.30	25.45	7.05	23.90	6.51
Water . . .	5.74	—	3.47	—	2.86	—
	100.30		100.00		100.06	

The oxygen ratio between the bismuth oxide and the tellurous oxide is nearly 1:1, but it is as yet uncertain whether the composition of the mineral is Bi²O³.TeO³.H²O or Bi²O³.TeO³.2H²O.

Lead Telluride or *Altaite*, PbTe, occurs at Red Cloud Mine, and at King's Mountain, Gaston Co. N.C.: at the latter locality in fine-grained quartz, accompanied by gold, galena, copper pyrites, fahl-ore, iron pyrites, and a greenish micaceous mineral resembling fuchsite, and rarely with nagyagite. One very small cubical piece was obtained which consisted partly of galena and partly of altaite, as was evident by the colours of the two, though there was no break in the surface of the specimen. At Red Cloud the altaite is found in larger quantities, together with native tellurium, sylvanite, pyrites, siderite, and quartz. It is sometimes found in small imperfect

cubes, usually coated with galena; more rarely in large cleavable masses: most frequently in coarse grains, which sometimes show an imperfect cubical cleavage, and a fracture inclining to conchoidal. It is distinguished from other tellurium ores by its tin-white colour, inclining to greenish-yellow. It contains:

SiO ₂	An	Ag	Cu	Pb	Zn	Fe	Te
0.19	0.19	0.62	0.06	60.22	0.15	0.48	37.99 = 99.90
0.32	0.16	0.79	0.06	60.53	0.04	0.33	37.51 = 99.74

Altaite occurs also, mixed with hessite and petzite, in the Stanislaus and Golden Rule Mines, California. Two specimens gave: (1) after deduction of 1.03 per cent.; (2) after deduction of 1.96 per cent. quartz:

	Pb	Ag	An	Te
(1).	60.71	1.17	0.26	37.31 = 99.45
(2).	47.84	11.30	3.86	37.00 = 100

These numbers show that (1) consisted of 99.25 per cent. altaite and 2.20 hessite; (2) of 77.42 altaite and 23.11 hessite.

Tellurides of Silver and Gold.—Hessite and Petzite. Auriferous silver tellurite or petzite is the most abundant of all the Californian tellurium ores. The specimens from the Stanislaus and Golden Rule mines are destitute of crystalline structure, exhibit a distinctly conchoidal fracture, metallic lustre, steel-grey to iron-black colour, and iron-black streak; hardness = 2.51, sp. gr. 9.94. Analyses gave 24.80-25.70 per cent. gold, 40.60-42.36 silver, and 31.64-34.16 tellurium, agreeing with the formula $\text{Au}^{\text{Te}}\text{Te}, 3\text{Ag}^{\text{Te}}\text{Te}$. They contain, therefore, more gold than the petzite or sylvanite of Nagyag, but need not on that account be regarded as a distinct species, inasmuch as gold can replace silver in various proportions. Petzite is also found abundantly in the Red Cloud Mine at Gold Hill, Boulder Co., Colorado.

Hessite, $\text{Ag}^{\text{Te}}\text{Te}$, containing little or no gold, is found in the Stanislaus Mine, but always mixed with other minerals, viz., native gold, altaite, and quartz. It is altogether a rare mineral. Genth obtained one specimen of a dark iron-grey colour inclining to black. It was granular, with uneven cleavage, and gave a dark lead-grey powder; soft; sp. gr. 8.178. It contained cavities lined with small crystals of heavy spar and pyrites. The differences in external characters between the other varieties of hessite are very small; those rich in gold are brighter and more brittle.

Analyses: 1 and 2. The pure hessite just described; 3, 4, and 5. *Auriferous hessite* containing from 3.3-13 per cent. gold; 6 and 7. *Petzite* containing more than 24 per cent. gold:

	Te	An	Ag	Cu	Pb	Fe	Zn	Bi	Quartz	Sp. gr.
(1).	37.86	0.22	59.91	0.17	0.45	1.35	trace	—	— = 99.96	8.178
(2).	38.07	0.20	60.19	0.16	0.18	1.20	trace	—	— = 100	
(3).	37.60	3.31	59.68	0.05	—	0.15	—	—	0.18 = 100.97	8.789
(4).	36.74	3.34	59.83	0.06	—	0.21	—	—	0.13 = 100.31	
(5).	34.91	13.09	50.56	0.07	0.17	0.36	0.15	—	0.70 = 100.01	8.897
(6).	33.49	24.10	40.73	trace	0.26	0.78	0.05	0.41	0.62 = 100.44	9.010
(7).	32.97	24.69	40.80	trace	—	1.28	0.21	—	0.05 = 100	9.020

For auriferous hessite and petzite the atomic relations are as follows:

	Au	Ag	Te
Auriferous hessite 3 and 4	1	32.7	34.3
" 5	1	7	8.2
Petzite 6 and 7	1	3.1	4.2

Sylvanite or Graphite Tellurium. For this mineral the Red Cloud Mine is the first authenticated locality in the United States. It occurs sometimes massive, with very distinct cleavage, sometimes in the well-known graphic forms (v. 647), and always very intimately mixed with iron pyrites.

Analysis: 1-3 by Genth (*J. pr. Chem.* [2], x. 355); 4. Sylvanite from Grand View Mine, Colorado, where it occurs imbedded in quartz, and intimately mixed with pyrites; a. Direct result of analysis, the sulphur, however, being calculated from the amount of iron as FeS_2 ; b. After deduction of FeS_2 :

Genth's analyses lead to the following atomic proportions :

	Au	Ag	Te	(Au,Ag):	Te
1.	1	0.96	6.98	1	3.6
2.	1	0.91	7.29	1	3.8
3.	1	0.84	6.45	1	3.5

Calaverite. This mineral, from the Keystone and Red Cloud Mines, has again been analysed by Genth (*Zeitschr. f. Kryst.* ii. 6), with results agreeing nearly with those of his former determinations (p. 371), and leading to the formula $(Au\frac{1}{2}Ag)Te^2$. The material obtained from the Keystone and Mount Lion Mines formed indistinct and unmeasurable crystals belonging either to the rhombic or to the monoclinic system, indistinctly cleavable, and having, after deduction of quartz, with which it was interpenetrated, a density of 9.043. Composition :

	Au	Ag	Te	V ² O ⁵	FeO	X (?)

* Al_2O_3 , MgO , &c.

Krennerite. A tellurium mineral from Nagyag in Transylvania, described by J. A. Krenner (*Ann. Phys. Chem.* [2], i. 636), who regards it as chemically and crystallographically distinct from sylvanite. It has not been analysed quantitatively; qualitative analysis detected nothing but tellurium and gold. It occurs implanted on quartz in small light steel-grey crystals, generally much weathered. The crystals are rhombic, and cleave parallel to the basal face. Observed faces, $\infty P \infty$, $\infty P \infty$, $0P$, ∞P , ∞P_2 , ∞P_3 , ∞P_2 , $P \infty$, P_2 . Fundamental angles, $\infty P : \infty P = 86^\circ 20'$; $\infty P : P = 71^\circ 53'$. From sylvanite, which Krenner also regards as rhombic, it differs by values amounting to 1° in the inclination of the corresponding faces. G. vom Rath (*Berl. Acad. Ber.* 1877, 292) observed the faces P , P_2 , $\frac{3}{2}P_3$, $P \infty$, $P \infty$, $\frac{1}{2}P \infty$, ∞P , ∞P_2 , ∞P_3 , $\infty P \infty$, $0P$. He also found the angle $\infty P : \infty P$ to have the value $86^\circ 30'$, nearly the same as that found by Krenner, whence he calculates the axial ratio $a : b : c = 0.940706 : 1 : 0.504455$. According to Schrauf (*Zeitschr. Kryst.* ii. 209), this ratio is $0.93961 : 1 : 0.50733$.

Coloradoite or Mercuric Telluride, $HgTe$ (Genth, *Jahrb. f. Min.* 1877, 949; *Zeitschr. f. Kryst.* ii. 4). This mineral is found, together with tellurium and quartz, in the Keystone and Mount Lion Mines, and together with tellurium and gold in the Smuggler Mine, Colorado. It is massive, somewhat granular, sometimes (especially if mixed with sylvanite) indistinctly cauliform; does not exhibit either crystalline form or cleavability. It is always intimately mixed with tellurium, tellurite, gold, sylvanite, quartz, and oxidation-products; the purest specimens that could be obtained had a density of 8.627.

Analyses.—1–5. From the Keystone Mine. 6 and 7. From the Smuggler Mine, Ballarat District, at a depth of 2.5–3 meters. In these last two analyses, the gold and silver have not been deducted, since Genth regards them as essential:

Material from still greater depths in the Smuggler Mine was found to consist merely of native tellurium, mixed with 1.75–2.20 per cent. coloradoite.

The following crystallographic determinations of native tellurides from Transylvania have been made by A. Schrauf (*Zeitschr. f. Kryst.* ii. 209; *Jahrb. f. Min.* 1878, 862):

Sylvanite: Monoclinic; $a : b : c = 1.63394 : 1 : 1.12653$; $\beta = 90^\circ 25'$. Three types are distinguished according as the crystals cross one another at angles of $69^\circ 44'$, $55^\circ 8'$, or 90° .

Krennerite (White Tellurium, Mullerin, Yellow ore): rhombic; $a : b : c = 0.9361 : 1 : 0.50733$.

Nagyagite (telluride of lead and gold, iv. 1): rhombic, or monoclinic, with an axial angle $= 90^\circ \pm 1^\circ$, but not quadratic; $a : b : c = 0.2807 : 1 : 0.2761$.

Telluric Silver-glance (Hessite, Petzite), Ag^2Te . Monometric.

Telluric Silver-blende (Stützite): a new species, probably Ag^4Te . Monoclinic; $a : b : c = 1.73205 : 1 : 1.25829$; $\beta = 89^\circ 33'$.

Tellurium Ochre.—This mineral, hitherto found only in Transylvania (v. 713), occurs also in the Keystone, Smuggler, and John-Jay Mines, Boulder County, Colorado, in cavities or clefs of native tellurium, sometimes in single crystals, sometimes in tufted groups of crystals (probably rhombic), mostly of prismatic habit, sometimes acutely pyramidal and cleavable in one direction (Genth, *Jahrb. f. Min.* 1878, 74).

Tellurium-compounds, Organic (F. Becker, *Liebig's Annalen*, clxxx. 262).

Tellurium Tartrate, $(\text{C}^4\text{H}^4\text{O}^6)^2\text{Te} \cdot 2\text{C}^4\text{H}^4\text{O}^6$, is formed on dissolving tellurous oxide in tartaric acid, and separates on leaving the filtered solution to evaporate, in long pointed transparent crystals, which effloresce on exposure to the air, becoming white and opaque. When dried at 100° they have the composition above given.

Triethyl-tellurium Iodide or *Iodotriethyl-tellurin*, $(\text{C}^2\text{H}^5)^3\text{TeI}$, is prepared by heating ethyl telluride, $(\text{C}^2\text{H}^5)^2\text{Te}$ (ii. 550), with a slight excess of ethyl iodide in a reflux apparatus at 50° . It dissolves easily in cold water, and crystallises therefrom by evaporation in a vacuum in light yellow monoclinic plates and prisms, easily soluble in alcohol, insoluble in ether. It melts at $90^\circ\text{--}92^\circ$, and resolidifies at 86° . Its aqueous solution, digested with recently precipitated silver oxide, yields an alkaline liquid, from which a platinum salt may be prepared, having the composition $[\text{Te}(\text{C}^2\text{H}^5)^3\text{Cl}]^2\text{PtCl}_4$, whence it follows that the alkaline liquid contains triethyl-tellurium hydroxide, $\text{Te}(\text{C}^2\text{H}^5)^3\text{OH}$; this compound, however, like its analogues, decomposes on evaporation at the temperature of the water-bath. The platinochloride may be prepared by mixing crude triethyltellurium chloride in aqueous solution with platonic chloride, and separates as an orange-coloured precipitate, insoluble in alcohol and ether, slightly soluble in water.

TEPHROITE. *Manganous Silicate*, Mn^2SiO_4 (v. 254).—This mineral, originally obtained from Sparta, New Jersey, has since been found: (1). In the Mino Hill Mine, Sussex, New Jersey, interpenetrated by red zinc-ore and pale green willemite. Hardness 5.5. Sp. gr. 4.00 (Mixer, *Sill. Am. J.* [2], xlv. 230). (2). At Laangban in Sweden, together with Jacobsite (Pisani, *Compt. rend.* lxxxiv. 1511). (3). At the same locality; light red; containing a considerable quantity of magnesin:

SiO_2	MnO	ZnO	FeO	MgO	CaO	Loss by ignition
29.44	57.31	7.36	0.87	2.50	2.51	0.27 = 100.26
31.70	47.70	—	0.80	9.48	9.80	— = 99.48
33.70	51.19	—	—	12.17	0.95	0.44 = 98.45

TERACRYLIC ACID, $\text{C}^7\text{H}^{12}\text{O}^2$ (O. Krafft, *Ber.* x. 521, 1659, 1740). This acid, homologous with pyroterebic acid, is produced by the action of heat on terpenylic acid, $\text{C}^8\text{H}^{12}\text{O}^4 = \text{CO}^2 + \text{C}^7\text{H}^{12}\text{O}^2$ (p. 1907). On neutralising the distillate with an alkali, removing the undissolved portion, acidulating the clear solution with sulphuric acid, and distilling, the teracrylic acid passes over with the steam in the form of oily drops. It is a colourless liquid, boiling at $216^\circ\text{--}218^\circ$. The *calcium salt*, $(\text{C}^7\text{H}^{11}\text{O}^2)^2\text{Ca} + 5\text{H}^2\text{O}$, is easily soluble, and crystallises in long transparent needles which effloresce on exposure to the air. The *silver salt*, $\text{C}^7\text{H}^{11}\text{O}^2\text{Ag}$, is obtained by recrystallisation from hot water in small colourless needles.

When potassium teracrylate is heated for some time on the water-bath with strong potash-ley, the teracrylic acid is converted into an isomeric acid which smells faintly of cymene, and forms a calcium salt which crystallises in needles an inch long, and is less soluble in hot than in cold water. The corresponding silver salt has not been obtained in the crystalline state. The acid of these salts fused with potash yields two acids, one of which is formic acid.

TERBIUM. See YTTRIUM-METALS.

TEREBENE. See TERPENES.

TEREBIC ACID. See TERPENES.

TEREPHTHALIC ACID, or PARAPHTHALIC ACID. See PHTHALIC ACIDS (p. 1615).

Bromoterephthalic acid, $C^6H^3Br(COOH)^2$, prepared by the action of potassium permanganate on bromotoluic acid, $C^6H^3Br(CH^3)(COOH)$, in alkaline solution, crystallises from boiling water or alcohol in microscopic needles melting at 304° – 305° . Contrary to the usual relations of solubility between aromatic acids and their bromine derivatives, it is more readily taken up by solvents than terephthalic acid itself. Dried at 100° it retains 1 mol. H^2O . Its *potassium salt* crystallises in silky needles; the *copper salt* is obtained as a blue crystalline precipitate; the *lead* and *silver salts* as flocculent precipitates, the last retaining 1 mol. H^2O at 100° .

Bromoterephthalic acid is decomposed by prolonged fusion with sodium hydroxide, yielding sodium phenate, carbonate, and bromide, according to the equation:

but, on adding the brominated acid to the soda in a state of fusion, stirring for a short time, and then leaving the liquid to cool, a different action takes place, resulting in the formation of hydroxyterephthalic acid:

The hydroxy-acid thus produced separates from its hot aqueous solution as a white crystalline powder, which does not melt at 330° , and is identical with the hydroxyterephthalic acid already described (p. 1534).

Bromoterephthalic Chloride, $C^6H^3Br(COCl)^2$, is a colourless oily liquid, boiling at 305° . The corresponding *amide*, $C^6H^3Br(CONH^2)^2$, crystallises in colourless needles which melt at 270° , and are not dissolved at ordinary temperatures by water, alcohol, or ether.

Methyl Bromoterephthalate, $C^6H^3Br(COOCH^3)^2$, formed by treating the chloride with methyl alcohol, crystallises in needles, melts at 42° , and boils at a temperature above 300° (H. Fischli, *Ber.* xii. 615).

TERPENES, $C^{10}H^{16}$. An examination by W. A. Tilden (*Pharm. J. Trans.* [3], viii. 188) of the terpenes from the volatile oils of turpentine, juniper, savine, sage, lavender, orange, bergamot, and lemon, has led to the following conclusions. The terpenes, $C^{10}H^{16}$, so widely diffused among volatile oils, have but little influence in determining their characteristic odours. Natural terpenes are colourless, of sp. gr. 0.84 – 0.86 , and may be divided into two groups: 1. *Turpentine-group*. Boiling point 156° – 160° . Melting point of the nitroso-derivative produced by the action of $NOCl$, 129° . The members of this group yield solid terpin-hydrates, having the composition $C^{10}H^{20}O^2.H^2O$. 2. *Orange-oil group*. B. p. 174° – 176° . M. p. of nitroso-derivative, 71° . The members of this group do not yield solid terpin-hydrates. The individual members of each group are allotropic modifications of the same hydrocarbon, distinguished from one another by their specific rotatory power.

(1). *Terebenthene* and *Isoterebenthene* (J. Riban, *Compt. rend.* lxxviii. 288; lxxix. 223, 314). Terebenthene is the chief constituent of French turpentine oil, from *Pinus maritima* (v. 920), and is obtained in the pure state by washing the turpentine-oil with an alkaline ley and submitting it to fractional distillation. *Isoterebenthene* is obtained by heating terebenthene to 300° , and purified by fractional distillation and repeated rectification over sodium. It is a laevogyrate liquid, having an orange-like odour, and boiling at 173° – 177° (corr.) When exposed to the air it quickly absorbs oxygen, and becomes resinous. In an atmosphere of carbon dioxide it remains unaltered, but absorbs the gas in considerable quantity. Its *hydrochloride*, $C^{10}H^{16}.HCl$, is a colourless mobile liquid having a sweetish and not camphorous odour. Under ordinary pressure it boils with partial decomposition at 210° , giving off hydrogen chloride. Under a pressure of 20 mm. it boils almost without decomposition, at 110° . It does not yield any solid product either by cooling, or by spontaneous evaporation, or by distillation in a vacuum, or by treatment with fuming nitric acid. It is easily saponified by boiling with water. It is not acted upon by alcoholic potash. The *dihydrochloride*, $C^{10}H^{16}.2HCl$, obtained by passing hydrogen chloride into an ethereal solution of isoterebenthene or of the monohydrochloride, forms white crystalline laminæ; melts at 49.5° ; is converted into terpinol, $C^{10}H^{18}.2H^2O$, by boiling with aqueous alcohol containing a small quantity of hydrochloric acid; remains unaltered when boiled with aqueous potash. It forms liquid compounds with the monohydrochloride of turpentine-oil, the isomeric solid mono-

hydrochlorides of active and inactive camphene, and the hydrochloric ether of borneol. *Isoterebenthene dibromide* is converted by boiling with potash-ley into cymene.

The following determinations of the physical properties of terebenthene and isoterebenthene have been made by Riban (*Compt. rend.* lxxviii. 788; lxxix. 314). Terebenthene boils at 156.5° (corr.); isoterebenthene at 175° . The optical rotatory power of terebenthene is $\alpha = -40.32^{\circ}$; that of isoterebenthene $\alpha = -9.44^{\circ}$ at 23° .

Specific Gravity.

Temp. 0°	Terebenthene 0.8767	Temp. 0°	Isoterebenthene 0.8586
17.88	0.8619	20.28	0.8427
39.74	0.8439	40.19	0.8273
59.38	0.8277	58.32	0.8131
79.59	0.8107	79.24	0.7964
		100.00	0.7798

Indices of Refraction.

Spectral lines	Wave-lengths acc. to Thalen	Terebenthene at 16°	Isoterebenthene at 25°
Red (Hydrogen)	0.00065618	1.4665	1.4677
Yellow (Sodium)	0.00058920	1.4697	1.4709
Green (Magnesium)	0.00051739	1.4740	1.4760
Blue (Magnesium)	0.00044810	1.4808	1.4839

The refractive index of terebenthene for the line D at 25° is 1.4648.

On Tetraterebenthene see p. 1917.

(2). Tilden (*Chem. Soc. J.* [1878], xxxiii. 80) has examined the terpenes from Russian turpentine-oil (from *Pinus sylvestris* and *P. Ledebauri*), and from the needles of *P. sylvestris*. The former, when freed from small quantities of creasote and acetic acid by agitation with soda-ley, yielded by distillation a terpene which boiled at 157° , and with the exception of its rotatory power ($+23.3^{\circ}$) agreed in its properties with australene (v. 921). The same oil further contained a considerable quantity of a second hydrocarbon, $C^{10}H^{16}$, boiling between 171° and 171.5° , having a density of 0.86529 at 15° , and a specific rotatory power of $+17^{\circ}$, and finally cymene. The oil from the needles of *Pinus sylvestris* contained, in addition to a hydrocarbon identical with australene (rot. power $+18^{\circ} 48'$), a terpene, agreeing with that above mentioned in boiling-point (171°) and density, but lævogyrate (about -4°), together with a small quantity of cymene.

(3). Flawitzky (*Ber.* xi. 1846), by distilling Russian turpentine-oil with steam and rectifying the product, has obtained a dextrogyrate terpene having a greater rotatory power than that described by Tilden; $[\alpha]_D = 27.7^{\circ}$ at 24.5° ; sp. gr. 0.8746 at 0° ; 0.862 at 16° ; 0.8547 at 24.5° . Dry hydrogen chloride converts it into a hydrochloride which melts and sublimes at 127° , boils at 204° , and separates from alcohol in large crystals. In alcoholic solution it has rotatory power of $[\alpha]_D = +24.5^{\circ}$ and $[\alpha]_D = +30.5^{\circ}$. By nitric acid and alcohol it is converted into a terpin, $C^{10}H^{16}, 2H_2O$.

(4). A terpene agreeing nearly in specific gravity and boiling point with the less volatile terpene of Russian turpentine oil, but optically inactive, is obtained by passing steam through a mixture of terpin crystals (76 pts.) and 50 pts. sulphuric acid diluted with seven or eight times its bulk of water. The terpene then passes over as an oily distillate, which may be purified by boiling it for several hours with a mixture of 1 vol. sulphuric acid and 2 vol. water, then distilling it fractionally and finally over sodium. It boils at 176° – 178° , and has a density of 0.8526 at 15° . It does not appear to be attacked by hydrochloric acid or nitrosyl chloride. When dissolved in hydrochloric and mixed with bromine it is converted into a dibromide, which is resolved by heat into hydrogen bromide and cymene. By oxidation, this hydrocarbon, as well as terpinol, yields, together with other products, para-toluic acid (Tilden, *Chem. Soc. J.* [1878], xxxiii. 250).

(5). From the Swedish wood-tar of *Pinus sylvestris* Atterberg (*Ber.* x. 1202) has obtained two terpenes, which he designates as australene and sylvestrene. The latter has already been described in this volume (p. 1885). The australene agrees very nearly in its physical properties with that obtained from English turpentine oil (v. 920). B. p. 156.5° – 157.5° . Sp. gr. 0.8631 at 16° . Rotatory power $+36.3^{\circ}$. When treated at low temperatures with hydrogen chloride, it yields a solid hydrochloride, which when purified by repeated crystallisation from alcohol, forms feathery crystals melting at 131° ; its rotatory power in alcoholic solution is $+29.8^{\circ}$. It is not attacked by water or by aqueous potash even at 100° , but by hydrogen chloride in ethereal solution it is partly converted into a dihydrochloride. A liquid

compound, probably an *isomeric hydrochloride*, is formed as a bye-product in the preparation of the solid hydrochloride; it appears to be less stable than the latter.

(6). The terpene of clove-oil, after repeated rectification over sodium in a stream of hydrogen, boils at 253.9° (corr.), has a density of 0.905 at 15° , and a vapour-density = 7.7: hence its molecular formula is $C^{15}H^{24}$ (Church, *Chem. Soc. J.* xxviii. 113).

(7) Nutmeg-oil yields by fractional distillation a terpene, $C^{16}H^{18}$, which boils at 163° – 164° (corr.), and is converted by oxidation with chromic acid mixture into carbonic acid, a volatile acid, probably formic, and a small quantity of terephthalic acid, probably due to admixed cymene. Nitric acid converts it into an acid called myristic acid, which, when dried over sulphuric acid, has the composition $C^{20}H^{26}O^{16}, 2H^2O$, together with oxalic acid, and small quantities of toluic and terephthalic acids (C. R. A. Wright, *Chem. Soc. J.* xxvi. 549).

On *Hesperidene*, the terpene of Orange-peel oil, see p. 1028. On the terpene of *Eucalyptus* oil, p. 761.

(8). The terpene of parsley-oil has been examined by E. v. Gerichten (*Ber.* ix. 258). It passes over, on rectifying the oil, as a liquid having a very strong odour of parsley, a density of 0.865 at 12° , and boiling at 164° . Rotatory power for yellow light in a column 100 mm. long = -30.8° . When treated with strong hydrochloric acid, it yielded only a very small quantity of a hydrochloride, and attempts to prepare a terpin from it were unsuccessful. Iodine converts it into a hydrocarbon which yields by oxidation *p*-toluic and *p*-phthalic acids, and is therefore probably cymene.

(9). A solid hydrocarbon, $C^{10}H^{16}$, originally regarded as *ethyl-terpene*, is obtained by the action of sodium and ethyl iodide on camphor chloride (V. Meyer a. Spitzer, *Ber.* ix. 877), also by the action of sodium alone on the same chloride. When purified by distillation and crystallisation from ether it forms a dazzling white crystalline mass, having a camphorous odour, melting at 63.5° and boiling at 153° . It volatilises very quickly on exposure to the air, and is insoluble in water (V. Meyer a. Petri, *Ber.* x. 990; Spitzer, *ibid.* 1034).

(10). A polymeric terpene has been obtained by Jacobsen (*Ber.* ix. 257) from the portion of coal-tar cumene (purified merely by agitation with soda-ley and distillation), which is not attacked (*i.e.* not converted into a sulphonic acid) by sulphuric acid. The greater part of this residual liquid distils between 170° and 180° , another smaller portion between 300° and 330° . The first portion contains a hydrocarbon $C^{10}H^{22}$, boiling under 770 mm. pressure at 170° – 171° . The polymeric terpene is contained in the second portion, and may be separated therefrom by fractional distillation finally over sodium. It is a colourless oily liquid, not miscible in all proportions with alcohol, boiling between 320° and 325° , having a density of 0.885 at 22° , and a refractive index = 1.5009 for the line D. Its formation is probably due to the polymerising action of the strong sulphuric acid on a lower-boiling terpene contained in the crude hydrocarbon.

Compounds of Terpenes with Nitrosyl Chloride, $C^{10}H^{16}(NO)Cl$; and Nitrosoterpenes, $C^{20}H^{15}(NO)$ (Tilden a. Shenstone, *Chem. Soc. J.* xxxi. 554). To prepare the nitrosochlorides, a solution of a terpene in 3 or 4 vol. chloroform (or $\frac{1}{2}$ vol. in the case of terpentine-oil) is saturated at -10° with nitrosyl chloride (p. 1419), care being taken to avoid rise of temperature. The reaction is complete when a sample of the product gives with alcohol a white crystalline precipitate, which is not visibly increased by further action of the nitrosyl chloride. The whole is then stirred into three times its volume of methyl alcohol; the mixture is left to itself for half an hour; and the resulting crystalline precipitate is washed with alcohol and then left to dry in the air. In operating on the terpenes of caraway, bergamot, lemon, and sweet orange, however, it is better to dissolve them in five or six times their volume of methyl alcohol instead of chloroform, keeping the temperature also at -10° . The end of the reaction is then indicated by a slight effervescence. The crude product may be purified, if necessary, by solution in chloroform and precipitation with alcohol.

Australene Nitrosochloride, prepared from American dextrogyrate turpentine-oil boiling at 160° – 161° , and having a rotatory power $[\alpha]_D = +1.75^{\circ}$, melts with decomposition at 103° , and is converted by heating with alcohol and alcoholic potash into a nitrosoterpene, $C^{10}H^{14}NO$, which remains on neutralising the alkaline solution and evaporating; it melts at 129° (corr.)

Terebenthene Nitrosochloride, from French lævogryrate turpentine-oil boiling between 156° and 160° , is very much like the australene compound. The nitrosoterpene obtained from it by the action of alcoholic potash likewise resembles nitroso-australene in melting point and in optical inactivity, but differs from it slightly in crystalline form.

Of the terpenes from *Salvia officinalis* (p. 1771), the one which boils at 158° – 160°

and has a rotatory power $[\alpha]_D = -32.2^\circ$, yields a nitroso-derivative identical with that obtained from australene; whereas the other, boiling at 168° – 176° , and having a rotatory power $[\alpha]_D = -17.7^\circ$, does not yield any analogous nitrosochloride, but is converted, with effervescence, into oily products.

Terpene of *Juniperus communis*, obtained from the portion of the crude oil which boils below 160° , and has a rotatory power $[\alpha]_D = -1^\circ$, yielded a nitrosochloride which was converted by alcoholic potash into a nitrosoterpene melting at 128.5° , and was therefore apparently identical with that prepared from australene.

Inactive terpene, prepared by the action of sulphuric acid either on dextro- or on lævogyrate turpentine-oil, and boiling at 156° – 159° , did not yield a crystalline nitrosochloride.

Hesperidene Nitrosochloride (m. p. 103°), prepared from 'essence de Portugal,' boiling at 174° – 175° , is dextrogyrate, $[\alpha]_D = +85.9^\circ$, and yields, with alcoholic potash, a brown oily product, from which a crystalline nitroso-derivative may be obtained. This latter may, however, be prepared in larger quantity by the action of heat on the nitrosochloride itself. For this purpose the nitrosochloride in portions of 1 gram each is fused in test-tubes, and cooled by water immediately after fusion; the resulting honey-like mass, after standing for some hours, is dissolved in alcohol, and the solution is left at rest. It then deposits the nitrosohesperidene in flat prisms, which melt at 71° , and are much more soluble in alcohol than the isomeric compounds above described. This nitroso-compound is sublimable, but polymerises when converted into vapour, so that its vapour-density cannot be ascertained. That it is isomeric and not identical with the nitroso-derivatives of australene and terebenthene is shown by the fact that it is lævogyrate ($[\alpha]_D = -36.6^\circ$), although it is prepared from a dextrogyrate terpene. On adding bromine to a solution of nitrosohesperidene in chloroform, and evaporating, the compound $C^{10}H^{15}(NO)Br$ separates out as a semi-crystalline mass.

Terpene from Oil of Caraway, which boils at 178° , and has a rotatory power (100 mm.) equal to $+11^\circ$, forms a nitrosochloride which, when decomposed by heat, yields a nitrosoterpene melting at 71° , and identical with that just described.

Terpene from Bergamot-oil, boiling at 176° , and having a rotatory power (100 mm.) $[\alpha]_D = +75.6^\circ$, yields a nitrosochloride which melts at 98° , and is thereby converted into a nitrosoterpene melting at 71° , which, like nitrosohesperidene, melts at 71° and is lævogyrate, but differs from that compound and from the nitroso-derivative obtained from oil of caraway, in crystallising, not in broad flat prisms, but in concentric or parallel groups of very long thin prisms.

Terpene from Lemon-oil yielded only a small quantity of a nitrosochloride, from which no crystalline nitroso-derivative could be obtained. The oil of *Juniperus Sabina* did not yield any derivatives analogous to those above described.

Products of the action of Sulphuric Acid on Terpenes. Deville (*Ann. Chim. Phys.* [1840], lxxv. 37), from an examination of the action of sulphuric acid upon oil of turpentine, inferred that the turpentine is thereby partly converted into 'terebene' (v. 924), an optically inactive liquid hydrocarbon having the same composition and boiling point (about 160°) as the original oil, and partly into colophene (i. 1086), a polymeric hydrocarbon probably of the formula $C^{20}H^{32}$. Riban in 1873 (*Compt. rend.* lxxvi. 1547) confirmed Deville's conclusion that terebene was an isomeride of the terpene from which it was prepared, but showed that the properties ascribed to it by Deville were not those of a pure substance, but of a mixture containing a considerable quantity of cymene; and a similar conclusion was arrived at by Orłowski (*Ber.* vi. 1257), according to whom the product contains more cymene than terebene.

Riban's 'terebene' remained liquid even at -27° , and had practically the same density, boiling point (156°), and refractive index as the terpene from which it was prepared, the only physical difference between them being their behaviour to polarised light; but whereas terpene monohydrochloride was found to melt at 131° – 132° , and to be decomposed only to a very slight extent on prolonged heating with water at 100° , 'terebene' monohydrochloride was found to melt at 125° , and to be very rapidly and completely decomposed by water at 100° , manifesting in this respect the very closest resemblance to the monohydrochloride obtained from inactive camphene, which, however, melts at 145° . Riban observes also that terebene hydrochloride is decomposed even by prolonged washing with cold water, yielding solid camphene and hydrochloric acid, whereas when decomposed by water at 100° , it yields liquid terebene.

The action of sulphuric acid on the terpenes has been further investigated by Armstrong a. Tilden (*Chem. Soc. J.* xxxv. 733), whose results are summarised as follows:

1. The action of sulphuric acid on the terpenes varies both according to the concentration of the acid and the temperature at which the action takes place.

2. The terpenes are most readily deprived of their optical activity by means of concentrated acid acting at an elevated temperature. By the action of the same acid at about 0° , they are chiefly polymerised, the rotatory power of the portion not polymerised being affected only to a comparatively slight extent.

3. Weak sulphuric acid acts very slowly on the terpenes at ordinary temperatures (1 vol. H_2SO_4 to 1 vol. water), and tends chiefly to polymerise them. By its action at about 80° , however, they are ultimately rendered optically inactive, a considerable proportion remaining unpolymerised. Acids intermediate in concentration between that just mentioned and the undiluted acid appear to furnish intermediate results.

4. The portion of the product of the action of concentrated acid which is volatile with steam does not contain, as Deville, Riban, and Orlowski state, a liquid optically inactive isomeride, boiling at about the same temperature as the parent terpene, neither is cymene the only other constituent of this portion of the product (Riban, Orlowski). So-called terebene, in fact, does not exist, the substance described under this name being merely impure optically inactive camphene; and in the said product it is associated with terpinene, the optically inactive liquid isomeride of the terpenes which boils at about 178° , also with cymene and a paraffin-like hydrocarbon of the formula $\text{C}^{10}\text{H}^{20}$. Terpinene is the chief constituent of the product in question, and next in amount is camphene; the quantity of cymene is relatively smaller, and that of the hydrocarbon, $\text{C}^{10}\text{H}^{20}$, still smaller.

5. The similar product of the action of acid (1 vol. H_2SO_4 to 1 vol. water) at about 80° does not appear to contain any camphene, but consists principally of terpinene; it also contains cymene, the hydrocarbon $\text{C}^{10}\text{H}^{20}$, and a certain amount of oxygenated substance which is but little, if at all, affected by sodium.

6. The portion of the product of the action of sulphuric acid of whatever strength, which does not volatilise with steam—crude colophene—is probably a mixture of polymerides of the form $(\text{C}^{10}\text{H}^{16})_n$. When submitted to distillation, it yields a considerable amount of matter volatile in steam. The product examined by Deville, Riban, and probably by Orlowski, was therefore a mixture of two products.

7. The steam distillate obtained from colophene prepared by the action of acids varying in strength from 2 vol. H_2SO_4 : 1 vol. water to the concentrated acid, resembles in composition the volatile product above described (4), but contains a considerably larger proportion of inactive camphene; it also contains a small quantity of an optically inactive camphol (borneol).

8. The distillate from the colophene obtained by the action of the acid (1 vol. H_2SO_4 : 1 vol. water) on the terpenes, and that from the colophene derived from terpinene, contains a relatively much larger amount of cymene and of the hydrocarbon $\text{C}^{10}\text{H}^{20}$ than the distillate from colophene prepared by means of stronger acid. It is doubtful whether it contains camphene.

9. The amount of distillate obtained from colophene prepared under various conditions is subject to considerable variations, the law of which has not yet been ascertained.

10. The small amounts of substances other than those mentioned which are found in the volatile product of the action of sulphuric acid, and also in the colophene distillate, are probably the result of the decomposition of a product of oxidation formed during the prolonged fractional distillation, and in the latter case also during the preparation of the colophene.

11. Probably the best method of preparing pure inactive camphene from the terpenes will be to polymerise the terpene completely by means of an excess of concentrated sulphuric acid at an elevated temperature, and having freed the colophene from cymene, &c., by steam-distillation, to distil it alone, then to fraction the colophene distillate, and treat the fraction collected at about 156° – 160° with hydrochloric acid, and afterwards decompose the camphene hydrochloride so formed by means of an alcoholic solution of potassium hydroxide.

12. Inactive camphene is converted into inactive camphor by oxidation with a mixture of potassium dichromate and sulphuric acid. This inactive camphor yields camphoric acid on oxidation with nitric acid, but the acid prepared in this manner has a much higher melting point than ordinary camphoric acid.

Terpenes and Camphenes have also been obtained from the following sources:

(1). G. Bouchardat (*Compt. rend.* lxxx. 1446) obtained a *terpinene* by heating isoprene, C^8H^8 (iii. 433), at 280° – 290° in sealed tubes from which the air had been displaced by carbon dioxide. The product contained a little unaltered isoprene, a hydrocarbon boiling between 170° – 185° , and higher condensation-products, including a certain quantity of the hydrocarbon $\text{C}^{10}\text{H}^{20}$, but chiefly amorphous colophene. *Terpinene*,

which forms the chief constituent of the fraction, passing over from 170° to 185° , and distills, after rectification, between 176° and 181° , has a very strong odour of lemons, resembling also that of isoterbenthene. Sp. gr. = 0.866 at 0° , = 0.853 at 21° . It quickly absorbs oxygen from the air. On passing hydrogen chloride into its ethereal solution, a mixture of two *hydrochlorides* is formed, which remains as an oil when the ether is evaporated off at 20° – 22° . On distilling this mixture under a pressure of 140 mm., a body passes over at 145° , which has nearly the composition $C^{10}H^{16}, HCl$, and remains liquid in a freezing mixture; the temperature then rises quickly to 175° – 180° , whereupon a slight decomposition begins, attended with evolution of hydrochloric acid; and, if the distillation be then interrupted, there remains in the retort a substance which solidifies completely in a freezing mixture, and has the composition $C^{10}H^{16}, 2HCl$. In the surfused state this body may be made to solidify completely by dropping into it a small quantity of the dihydrochloride prepared from turpentine oil, or of the dihydrochloride of caoutchou (1.736). After pressure and recrystallisation from ether, it melts at 49.5° .

(2). A *terpiline*, very similar in properties to that just described is obtained in like manner from valerylene, C^8H^8 . After several rectifications, it has a density of 0.848 at 0° and 0.836 at 15° , and distills at about 180° . On passing hydrogen chloride into its solution in a six-fold volume of ether, a *monohydrochloride* is formed, distilling under a pressure of 20 mm. at 115° – 120° , and a *dihydrochloride* boiling under the same pressure at 125° – 140° , and remaining liquid at -14° . The residue contains another dihydrochloride, which cannot be distilled without decomposition even in a vacuum, solidifies at -14° after contact with dihydrochloride of citrene, and then does not liquefy till heated to 25° . These last compounds give a blue colour with ferric chloride. The liquid mono- and di-hydrochloride treated with alcoholic potash, yield terpinol (Bouchardat, *Compt. rend.* lxxxvii. 654).

(3). *Camphenes*.—The name 'camphene,' originally used as a generic term for the hydrocarbons, $C^{10}H^{16}$, was restricted by Berthelot to the solid members which he obtained by the action of certain weak reagents, such as the alkaline stearates, on the hydrochlorides of the terpenes (v. 924). They have since been formed, as already observed, by the action of sulphuric acid on the terpenes, and by other processes. The following have been examined by Riban (*Ann. Chim. Phys.* [5], vi. 353; *Compt. rend.* lxxx. 1307).

Lævorotatory Camphene, or *Terecamphene*, was obtained by Berthelot from terebenthene hydrochloride by the action of potassium stearate. Riban prepares it by heating the hydrochloride with about an equal weight of potassium hydroxide and three or four times the same weight of alcohol of 94 per cent. in a closed vessel for seventy-eight hours, treating the product with water, distilling, pressing, and fractionating. It has a faint taste, melts at 45° – 47° , and boils at 156° – 157° (corr.) In the fused state it has at 47.7° a density = 0.8481 ; at 58.9° = 0.8387 ; at 79.9° = 0.8211 ; and at 97.7° = 0.8062 , giving for the dilatation-coefficient the formula $D_t = 0.1881 - 0.00839t$. The rotatory power of the camphene in alcoholic solution varies with the degree of dilution. Denoting by e the quantity of alcohol in 100 pts. of the solution, the following values are obtained:

Temp.	e	Rotatory power
13	62.11 p. c.	-51.88°
13	71.50	-51.60
14	80.30	-51.37
14	90.44	-50.99

The rotatory power may be expressed by the equation $[\alpha]_D = 53.80 - 0.3081e$. The *monohydrochloride*, $C^{10}H^{16}, HCl$, is prepared by dissolving 100 pts. of the camphene in 150 pts. absolute alcohol, and saturating the solution with gaseous hydrogen chloride. Rotatory power $[\alpha]_D = +30.25^{\circ}$. It dissociates readily, and must therefore be sublimed in a current of hydrogen chloride; in such an atmosphere it melts at 147° . It is decomposed rather slowly by water at ordinary temperatures, completely by heating for ninety hours with fifty times its weight of water at 100° , the regenerated hydrocarbon being *lævorotatory*: $[\alpha]_D = -8.5^{\circ}$.

Inactive camphene was obtained by Berthelot, together with active camphene, from which it could not be separated, by heating terebenthene monohydrochloride with sodium benzoate. This statement is confirmed by Riban, who has also prepared perfectly inactive camphene by heating terebenthene monochloride for eighty hours with twice its weight of sodium or potassium acetate at 170° , distilling, and washing with potash-ley and water to remove acetic acid. Inactive camphene resembles the active modification in all its properties, except the rotatory power. It melts at 470° , boils at 157° (corr.), and yields a monohydrochloride, which is decomposed by water and potash-ley, and melts in an atmosphere of hydrogen chloride at 145° (corr.)

Borneo-camphene, or *Borneene*, originally obtained from *Dryobalanops Camphora* (i. 626), may be formed artificially from common camphor by treating a solution of that substance in toluene with sodium, and the product with carbonic acid, whereby borneol is obtained (vii. 206), and heating the latter with fuming hydrochloric acid at 100°, whereby it is converted into the hydrochloride $C^{10}H^{16}.HCl$, which is optically inactive, resembles ordinary camphene hydrochloride in its properties, melts in an atmosphere of hydrogen chloride at 145°, and is slowly decomposed by water at ordinary temperatures, more quickly at 100°, with formation of borneocamphene.

Conversely, levogyrate camphene from French turpentine-oil can be converted into camphor by boiling 100 pts. of it for fifteen or sixteen hours in a reflux apparatus with 570 pts. potassium dichromate, 700 sulphuric acid, and 1420 water, acetic acid and apparently a small quantity of butyric acid being formed at the same time. The camphor thus obtained may be freed from traces of camphene by fractional sublimation, rejecting the first sublimate, and from higher-boiling oily bodies by solution in nitric acid, precipitation with water, and sublimation from lime. When thus purified it exhibits the pungent odour and other properties of ordinary camphor, melts at 172° (corr.), and has a levorotatory power $[\alpha]_D = -13.7^\circ$, opposite therefore in direction to that of ordinary camphor. The camphoric acid formed from it is also levogyrate; $[\alpha]_D = -6.5^\circ$, and melts at 197°–198° (corr.); camphoric acid from common camphor melts at 187° (corr.)

TERPENYLIC ACID, $C^8H^{12}O^4$ (C. Hempel, *Ber.* viii. 357). This acid is formed by oxidising terpin or turpentine-oil with a quantity of chromic acid not sufficient for complete oxidation; and in like manner, according to Sauer (*ibid.* x. 522), from terebene (impure inactive camphene) and the terpene of lemon-oil. It is obtained at first in the form of a syrup resembling glycerol, but on leaving its concentrated solution for some time exposed to the air, it solidifies almost completely, and is easily obtained pure by pressure and recrystallisation. It is very soluble in water, and crystallises therefrom in radiate groups of colourless laminae, having the composition $C^8H^{12}O^4 + H^2O$, which give off their water in the exsiccator, and crumble to a powder melting at 90° (Hempel). It is resolved by heat into carbon dioxide and teracrylic acid, $C^7H^{10}O^2$ (Krafft, p. 1900).

Terpenylic acid is monobasic. Its salts are so soluble that even a tolerably concentrated solution of the ammonium salt forms no precipitate with any of the ordinary metals. The *silver salt*, $C^8H^{11}O^4Ag$, separates from a hot concentrated solution as a white loosely coherent crystalline mass, which does not blacken at 90° or on exposure to light. The *copper salt*, $(C^8H^{11}O^4)^2Ca$, separates from solution on spontaneous evaporation in small well-defined dark-blue crystals. The *ethyl ether*, which melts at 36°–38°, and boils almost without decomposition at about 300°, is not attacked by acetyl chloride at 100°; consequently terpenylic acid does not contain any hydroxyl-groups. According to its formula it should be the next homologue of terebic acid, to which indeed it exhibits a certain degree of analogy (Hempel). When treated with barium hydrate, it is converted into the barium salt of diaterpenylic acid, $C^8H^{12}BaO^5$. The ethyl ether of this acid is solid (E. Sauer, *Ber.* x. 522; Krafft, *ibid.* 1660).

TERPIN and **TERPINOL** (v. 923). Tilden (*Chem. Soc. J.* xxxiii. 247) prepares terpin, $C^{10}H^{20}O$, by leaving a mixture of 1 vol. nitric acid (sp. gr. 1.4), 1 vol. methyl alcohol, and $2\frac{1}{2}$ vol. pure turpentine-oil (either French or American) to itself for two days, then pouring it into an open dish, and gradually pouring upon it, at intervals of two days, small quantities of methyl alcohol. Orange terpenes thus treated do not yield terpin. Contrary to the statements of former observers, Tilden finds that terpinol (prepared by the action of hydrochloric acid upon terpin) boils between 205°–215°, and has the composition $C^{10}H^{18}O$ or $C^{10}H^{18}O^2$. Accordingly terpin may be represented by the rational formula $C^{10}H^{18}(OH)^2$, and terpinol by $C^{10}H^{18} \begin{smallmatrix} \diagup O \diagdown \\ \diagdown O \diagup \end{smallmatrix} C^{10}H^{18}$. The latter treated with dry hydrogen chloride yields the *di-hydrochloride of turpentine oil*, $C^{10}H^{16}.2HCl$, in crystals which melt at 50°, and are converted by sodium ethylate at the boiling heat into a mixture of the compounds $C^{10}H^{18} \begin{smallmatrix} \diagup OC^2H^5 \\ \diagdown Cl \end{smallmatrix}$, and $C^{10}H^{18}(OC^2H^5)^2$. An alcoholic solution of terpinol mixed with *hydrochloric acid* gradually deposits terpin.

Terpin treated with dilute sulphuric acid (1 pt. H^2SO^4 to 7 or 8 pts. water) yields, together with a small quantity of terpinol, a terpene apparently identical with one of the terpenes obtained from Russian turpentine-oil (p. 1902).

TETRABENZOYL-DIAMIDOPHENOLS. See PHENOLS, AMIDO- (pp. 1522, 1523).

TETRABENZOYL-MORPHINE. See MORPHINE (p. 1340).

TETRABROMACETIC ETHER, $C^4H^4Br^4O^2$, is formed by the action of bromine at 160° on the dibromacetic ether, $C^4H^4Br^2O^2$, which is obtained by heating ethylidene acetoxychloride, $CH^2.CH(OC^2H^3O)Cl$, with bromine at 102° – 103° . When freed from absorbed hydrogen bromide by heating in a stream of carbon dioxide, it forms an oily liquid which fumes strongly in the air, and decomposes when distilled. It is also decomposed by water and alcohol, yielding products which reduce an ammoniacal silver solution. Heated with bromine in sealed tubes at 170° , it is converted into pentabromacetic ether, $C^4H^2Br^6O^2$, probably $CH^2.Br.CO.OCBBr^2.CHBr^2$, which is a liquid, fuming very slightly in the air, and boiling without decomposition at 175° – 177° . With water it yields a product of decomposition which does not reduce ammoniacal silver-solution. With alcohol it yields 1 mol. monobrom- and 1 mol. dibromacetic ether (b. p. 194°), together with hydrogen bromide and traces of brominated acetic acid, but no silver-reducing substance. It is different from the pentabromacetic ether obtained by heating ethyl acetate with bromine (p. 11). Heated with excess of bromine at a very high temperature, it is converted into hexbromacetic ether, $C^4H^2Br^6O^2$, a liquid boiling almost without decomposition at 195° – 198° (F. Kessel, *Ber.* xi. 1917).

TETRABROMALIZARIN, $C^{14}H^4Br^4O^2$, is obtained by heating alizarin with excess of bromine at 180° , and may be purified by repeatedly crystallising the product from glacial acetic acid, in which it dissolves with rust-brown colour. It is nearly insoluble in water and in alcohol. In alkalis and in strong sulphuric acid it dissolves with dark red to brown-red colour, and the solutions yield brown-red precipitates with lime-water, baryta-water, and alcoholic lead acetate. It melts at a high temperature, and sublimes as a light brown deposit, with considerable carbonisation. When heated with iodine bromide it is decomposed, partially at 200° , completely at 250° , into carbon dioxide, perbromethane, and pentabromobenzene (Diehl, *Ber.* xi. 187).

TETRABROMANILINE, $C^6HBr^4.NH^2$ [1 : 2 : 4 : 6, NH^2 in 1]. See BENZENES, BROMAMIDO- (p. 195).

TETABROMANTHRACENE **TETRABROMIDE**, $C^{14}H^6Br^4.Br^4$ (p. 1499).

TETRABROMAZOPHENOLS. See PHENOLDIAZINS in the ADDENDA.

TETRABROM-ETHANE or **TETRABROMETHYLENE HYDRIDE**, $C^2H^2Br^4$, produced by the action of bromine on dibromosuccinic acid at 170° , is a crystalline body, isomeric with acetylene tetrabromide or dibromethylene dibromide, formed by the action of bromine on a saturated solution of acetylene in absolute alcohol. Tetrabromethane melts at 54.5° , and boils with partial decomposition at 206° ; whereas acetylene bromide is liquid at ordinary temperatures, and is resolved at 190° into HBr and tribromethylene (Bourgoin, *Ann. Chim. Phys.* [5], iii. 421); compare p. 35.

The same tetrabromethane appears to be formed, together with other products, by heating ethylidene oxychloride with bromine in sealed tubes till carbonisation takes place. The syrupy product is resolved by distillation into three portions, the second of which, passing over between 190° and 240° , has the composition $C^2H^2Br^4$. It is insoluble in water, dissolves easily in ether, alcohol, and carbon sulphide, crystallises therefrom in nacreous scales, melts at 52° , and boils at 220° (Kessel, *Ber.* x. 1667).

TETRABROM-ETHYLACETYLENE, $C^4H^2Br^4$, obtained by the action of bromine on ethyl-acetylene, $CH^3.CH^2.C\equiv CH$ (produced by the action of PCl^5 on methylethyl ketone, and treatment of the product with alcoholic potash), is a crystalline body soluble in alcohol, ether, and carbon sulphide, subliming without fusion at 105° (Bruylants, *Ber.* viii. 410).

TETRABROM-ETHYLENE, C^2Br^4 , is formed, together with hexbromethane, by gradually heating ethyl iodide with bromine to 250° . It boils at 53° (Merz a. Weith, *Ber.* xi. 2235).

TETRABROM-ETHYLENE HYDRIDE, syn. with TETRABROMETHANE.

TETRABROM-ETHYL OXIDE, $C^4H^2Br^4O = (CH^2Br.CHBr)^2O$, obtained by saturating ethylidene oxychloride with bromine at 115° – 120° , is a faintly-yellowish syrupy liquid, which fumes in the air and is decomposed by water (Kessel, *Ber.* x. 1667).

TETRABROMOBENZENES, $C^6H^2Br^4$ (p. 169).

TETRABROMOBENZENESULPHONIC ACID, $C^6HBr^4.SO^2H$. See p. 243.

TETRABROMOBUTYRIC ACID, $C^4H^4Br^4O^2$ (m. p. 120° – 130°), is formed, together with other products, by heating mucobromic acid, $C^4H^2Br^2O^2$, with bromine and water at 120° – 130° (vii. 828).

TETRABROMOCAPROIC ACID, $C^6H^8Br^4O^6$. Identical with Sorbic Tetrabromide (p. 1897).

TETRABROMOCARBAZOL, $C^{12}H^8Br^4N$. A product having nearly this composition is formed by the action of bromine on carbazol (vii. 253), either in the dry state or dissolved in carbon sulphide (Graebe a. Glaser, *Liebigs Annalen*, clxiii. 343).

TETRABROMOCATECHOL or **TETRABROMOPYROCATECHIN**, $C^8H^2Br^4O^2$. See p. 1709.

TETRABROMOCORALLIN-PHTHALEIN, $C^{20}H^{10}Br^4O^4$. See Corallin, under ROSAURIN (p. 1764).

TETRABROMODECANE, $C^{10}H^{18}Br^4$, is formed by direct combination of bromine with menthene, $C^{10}H^{18}$ (iii. 880), and is resolved by heat into hydrogen bromide and cymene: $C^{10}H^{18}Br^4 = 4HBr + C^{10}H^{14}$ (Beckett a. Wright, *Rep. Br. Assoc.* 1875, [2 Abth.], 38).

TETRABROMODIHYDROXYDIPHENYLMETHANE, $C^{18}H^8Br^4O^2$, is formed on adding bromine-water to a hot aqueous solution of dihydroxyphenylmethane, $CH^2(C^6H^4OH)^2$, [produced by the action of melting potash on the potassium salt of diphenylmethanedisulphonic acid (p. 684)], and separates in the form of a white precipitate. When purified it forms laminae having a reddish shimmer, soluble in alcohol and in ether, insoluble in water, melting at 225° , and decomposing at a higher temperature. Its *hydrobromide*, $C^{18}H^8Br^5O^2$, may be prepared by slowly dropping bromine into an ethereal solution of dihydroxydiphenylmethane, and leaving the resulting solution to evaporate below 0° . The yellow crystalline masses thus obtained decompose on exposure to the air, with separation of hydrogen bromide, and dissolve in alcohol with formation of ethyl bromide (C. Beck, *Ber.* x. 1837).

TETRABROMODIPHENYLAMINE, $NH(C^6H^3Br^2)^2$. See PHENYLAMINES (p. 1549).

TETRABROMOFLUORENE, $C^{18}H^8O^1$, resembles the tribromo-derivative (q.v.).

TETRABROMOFLUORESCEIN, or **EOSIN**, $C^{20}H^8Br^4O^5$. See PHTHALEINS (p. 1609). The following observations on eosin and allied colouring matters have been made by Bindschedler a. Busch (*Chem. News*, xxxviii. 226). *Yellowish Eosin*, soluble in water (*sodium-tetrabromofluorescein*), is obtained by adding 1.1 kg. bromine, with agitation to 1 kg. finely pulverised fluorescein suspended in ten litres of alcohol; the fluorescein already partially brominated then passes into solution, and is again gradually treated with 1.1 kg. bromine, each drop of which produces a crystalline precipitate of tetrabromofluorescein. The precipitate is left to settle, separated by decantation, and washed, first with alcohol, then with water, till the liquid runs away perfectly neutral. The product is then dissolved in caustic soda, and the solution, which must not have an alkaline reaction, is evaporated to crystallisation. *Bluish Eosin*, soluble in water (*sodium-tetraiodofluorescein*), is obtained by adding the calculated quantity of iodine dissolved in alkali to an alkaline solution of fluorescein, and then adding an acid, whereby a crystalline precipitate is formed; and, on dissolving this precipitate in caustic soda and evaporating, the commercial product is obtained. Its aqueous solution does not exhibit any sign of fluorescence. *Safrasin*, soluble in water, is a sodium salt of nitrated eosin, and is obtained on mixing 9 kg. eosin in alkaline solution with 8 kg. sodium nitrate, heating the mixture to the boiling point, and then adding 15 kg. sulphuric acid of 66° B. The resulting precipitate, which has the colour of manganous sulphide, is washed, and dissolved in caustic soda, and the solution is evaporated. The colouring matter thus obtained dyes wool of a deeper and more bluish-red than eosin, and yields with naphthalene-orange a good substitute for cochineal.

Eosin soluble in alcohol exhibits a greater variety of tints, like those of flowers, than eosin soluble in water, and is more permanent. It is obtained by heating 5 kg. eosin with 15 litres of pure methyl alcohol and 9 kg. sulphuric acid of 66° B. for four hours in the water-bath. The resulting methyl-derivative of tetrabromofluorescein is purified by pouring it into a large quantity of water, filtering and washing, and is sent into the market in the form of a potassium salt. In the dried state it is soluble in a mixture of equal parts of water and alcohol, the solution exhibiting a splendid fluorescence. The *ethyl*-derivatives prepared in like manner have a somewhat fainter

yellowish colour. For further details see *Die Chemische Industrie redigirt von Dr. E. Jacobsen*, Berlin, 1878, 370; also *Monit. Scientif.* [3], viii. 1169).

TETRABROMOHYDROXYPIPERHYDRONIC ACID, $C^{12}H^{10}Br^4O^5$. See PIPERIC ACID (p. 1632).

TETRABROMOLEUCROSAURIN. See ROSAURIN (p. 1763).

TETRABROM METHYLFLUORESCHEIN (p. 1909).

TETRABROMONAPHTHOIC ACIDS, $C^{10}H^8Br^4.COOH$. See NAPHTHALENE-CARBOXYLIC ACIDS (p. 1660).

TETRABROMOPHENANTHRENE, $C^{14}H^6Br^4$ (p. 1514).

TETRABROMOPHENOL-PHTHALEIN, $C^{20}H^{10}Br^4O^4$, and **-PHTHALEIN**, $C^{20}H^{10}Br^4O^4$ (pp. 1604-1605).

TETRABROMOPIPERHYDRONIC ACID, $C^{12}H^{10}Br^4O^4$. See PIPERIC ACID (p. 1633).

TETRABROMORCINOLPHTHALEIN, $C^{22}H^{12}Br^4O^5$, formed by adding bromine to a boiling solution of orcinol-phthalein (p. 1612) in glacial acetic acid, is a faintly yellowish crystalline powder, only sparingly soluble in nearly all solvents, but dissolving readily and with dark brown colour in dilute alkalis (E. Fischer, *Ber.* vii. 1214).

TETRABROMOSTRUTHIN, p. 1445.

TETRABROMOROSAURIN, $C^{20}H^{12}Br^4O^3$. See ROSAURIN (p. 1763).

TETRACETYL-BRAZILIN, $C^{18}H^{10}(C^2H^3O)^4O^5$ (p. 348).

TETRACETYL-CONIFERIN, $C^{16}H^{18}(C^2H^3O)^4O^5$, is obtained by digesting coniferin (p. 553) with acetic anhydride at 100° , and precipitating with water, and separates as a white crystalline precipitate, which softens at 90° , and melts at 125° - 126° to a clear liquid solidifying to a transparent mass on cooling. It is insoluble in cold, slightly soluble in hot water, dissolves with moderate facility in cold alcohol and ether, very easily in boiling alcohol (Tiemann a. Naganosi Nagai, *Ber.* viii. 1140).

TETRACETYL-CODEINE, $C^{72}H^{80}(C^2H^3O)^4N^4O^{12}$. See CODEINE, under MORPHINE (p. 1340).

TETRACETYL-MORPHINE, $C^{34}H^{34}(C^2H^3O)^4N^2O^6$ (vii. 820).

TETRACETYL-QUINATE, ETHYLIC, $C^6H^7(OC^2H^3O)^4.COO C^2H^5$. See QUINIC ACID (p. 1734).

TETRACETYL-SULPHOTANNIC ACID, $C^{16}H^{16}S^2O^{13}$. See TANNIC ACID (p. 1889).

TETRACETYL-TETRABROMO-DIIMIDOPHENOL-PHTHALEIN, $C^{28}H^{20}Br^4N^2O^6$. See PHTHALEINS (p. 1605).

TETRABUTYRYL-MORPHINE, $C^{34}H^{34}(C^4H^7O)^4N^2O^6$ (vii. 820).

TETRACHLORACETONE, $C^3H^2Cl^4O$. See ACETONE (p. 26).

TETRACHLORALIZARIN, $C^{14}H^4Cl^4O^4$, is prepared by heating alizarin at 100° in a sealed tube with antimony pentachloride, boiling the dark brown product with acid, dissolving it in soda-ley, precipitating with an acid, and finally dissolving it in a mixture of benzene and alcohol, from which it separates in the form of a red-brown crystalline powder. It begins to melt at 260° , but is almost entirely carbonised at a higher temperature. It is insoluble in water, but dissolves readily in glacial acetic acid, benzene, chloroform, carbon sulphide, and hot alcohol. Soda-ley dissolves it with brown colour. It does not dye mordants (Diehl, *Ber.* xi. 187).

TETRACHLORANILINES, $C^6H^3Cl^4N$. See PHENYLAMINES (p. 1549).

TETRACHLORANTHRACENE, $C^{14}H^4Cl^4$, is formed by the action of alcoholic potash on dichloranthracene dichloride, $C^{14}H^6Cl^2Cl^4$ (Diehl, *Ber.* xi. 173). See also vi. 179.

TETRACHLORANTHRAQUINONE, $C^{14}H^4Cl^4O^2$, is obtained by heating dichloranthraquinone for some time in a sealed tube at 200° - 220° with six times its weight of antimony pentachloride, and may be separated from adhering trichloranthraquinone by exhausting the crude product with hot glacial acetic acid, and fractional crystallisation, and finally purified by sublimation. It crystallises in yellow needles melting without decomposition at 320° - 330° , easily soluble in chloroform, toluene, carbon sulphide, and boiling glacial acetic acid (Diehl, *Ber.* xi. 179).

TETRACHLORAZOXYBENZENE, $\begin{matrix} \text{C}^6\text{H}^3\text{Cl}^2\text{N} \\ \text{C}^6\text{H}^3\text{Cl}^2\text{N} \end{matrix} \rangle \text{O}$. This compound is

known in two modifications, one of which is formed by heating $[1:3:4]$ nitrodichlorobenzene, $\text{C}^6\text{H}^3\text{NO}^2\text{H}^2\text{Cl}^2$ (m. p. 545°), with alcoholic potash, the solution on cooling depositing a dark-coloured mass, from which the tetrachlorazoxybenzene may be obtained by washing with cold alcohol and boiling with carbon sulphide, which dissolves the azoxy-compound and leaves a brown powder. Pure tetrachlorazoxybenzene crystallises in very small light-yellow needles melting at 141.5° ; soluble in chloroform, benzene, and glacial acetic acid. Strong sulphuric acid dissolves it with red colour (Laubenheimer, *Ber.* vii. 1600; viii. 1626).

The second modification, formed by the action of alcoholic potassium hydrosulphide on symmetrical or $[1:3:5]$ dichloronitrobenzene, melts at 171° – 172° (Beilstein a. Kurbatow, *Ber.* xi. 514).

TETRACHLOROBENZENES, $\text{C}^6\text{H}^2\text{Cl}^4$ (p. 173). The consecutive modification may be obtained from nitrotrichlorobenzene, $\text{C}^6\text{HCl}^3\text{NO}^2$, by reduction and subsequent replacement of the amido-group by chlorine.

TETRACHLOROBENZOIC ACID, $\text{C}^6\text{HCl}^4\text{CO}^2\text{H}$, is formed by heating orthochlorobenzoic acid with six times its weight of antimony pentachloride for three or four hours at 230° . Its *barium salt*, after repeated crystallisation from alcohol, forms beautiful needles containing $(\text{C}^6\text{HCl}^4\text{O}^2)^2\text{Ba} + 4\text{H}^2\text{O}$ (Beilstein, *Ber.* viii. 435).

TETRACHLOROBILIRUBIN. See BILE-PIGMENTS (p. 325).

TETRACHLOROCARBAZOL, $\text{C}^{12}\text{H}^2\text{Cl}^4\text{N}$, is formed, together with less highly chlorinated products, by passing chlorine into a solution of carbazol in carbon sulphide (Graebe a. Glaser, *Liebig's Annalen*, cxiii. 343).

TETRACHLOROCOUMARIN, $\text{C}^8\text{H}^2\text{Cl}^4\text{O}^2$, is obtained by passing chlorine into a solution of coumarin and iodine in carbon tetrachloride. It crystallises from alcohol in white needles melting at 144° – 145° (Perkin, *Chem. Soc. J.* xxv. 37).

TETRACHLORODIETHYL-GLYCOL,

$\text{C}^6\text{H}^2\text{Cl}^4\text{O}^2 = \text{CCl}^3-\text{CH} \begin{matrix} \text{O} \\ \diagup \end{matrix} \text{CH}^2-\text{CH}^2-\text{O} \begin{matrix} \text{O} \\ \diagdown \end{matrix} \text{CH}-\text{CCl}^3$, formed by the action of phosphorus pentachloride on the compound of glycol and chloral, is a viscid liquid, having a density of 1.73 at 17° , insoluble in water, and decomposing when distilled (L. Henry, *Ber.* vii. 762).

TETRACHLORODIMETHYLQUINOL, $\text{C}^8\text{Cl}^4(\text{OCH}^3)^2$. See QUINOL (p. 1738).

TETRACHLORODIPHENYLAMINE, $\text{NH}(\text{CH}^2\text{Cl}^2)^2$. See DIPHENYLAMINE (pp. 200, 1549).

TETRACHLORONAPHTHALENE, $\text{C}^{10}\text{H}^4\text{Cl}^4$ (p. 1350).

TETRACHLORONITROBENZENE, $\text{C}^6\text{H}(\text{NO}^2)\text{Cl}^4$, crystallising in needles, at 20° – 22° , is obtained by the action of strong nitric acid on symmetrical tetrachlorobenzene, $[1:2:4:5]$. It dissolves readily in carbon sulphide, benzene, and hot alcohol (Beilstein a. Kurbatow, *Ber.* ix. 579).

TETRACHLOROPHENANTHRENE, $\text{C}^{14}\text{H}^6\text{Cl}^4$. See PHENANTHRENE (p. 1515).

TETRACODEINE, $\text{C}^{144}\text{H}^{168}\text{N}^8\text{O}^{24}$. See CODEINE (vii. 372).

TETRADYMITÉ. Native Telluride of Bismuth (p. 1897).

TETRAHEDRITE. *Fahl-ore*. A number of tetrahedrites and other sulphur salts from Sweden have been examined by N. Nilson (*Zeitschr. Kryst.* i. 417):—

1–5. Tetrahedrite agreeing with the formula $2(4\text{R}^2\text{S}, \text{Sb}^2\text{S}^3) + 4\text{R}''\text{S}, \text{Sb}^2\text{S}^3$. This mineral was formerly regarded as identical with Svanberg's *aphthonite* from Gärdgön, Wermland (v. 729); but Nilson shows that Svanberg's original analysis of *aphthonite* (No 6), from which he deduced the formula $7\text{RS}, \text{Sb}^2\text{S}^3$ (in which RS must be supposed to denote partly CuS in place of Cu²S), agrees equally well with the formula $2(4\text{Cu}^2\text{S}, \text{Sb}^2\text{S}^3) + 4\text{ZnS}, \text{Sb}^2\text{S}^3$, in which 1 Cu is replaced by 1 Ag, and 1 Zn by 1 Fe. The values calculated from this formula, $\text{Cu}^{15}\text{AgZn}^3\text{FeSb}^6\text{S}^{27}$, are given under No. 7. Nilson further observes that Atterberg's analysis of a mixture of metallic bismuth with a sulphur-salt (No. 8), gives for the latter the formula $3\text{RS}, 2\text{Bi}^2\text{S}^3$, in which $3\text{R} = 2\text{Pb} + 1\text{Fe}$ (No. 9), supposing the mineral to contain 36.81 per cent. metallic

bismuth. Lastly Nilson reproduces Lundström's analyses (No. 10) of the mineral called *Bjellkite* by Nordenskiöld, the composition of which is represented by the formula $\text{FePb}^2\text{Bi}^2\text{S}^2 = 3\text{RS}, \text{Bi}^2\text{S}^2$. The only other sulphur salts found in Sweden are *Geocronite*, *Boulangerite*, and *Kobellite*.

	S	Sb	Bi	Pb	Fe	Cu	Ag	Zn

(¹) Containing Cobalt. (²) Including 3.15 per cent. Se and 1.60 per cent. gangue. (³) Including 1.84 per cent. Se.

Fahl-ore from Brixlegg crystallised in rhombic dodecahedrons, and imbedded in heavy spar, has been analysed (1) by G. Untchj (*Jahrb. f. Min.* 1873, 80) and (2) by F. Becke (*Min. Mitt.* 1877, 273) with the following results:

S	Sb	As	Bi	Cu	Zn	Ag	Fe
25.59	20.44	6.96	—	39.37	4.43	—	3.21 = 100
23.0	17.0	11.2	0.4	40.2	3.0	0.9	4.2 = 99.9

Unlike most rhombic-dodecahedral fahl-ores, therefore, it is *not* a mercury fahl-ore.

The decomposition-products of the mercury fahl-ore of Maschellandsberg in the Pfalz have been examined by F. Sandberger (*Jahrb. f. Min.* 1872, 646). This mineral (sp. gr. 5.095) contains, according to an analysis by Oellacher:

S	As	Sb	Bi	Ca	Hg	Fe	Co	Zn	Gangue
21.90	0.31	23.45	1.57	32.19	17.32	1.41	0.23	0.10	1.39 = 99.87

Hence its proximate constitution may be calculated as:

As^2S^2	Sb^2S^2	Bi^2S^2	Cu^2S	HgS	FeS	CoS	ZnS
0.51	32.81	1.93	40.31	20.09	2.22	0.35	0.15

By decomposition the fahl-ore is converted into a light, lead-grey, porous mass, which qualitative analysis shows to consist of Cu^2S . The material filling up the cavities consists, according to an analysis by E. Prior, of 24.70 per cent. HgS , 46.85 Cu^2S , 1.04 insoluble residue, and 27.41 FeCO_3 (determined by difference). The iron-carbonate is evidently an accidental admixture, and the ratio of the cinnabar to the copper-glance (1 : 2 in the fahl-ore) is scarcely altered by the decomposition (1 : 1.9 in the product); but the sulphur-acids have been removed (probably by barium sulphide). The ultimate product of the decomposition is a mixture of malachite, stilbite, and cinnabar.

Antimony fahl-ore, crystallised in tetrahedrons and in crystalline crusts 3 mm. thick, from a well-shaft at Bourbonne-les-Bains, has been analysed by G. Krause (*Arch. Pharm.* [3], vi. 409) with the following result:

S	Sb	As	Cu	Fe	Ni	Sn	Sp. gr.
23.44	26.40	trace	43.20	4.00	strong traces =		97.04 5.137

On the Crystallography of Fahl-ore and its regular intergrowth with Copper-pyrites, see Sadebeck (*Zeitschr. geol. Ges.* xxiv. 173, 427; *Jahrb. f. Min.* 1873, 801; further, *Ann. Phys. Chem.* [2], v. 578).

TETRAHYDROISOLEPIDIN, $\text{C}^{25}\text{H}^{24}\text{O}$. See LEPIDIN (p. 1177).

TETRAIODHYDROXYSULPHOBENZIDE, $\text{SO}^2[\text{C}^6\text{H}^2\text{I}^2(\text{OH})]^2$. See OXYSULPHOBENZIDE (p. 1475).

TETRAIODODIPHENYL DIOXIDE, $\left[\begin{array}{c} \text{C}^6\text{H}^2\text{I}^2\text{O} \\ | \\ \text{C}^6\text{H}^2\text{I}^2\text{O} \end{array} \right]$, apparently identical with

the compound $\text{C}^8\text{H}^2\text{I}^2\text{O}$, which Lautemann obtained by the action of alkalis on tri-iodosalicylic acid (v. 158), is formed by the action of iodine on phenol in alkaline solution. To prepare it, a boiling solution of 300 g. sodium carbonate in a litre of

TETRAMETHYL-ALLENE—TETRAMETHYLETHYLENE. 1913

water is mixed with 10 g. phenol, and then with 70–75 g. iodine (dissolved in a solution containing 45 g. potassium iodide); 30 g. more sodium carbonate are added to remove excess of iodine; the hot solution is filtered; and the red precipitate is washed first with water, then with alcohol, and repeatedly crystallised from carbon sulphide, in which it dissolves easily with deep red colour. It is insoluble in ether, benzene, and chloroform. By sodium-amalgam it is converted into di-iodo-diquinol, $C^6H^2IOH.C^6H^2IOH$; by sulphurous acid into tetraiodo-diquinol, $C^6H^2I^2OH.C^6H^2I^2OH$ (Kämmerer a. Benzinger, *Ber.* xi. 357).

TETRA-IODOFLUORESCIN. See p. 1909.

TETRA-ISOBUTYLAMMONIUM IODIDE. See TRI-ISOBUTYLAMINE.

TETRAMETHYL-ALLENE, $C^3H^{12} = (CH^3)^2C=C=C(CH^3)^2$, is formed by the action of alcoholic potash on the chloride $C^3H^{13}Cl$, which is produced by treating di-isopropyl ketone or isobutyron, $(CH^3)_2CH.CO.CH(CH^3)^2$, with phosphorus pentachloride. This hydrocarbon is a liquid having a very disagreeable odour, boiling at about 70° , and forming an addition-product with bromine. The chloride, $C^3H^{13}Cl$, is a colourless liquid which boils between 118° and 120° , and has a density of 0.9513 at 9° . The crude product of the action of phosphorus pentachloride on isobutyron also contains a dichloride, $C^3H^{14}Cl_2$, which, however, is converted during distillation into the monochloride (L. Henry, *Ber.* viii. 400).

TETRAMETHYLAMMONIUM, $N(CH^3)^4$. According to Rabuteau (*Monit. scient.* [3], iii. 451), the salts of this base, and those of tetramethylammonium, exert a poisonous action on the animal organism similar to that of curare.

The chloride, $N(CH^3)^4Cl$, is formed, together with trimethylamine hydrochloride, methylamine, and methyl oxide, by heating sal-ammoniac with excess of methyl alcohol (Weith, *Ber.* viii. 458). The iodide, well crystallised, has a density of 1.827 at 17° , and 1.831 at 19.5° (Clarke, *Sill. Am. J.* [3], xvi. 401). It is perfectly stable at high temperatures (Hofmann, *Ber.* vii. 526). On tetramethylammonium ferrocyanide, $FeCy_4[(CH^3)^4N] + 13H^2O$, see METHYLAMINES (p. 1306). E. Fischer (*Liebigs Annalen*, xc. 184) represents it by the formula $FeCy^2H^2[(CH^3)^4N]^2 + 2H^2O$.

TETRAMETHYLBENZENES, $C^{10}H^{14} = C^6H^2(CH^3)^4$. On symmetrical tetramethylbenzene or durene, $[1 : 2 : 4 : 5]$, see pp. 695, 1444. Another modification, distinguished as β , is produced by heating a solution of 25 g. monobromomesitylene and 40 g. methyl iodide in benzene with 14 g. sodium: hence it must be the unsymmetrical modification $[1 : 3 : 4 : 5]$:

When purified by fractional distillation over sodium, it is a liquid which has a faint pleasant aromatic odour, does not solidify in a freezing mixture, boils at 192° – 194° (Durene is solid at ordinary temperatures, melts at 79° – 80° , boils at 189° – 191°). Bromine in excess converts it, with violent reaction, into a dibromo-derivative, $C^{10}H^{12}Br^2$, which dissolves sparingly in cold, much more readily in boiling alcohol, and separates therefrom in shining needles melting at 199° (Jannasch, *Ber.* viii. 355).

TETRAMETHYLDIAMIDAZOXYBENZENE, $C^{12}H^4(CH^3)^4(NH^2)^2N^2O$, is formed by the action of alcoholic potash on the hydrochloride of nitrosodimethylaniline, and crystallises in brown shining needles (p. 1309).

TETRAMETHYL - DIAMIDOBENZOPHENONE, $CO[C^6H^4N(CH^3)^2]^2$. See KETONES (p. 1153).

TETRAMETHYLDIAMIDOTRIPHENYLMETHANE,

This constitution is assigned by O. Fischer (*Ber.* xi. 950) to the condensation-product formed by the action of zinc chloride on a mixture of benzaldehyde and dimethylaniline (p. 1308). The alcoholic solutions of its salts are converted by oxidation into blue-green colouring matters. Its *hexanitro-derivative* forms golden-yellow needles melting at 200° .

TETRAMETHYLDIPHENYLCHLORETHANE,

is formed by the action of sulphuric acid on a mixture of xylene and dichlorethyl oxide, and is converted by dry distillation into tetramethylstilbene, $C^{18}H^{20}$.

TETRAMETHYLETHYLENE, $(CH^3)^2C=C(CH^3)^2$. See HEXYLENES (p. 1036).

TETRAMETHYLMETHANE, $C^5H^{12} = C(CH^3)^4$. This pentane is formed by the action of zinc-methyl on tertiary butyl iodide, $C(CH^3)_3I$, and on dichloropropane, $CH_2.CCl_2.CH^3$ (vii. 63, 1037; viii. 1499).

TETRAMETHYL-ROSANILINE HYDROBROMIDE,

is formed, according to Brunner a. Brandenburg, by the action of bromine on dimethylaniline (p. 1305).

TETRAMETHYL - RUFIGALLOL, $C^{14}H^4(CH^3)^4O^8$. See RUFIGALLOL (p. 1768).

TETRAMETHYL-STILBENE, $C^{18}H^{20} = (CH^3)^2C^6H^3.CH=CH.C^6H^3(CH^3)^2$, is formed by the dry distillation of tetramethyl-diphenylchloroethane (p. 1913); crystallises after some time from the portion of the crude liquid product which boils between 325° and 340° ; and may be purified by draining, pressing, and recrystallisation from alcohol. It forms shining crystalline spangles, melts at 105° – 106° , and volatilises without decomposition. It is moderately soluble in boiling alcohol, somewhat more soluble in ether and in carbon sulphide. When dissolved in either of these last two solvents, it unites directly with bromine, the solution after some time depositing small shining needles, which are but very slightly soluble in ether or in carbon sulphide.

Together with the solid tetramethylstilbene there is formed a somewhat considerable quantity of a liquid isomeric compound boiling at 335° ; it has not, however, been obtained quite free from dissolved stilbene. A solution of bromine in carbon sulphide, even when very dilute, is decolorised by this liquid compound, with evolution of hydrogen bromide, and after filtering from traces of tetramethyl-stilbene bromide, there remains a colourless oil which does not solidify even after prolonged contact with the air.

Xylene prepared from parabromotoluene yields, when treated with dichlorethyl oxide and sulphuric acid, a tetramethyldiphenylchloroethane, from which, by dry distillation, there is obtained a large quantity of a liquid and a small quantity of a solid tetramethylstilbene, the latter, however, being not identical but isomeric with that above described, inasmuch as it crystallises in shining laminae melting at 157° .

Solid tetramethylstilbene (m. p. 105° – 106°), boiled for twenty-four hours with dilute nitric acid (1 vol. HNO^3 of sp. gr. 1.4 and 3 vol. water), yields [1 : 2 : 4] xylie acid (CO^2H in 1), melting at 122° : consequently tetramethylstilbene from coal-tar oil consists for the most part of the modification in which the CH -groups occupy the position 1, and the methyl-groups the places 2 and 4:

TETRAMORPHINE, $C^{136}H^{152}N^8O^{24}$, is formed by the action of dilute sulphuric acid on morphine, first at 100° , and afterwards at 140° (vii. 821); also by the action of sodium ethylate on a solution of tetracetylmorphine in benzene (Beckett a. Wright, *Chem. Soc. J.* xxviii. 323).

TETRANAPHTHOL - HEMIANTHYDRIDE - PYROMELLITIC ACID, $C^{50}H^{28}O^7$. See PYROMELLITIC ACIDS (vii. 840).

TETRANITRO-ANTHRAFLAVONE, $C^{14}H^4(NO^2)^4O^4$, is prepared by heating 5 g. anthraflavone (p. 107) with 150–160 g. nitric acid sp. gr. 1.4 in a reflux apparatus till the whole is dissolved, and separates on cooling and dilution with water in shining yellow needles which melt at 307.6° (corr.) with explosion and combustion. In water, especially when hot, it dissolves readily with yellow colour; in alcohol and ether with red colour; from its yellow alkaline solutions it is precipitated by acids. Strong nitric acid converts tetranitro-anthraflavone into a compound which is not precipitable by water, and crystallises in yellow plates. Tetranitro-anthraflavone sometimes remains unaltered in dry air, sometimes turns red on the surface. It absorbs dry ammonia gas, forming a light red compound, $C^{14}H^2(NO^2)^4(NH^4)^2O^4.2NH^3$, which gives off 1 mol. ammonia over calcium chloride, and 2 mol. when heated. $C^{14}H^2(NO^2)^4(NH^4)^2O^4$ is a dark-red body which dissolves readily in water, the solution when exposed to the air emitting a faint musk-like odour, arising from decomposition of the salt, which takes place with deposition of free tetranitro-anthraflavone. From the aqueous solution of the ammonium salt, *silver fluoride* or *nitrate* throws down the compound $C^{14}H^2(NO^2)^4Ag^2O^4$ in slender brownish needles having a silky lustre. With *sodium-amalgam*, and with *tin* and *hydrochloric acid*, tetranitro-anthraflavone yields

ill-defined or easily decomposable compounds. The mother-liquors of the preparation of tetranitro-anthraflavone contain trinitro-hydroxybenzoic acid (F. Schardinger, *Ber.* viii. 1487).

TETRANITRO-AZOXYBENZENE, $C^{12}H^6(NO^2)^4N^2O$, is formed, with energetic action, when diphenylthiocarbamide is added by small portions to fuming nitric acid, and on pouring the solution into water, boiling the resulting precipitate with alcohol, and crystallising the residue from strong nitric acid, the tetranitro-compound separates in yellow crystals (A. Fleischer, *Ber.* ix. 993).

TETRANITRO - BENZYL TOLUENE, $C^{14}H^{10}(NO^2)^4$. See **TOLUENE (BENZYL-)**.

TETRANITROCARBANILIDE, $CO[NH.C^6H^3(NO^2)^2]^2$ (Losanitsch, *Ber.* x. 690; xi. 1539). This compound is formed by the action of nitric acid on thiocarb-anilide or dinitrothiocarb-anilide. It is insoluble in water, slightly soluble in alcohol and ether, and crystallises from solution in hot nitric acid in yellow needles, melting at a temperature above 200° . With alkalis it forms red salts, from which it is precipitated by acids. When drenched and afterwards boiled with alcoholic potash, it yields the potassium salt $CO[NK.C^6H^3(NO^2)^2]^2$, which is red when first prepared, but afterwards turns green, and is converted, by contact with water at ordinary temperatures, into a red compound, at the boiling heat into a yellow precipitate consisting of dinitraniline. The potassium salt is decomposed in a similar manner in alcoholic solution. Acids also act upon it in like manner, but in this case the greater part of the product is reconverted into tetranitrocarbanilide. The potassium salt, when heated, decomposes with explosion, formation of hydrocyanic acid, and separation of carbon. Tetranitrocarbanilide likewise unites with other bases, but the resulting compounds are very unstable, the yellow needles of the calcium salt falling to pieces as soon as they are removed from the mother-liquor, and the red ammonium salt decomposing when its solution is heated. The action of aqueous potash on tetranitrocarbanilide is different from that of alcoholic potash.

Tetranitrocarbanilide may also be conveniently prepared by the action of hot strong nitric acid on diphenyl-guanidine, and on carbanilide; but in this case there is also formed a small quantity of picric acid, together with a yellow body melting at 204° , which is found in the last mother-liquors, crystallises in spherical groups of needles, and appears to be an isomeride of tetranitrocarbanilide.

TETRANITROCHRYSAZIN, $C^{14}H^4(NO^2)^4O^4$. See **CHRYSAZIN**, under **DIOXY-ANTHRAQUINONES** (p. 108).

TETRANITROCHRYSOPHANIC ACID, $C^{15}H^6(NO^2)^3O^4$. This compound, originally obtained from chrysophanic acid, is also formed by heating chrysarobin (p. 462) with nitric acid of sp. gr. 1.4 (Liebermann a. Seidler, *Ber.* xi. 1603).

TETRANITROCORALLINPHTHALEÏN, $C^{20}H^{10}(NO^2)^4O^4$. See **CORALLIN-PHTHALEÏN**, under **ROSAURIN** (p. 1764).

TETRANITRO- β -DINAPHTHYLTRICHTHLORETHANE, $C^{22}H^{10}(NO^2)^4Cl^2$. See **NAPHTHALENE** (p. 1347).

TETRANITRODIPHENYLAMINE, $C^{12}H^7(NO^2)^4N$. See **PHENYLAMINES** (p. 1549).

Tetranitrodibromodiphenylamine, $C^{12}H^3Br^2(NO^2)^4N$, is produced by the action of fuming nitric acid on tribromomethyl-diphenylamine, and crystallises from glacial acetic acid in yellow nacreous laminae or rhombohedral tablets. It does not appear, however, to have been obtained pure, as the product examined turned dingy green on exposure to the air, and varied in melting point between 235° and 242° . It exhibits acid properties (Gnehm, *Ber.* viii. 925).

TETRANITROFLUORESCEÏN, $C^{20}H^6(NO^2)^4O^5$. See **PHTHALEÏNS** (p. 1608).

TETRANITRONAPHTHALENE, $C^{10}H^4(NO^2)^4$ (p. 1353).

TETRANITROPHENYL SULPHIDE, $[C^6H^3(NO^2)^2]^2S$, is formed on passing hydrogen sulphide into a warm alcoholic solution of chlorodinitrobenzene [1 : 2 : 4, Cl in 1] (p. 183), mixed with a small quantity of strong ammonia:

also by treating the same chlorodinitrobenzene with sulphide or hydrosulphide of potassium. It dissolves sparingly in glacial acetic acid, and crystallises therefrom in yellow needles melting at 193° . It is nearly insoluble in benzene, alcohol, and carbon sulphide. Heated at 120° with fuming nitric acid, it is converted into a sulphone,

1916 TETRAPHENYLETHANE—TETRAPHENYLMELAMINE.

which crystallises from glacial acetic acid in yellow prisms melting at 240°–241° (Beilstein a. Kurbatow, *Ber.* x. 1993).

TETRANITRO-OXYSULPHOBENZIDE, $[\text{C}^6\text{H}^2(\text{NO}^2)_2\text{OH}]^2\text{SO}^2$ (p. 1476).

TETRAPHENYLETHANE, $\text{C}^{26}\text{H}^{22} = \text{C}^2\text{H}^2(\text{C}^6\text{H}^5)^4 = (\text{C}^6\text{H}^5)^2\text{H.C.CH}(\text{C}^6\text{H}^5)^2$, or $(\text{C}^6\text{H}^5)^2\text{C.CH}^2(\text{C}^6\text{H}^5)^2$. This hydrocarbon is formed: 1. From β -benzpinacolin (p. 1629) by the action of hydriodic acid and phosphorus (Thörner a. Zincke, *Ber.* xi. 65):

2. In like manner from benzpinacone (p. 1628) (Graebe, *Ber.* viii. 1054):

or

3. By the action of finely divided copper on thiobenzpinacone,

in alcoholic solution (Engler, *Ber.* xi. 922).

4. By heating benzophenone (diphenyl ketone) with zinc-dust (Staedel, *Liebig's Annalen*, xciv. 307):

5. By the action of copper on thiobenzophenone, $\text{C}^6\text{H}^5.\text{CS.C}^6\text{H}^5$. This method is well adapted for preparing large quantities of tetraphenylethane. The thiobenzophenone is dissolved to saturation in boiling alcohol, and the solution is boiled for several hours in a reflux apparatus with copper precipitated by zinc; or the thiophenone may be mixed with several times its weight of copper, and the mixture distilled from a retort (C. Engler, *Ber.* xi. 926).

6. By the action of sodium on diphenylchloromethane, $\text{CHCl}(\text{C}^6\text{H}^5)^2$, the materials being boiled together in a reflux apparatus for four hours (Engler).

7. By the action of zinc and strong hydrochloric acid on diphenylcarbinol, $\text{C}^6\text{H}^5.\text{CHOH.C}^6\text{H}^5$, dissolved in glacial acetic acid at the boiling heat (Zagoumeny, *Liebig's Annalen*, clxxxiv. 174).

Most of the above reactions are in favour of the symmetrical formula of tetraphenylethane; its formation from β -benzpinacolin, on the other hand, is in favour of the unsymmetrical formula; while the formation from benzpinacone affords no decisive evidence in favour of either formula, since the constitution of benzpinacone itself is still uncertain (p. 1628).

Tetraphenylethane dissolves readily in carbon sulphide and in chloroform, from the latter of which it crystallises remarkably well.

Tetranitrodiphenylethane, $\text{C}^{26}\text{H}^{18}(\text{NO}^2)^4$, is obtained by treating the hydrocarbon with nitric acid at ordinary temperatures; it dissolves in aniline, and separates therefrom in crystals. It is converted by reduction into an amido-compound. *Tetraphenylethane-sulphonic acid*, $\text{C}^{26}\text{H}^{18}(\text{SO}^3\text{H})^4$, is formed from the hydrocarbon by heating with ordinary strong sulphuric acid, and separates from alcoholic solution in crystals. Its barium salt, $\text{C}^{26}\text{H}^{18}(\text{SO}^3)^4\text{Ba}^2$, is an easily soluble crystalline mass. The phenol, $\text{C}^{26}\text{H}^{18}(\text{OH})^4$, is produced from the sulphonic acid by fusion with potash. When decolorised by animal charcoal, and crystallised from alcohol, to which water is added till the solution becomes turbid, it forms slightly coloured laminæ melting at 248° (Lauenstein a. Klotz, *Ber.* xi. 929).

TETRAPHENYLETHYLENE, $\text{C}^{26}\text{H}^{20} = \text{C}^2(\text{C}^6\text{H}^5)^4$. This hydrocarbon, which Behr obtained by the action of finely divided silver on diphenylketonic chloride, $\text{C}^6\text{H}^5.\text{CCl}^2.\text{C}^6\text{H}^5$ (vii. 1150), is also produced by reduction of benzophenone with zinc-dust (Staedel, *Ber.* vi. 178; *Liebig's Annalen*, xciv. 307), and by the action of a strong heat on diphenylmonochlorethane: $2(\text{C}^6\text{H}^5)^2\text{CHCl} = 2\text{HCl} + \text{C}^2(\text{C}^6\text{H}^5)^4$ (Engler a.

Bethge, *Liebig's Annalen*, clxxiv. 194). It melts at 221°. Its oxide, $\begin{matrix} (\text{C}^6\text{H}^5)^2\text{C} \\ | \\ (\text{C}^6\text{H}^5)^2\text{C} \end{matrix} \text{O}$, is probably identical with α -benzpinacolin (p. 1629) (Thörner a. Zincke, *Ber.* xi. 1396).

TETRAPHENYLGUANIDINE, $\text{CH}(\text{C}^6\text{H}^5)^4\text{N}^3$. See GUANIDINE (p. 908).

TETRAPHENYLMELAMINE, $\text{C}^{27}\text{H}^{22}\text{N}^6 = \text{C}^3\text{H}^2(\text{C}^6\text{H}^5)^4\text{N}^6$ (A. W. Hofmann, *Ber.* vii. 1736). This compound is obtained by heating diphenylguanidine for several hours at 170°–180°:

TETRAPHENYLMETHANE—TETRETHYL-CARBAMIDE. 1917

The hard cake resulting from the reaction is dissolved in alcohol, and the solution is either evaporated or precipitated with water. The body obtained in either way gradually solidifies, but often only after a considerable time; the solidification may, however, be accelerated by heating, solution in alcohol, and reprecipitation with water, or by solution in hydrochloric acid, and precipitation by an alkali; and by repeatedly crystallising the crude crystalline mass from alcohol, the tetraphenylmelamine is obtained in felted needles slightly soluble in ether, insoluble in water, melting at 217°. The *hydrochloride* of this base forms elongated rhombic prisms; the *platinochloride* rhombic needles; the *nitrate* slender needles. Tetraphenylmelamine is not altered by boiling with hydrochloric acid, whereas triphenylmelamine is easily decomposed thereby, taking up water and forming ammonia and phenyl cyanurate.

TETRAPHENYLMETHANE, $C(C^6H^5)^4$, is formed, with evolution of hydrogen chloride, when a mixture of benzene and carbon tetrachloride is heated with aluminium chloride, zinc chloride, or ferric chloride: $4C^6H^6 + CCl^4 = 4HCl + C(C^6H^5)^4$ (Friedel a. Craft, *J. pr. Chem.* [2], xvi. 233).

TETRAPHENYLPHOSPHOTRISULPHIDE, $P^2S^3(C^6H^5)^4$, is formed, together with isophosphophenylsulphide (p. 1575), by the action of dry hydrogen sulphide on phosphenyl dichloride (p. 1576).

TETRAPHENYL-TETRAZONE, $(C^6H^5)^2N=N=N-N(C^6H^5)^2$, is formed by oxidation of diphenylhydrazine with mercuric oxide at ordinary temperatures and in dilute solution (see HYDRAZINES, p. 1059).

TETRAPLATINOSULPHOPLATINATE, Pt^4S^6 , and **TETRAPLATINOSULPHOSTANNATE**, Pt^4SnS^6 . See SULPHIDES (pp. 1847, 1848).

TETRAPOTETRAMORPHINE, $C^{130}H^{144}N^8O^{20} = 4C^34H^{38}N^2O^6 - 4H^2O$, is formed by heating codeine with hydrochloric acid at 100° (vii. 375).

TETRAPROPYLARSONIUM IODIDE, $As(C^3H^7)^4I$. When propyl iodide is heated with arsenic at 175°–185° for twenty-four to thirty hours, a brown-red liquid is formed, which solidifies in the cold to reddish-brown crystals having the composition $AsI^3, As(C^3H^7)^4I$. This compound is decomposed by boiling concentrated potash-ley, with separation of an oil, and, after the excess of potash has been saturated with carbonic acid, absolute alcohol extracts from the product, tetrapropylarsonium iodide. The solution of this salt dissolves iodine when heated, giving rise to a *periodide*, which separates on cooling in blackish-brown crystals having a metallic lustre. On distilling the compound $AsI^3, As(C^3H^7)^4I$ with potash, *tripropylarsine*, $As(C^3H^7)^3$, passes over as a very fetid liquid, which unites directly with iodides of alcohol-radicles (Cahours, *Compt. rend.* lxxvi. 1383).

TETRAPROPYLPHOSPHONIUM IODIDE, $P(C^3H^7)^4I$. See PHOSPHINES (vii. 955).

TETRATEREBENTHENE, $C^{10}H^{64}$, is formed by the action of antimony trichloride on terebenthene. It is an amorphous brittle solid resembling colophony, of faint yellow colour, almost insoluble in alcohol, soluble in ether, carbon sulphide, petroleum, and turpentine oil, and remains on evaporating the solvent in the form of a yellow varnish. It is dextrogyrate; $\alpha_D = +20^\circ$. Sp. gr. at 0° = 0.977. It softens at about 100°, and begins to decompose at an incipient red heat, yielding a terpene, $C^{10}H^{16}$, boiling at 176°, colophene, $C^{10}H^{32}$, and other high-boiling products soluble in alcohol. Pulverised tetraterebenthene absorbs oxygen from the air, especially when heated, but does not produce an acid. It absorbs dry hydrogen chloride, forming $C^{10}H^{64}, HCl$, and when hydrogen chloride or bromide is passed into its ethereal solution, the compound $C^{10}H^{64}, 2HCl$ or $C^{10}H^{64}, 2HBr$ is produced. The dihydrochloride remains on evaporating the ether, and heating the residue in a vacuum at 100°, as a brittle easily friable mass (Riban, *Compt. rend.* lxxix. 389).

TETRATHIONIC ACID, $H^2S^4O^6$. See SULPHUR, ACIDS OF (p. 1882).

TETRATHIOPHOSPHATE, **TRIPHENYLIC**, $PS(SC^6H^5)^3$. See PHOSPHORIC ETHERS (p. 1603).

TETRAOLYLMELAMINE, $C^3H^2(C^7H^7)^4N^6$, is prepared, like the corresponding phenyl-compound, by the action of heat on ditolylguanidine, and is obtained as a resin which slowly acquires a crystalline structure. Its hydrochloride crystallises in concentric groups of slender needles (Hofmann, *Ber.* vii. 1736).

TETRETHYL-CARBAMIDE, $N(C^2H^5)^2.CO.N(C^2H^5)^2$. See CARBAMIDES (p. 390).

TETRETHYL-DIAMIDOBENZOPHENONE, $\text{CO}[\text{C}^6\text{H}^4\text{N}(\text{C}^6\text{H}^5)^2]^2$. See **KETONES** (p. 1154).

TETRETHYL-TETRAZONE, $(\text{C}^6\text{H}^5)^2\text{N}=\text{N}=\text{N}(\text{C}^6\text{H}^5)^2$. See **HYDRAZINES** (p. 1062).

TETRIC ACID AND ITS HOMOLOGUES (Demarçay, *Compt. rend.* lxxxiii. 449; lxxxvi. 1085; lxxxvii. 351; lxxxviii. 126, 289; *Bull. Soc. Chim.* [2], xxvii. 483; xxxiii. 516, 575; xxxiv. 31; *Chem. Soc. J.* xxxv. 457-460; xxxvii. 625). These acids, represented by the general formula $\text{C}^n\text{H}^{2n-4}\text{O}^2$, are formed by the successive action of bromine and alcoholic potash on the ethylic ethers of aceto-acetic acid and its homologues: see **HEPTIC ACID** (p. 1020). In the free state they have the composition $3\text{C}^n\text{H}^{2n-4}\text{O}^2 + \text{H}^2\text{O}$ or $\text{C}^{3n}\text{H}^{6n-10}\text{O}^7$, and this triple molecule may exist in their salts, barium heptate, for example, having the composition $\text{C}^{3n}\text{H}^{6n}\text{BaO}^7$; but it is broken up by the more powerful reagents, such as bromine, phosphorus pentachloride, &c.

Tetric acid, $\text{C}^1\text{H}^4\text{O}^2 = 3\text{C}^1\text{H}^4\text{O}^2 + \text{H}^2\text{O}$, is a colourless body crystallising from its aqueous solution in triclinic prisms. It is sparingly soluble in cold water, readily in hot water and in alcohol, ether, and a hot mixture of chloroform and alcohol, but insoluble in chloroform alone. It melts at 189° , and, like its homologues, gives a violet-red colour with ferric chloride.

On *Heptic*, *Pentic*, and *Hexic acids*, see pp. 1020, 1499, 1501.

These acids are decomposed by strong aqueous potash at 150° , yielding formic acid and a higher acid of the fatty series; tetric acid, for example, yielding formic and propionic acids:

They are said to form remarkable salts, in which the radicle $\text{C}^1\text{H}^4\text{O}^2$, &c., acts like silica, several molecules uniting with one or more molecules of a base. With fuming nitric acid, they yield nitro-derivatives. In sulphuric acid they dissolve without decomposition even at 100° . When treated with chlorine or bromine, they form additive compounds which are not decomposed by water. Nascent hydrogen does not act upon them.

By the action of phosphorus pentachloride on tetric acid, an oily chlorinated product is obtained according to the equation $(3\text{C}^1\text{H}^4\text{O}^2 + \text{H}^2\text{O}) + 4\text{PCl}^5 = 2\text{HCl} + 4\text{PCl}^3\text{O} + 3\text{C}^1\text{H}^4\text{Cl}^2\text{O}$. The oil may be separated from the other products by treatment with water, in which it is insoluble. It has a faint aromatic odour, boils at 171° - 172° with slight decomposition, and has a density of 1.471 at 10° . It unites readily with bromine or chlorine, forming the compounds $\text{C}^1\text{H}^4\text{Cl}^2\text{Br}^2\text{O}$, m. p. 67° - 67.5° , and $\text{C}^1\text{H}^4\text{Cl}^4\text{O}$, m. p. 48° - 48.5° . These are crystalline bodies, which are not decomposed by water, alcohol, ammonia, or potash, and probably consist of chlorobromo- and tetrachloro-ketones. Fuming nitric acid dissolves the compound $\text{C}^1\text{H}^4\text{Cl}^2\text{O}$, forming a nitro-acid. Sulphuric acid dissolves it with purple colour.

The homologues of tetric acid form analogous compounds, resembling $\text{C}^1\text{H}^4\text{Cl}^2\text{O}$ in their chemical and physical properties. $\text{C}^3\text{H}^6\text{Cl}^2\text{O}$ boils at 189° - 192° , decomposing at the same time. Its homologues are not volatile without decomposition.

Hydroxytetric Acid and its Homologues, $3\text{C}^n\text{H}^{2n-4}\text{O}^3 + \text{H}^2\text{O} = \text{C}^{3n}\text{H}^{6n-10}\text{O}^{10}$. These acids, also called *tetrenic*, *pentic acid*, &c., are formed by acting on the ethylic ethers of aceto-acetic acids with 2 mols. bromine, and treating the products with alcoholic potash (pp. 1020, 1499, 1501).

Hydroxytetric acid, $3\text{C}^1\text{H}^4\text{O}^3 + \text{H}^2\text{O}$ (m. p. 203° - 204°), crystallises from boiling water in small rounded masses formed of minute needles. It is very soluble in boiling water, alcohol, and ether, but is insoluble in chloroform, as are also its homologues.

Hydroxypentic acid, $3\text{C}^2\text{H}^6\text{O}^3 + \text{H}^2\text{O}$ (m. p. 193°), behaves with boiling water like the preceding, but is less soluble in cold water, and its crystalline form is different.

Hydroxyhexic acid, $3\text{C}^3\text{H}^8\text{O}^3 + \text{H}^2\text{O}$ (m. p. 173° - 174°), derived from ethylic propyl-acetoacetate, separates from its solution in boiling water in very small nacreous plates.

Ischydroxyhexic acid (m. p. 186° - 187°), derived, in like manner, from ethylic isopropylacetoacetate, separates from alcoholic solution in fine monoclinic crystals.

All these acids easily decompose carbonates. Their salts correspond with the formula (for hydroxytetric acid) $3\text{C}^1\text{H}^2\text{MO}^3 + \text{M}^2\text{O}$, and are generally well crystallised. The copper and silver salts are but slightly soluble in water.

The acids are easily converted into ethereal salts by treatment with alcohol at 150° . Nascent hydrogen is fixed by them thus: $(3\text{C}^1\text{H}^4\text{O}^3 + 3\text{H}^2\text{O}) + 3\text{H}^2 = 3\text{C}^1\text{H}^6\text{O}^3 + 3\text{H}^2\text{O}$. The *hydro-hydroxytetric acid* thus obtained (m. p. 111°), crystallises easily in indistinct masses, and is very soluble in water, alcohol, and ether. Its homologues

are less and less soluble in cold water. These bodies on treatment with alcohol at 150° are converted into ethereal salts having a faint and agreeable odour.

Phosphorus pentachloride acts on hydroxytetric acid and its homologues, in the manner shown by the equation $(3C^4H^4O^3 + H^2O) + 7PCl^5 = 7POCl^3 + 5HCl + 3C^4H^3Cl^2O$.

The chlorinated oils from the higher homologues are attacked by water with difficulty, but hydroxytetric chloride is easily attacked by cold water. These chlorides cannot be distilled at the ordinary pressure without decomposition. They react with alcohol in two stages, the first being represented by $C^4H^3Cl^2O + 2C^2H^6O = 2HCl + C^4H^3ClO(OC^2H^5)^2$. This reaction takes place on dissolving the chloride in a large excess of cold alcohol; if ammonia be then added, the following reaction occurs: $C^4H^3ClO(OC^2H^5)^2 + NH^3 = HCl + C^4H^3(NH^2)O(OC^2H^5)^2$. This amidated ethereal salt crystallises easily in large satiny needles, slightly soluble in cold water.

The second stage of the action of alcohol on these chlorides is represented by the equation $C^4H^3ClO(OC^2H^5)^2 + HOC^2H^5 = C^4H^3O(OC^2H^5)^3 + HCl$; and if the alcohol contains water, the following reaction also occurs: $C^4H^3OCl(OC^2H^5)^2 + H^2O = C^4H^3O(HO)(OC^2H^5)^2 + HCl$. This last ethereal salt is also produced in a state of purity by prolonged boiling of the amidated ethereal salt with water.

These ethers, when treated with aqueous ammonia, ultimately yield an amide, which is also obtained as the final product of the action of aqueous ammonia on the chloride of the corresponding acid, e.g.:

The body $C^{12}H^9(NH^2)^3O^3$ thus produced is the true amide of hydroxytetric acid.

TEUCRIN, $C^{21}H^{24}O^{11}$. A glucoside obtained from *Teucrium fruticans*, a Sicilian plant used as a remedy for intermittent fever. Nitric acid converts it into a crystallised acid having the composition $C^8H^8O^3$ (Ogialoro, *Gazz. chim. ital.* viii. 440).

THALLENE. A solid hydrocarbon, isomeric with anthracene, obtained from the last products which pass over in the distillation of American petroleum. It is distinguished by a splendid green fluorescence, and when illuminated by violet and ultra-violet light, exhibits a fluorescence-spectrum containing light green bands (H. Morton, *Chem. News*, xxvi. 199, 272; xxxiv. 18; *Phil. Mag.* [4], xli. 89; *Chem. Soc. J.* xxvi. 285; xxvii. 14; xxxii. 422; *Jahresb. f. Chem.* 1872, 150; 1873, 158).

THALLIUM. Atomic Weight 203.642 (Crookes).

Occurrence.—Thallium is found in the form of an alum on the island of Vulcano (see MINERALS, p. 1331).

Preparation.—A method of separating thallium from the flue-dust of pyrites-burners, depending on the formation of thallium-alum, is described by F. Stolba (*Ber. d. Königl. böhm. Gesellsch. d. Wissenschaften*, Nov. 7, 1873). The flue-dust is first separated from extraneous matters by passing it through a coarse sieve, and then boiling it with water acidified with sulphuric acid. The pasty mixture is thrown on a large filter, and after the dropping has ceased, hot water is added with vigorous stirring. The wash-water serves, after acidification, for lixiviating a fresh portion. The first tolerably concentrated filtrate is evaporated to the crystallising point in very shallow basins, when, on cooling, large beautiful reddish crystals of thallium-aluminium-iron alum are formed. The mother-liquors, after addition of aluminium sulphate, and one more evaporation, yield a small quantity of mixed alums. The last mother-liquors, with the washings of the crystals precipitated by crude hydrochloric acid, deposit a very small quantity of thallium chloride. The crude thallium-alum crystals are twice crystallised from an aqueous solution acidified with sulphuric acid, whereby a pure alum is obtained, yielding pure metallic thallium when treated with zinc and dilute sulphuric acid, and pure thallium chloride on treatment with hydrochloric acid. Crude thallium chloride may also be first prepared, converted by sulphuric acid into sulphate, and then by means of aluminium sulphate into thallium alum, which is purified by recrystallisation. The first-named method is, however, the more convenient, the decomposition of the chloride by sulphuric acid being troublesome. The thallium alum is much more readily soluble in hot than in cold water: hence the advantage gained by the conversion of the much less soluble thallious sulphate into the corresponding alum.

Another method of preparation is described by R. Nietzki (*Dingl. pol. J.* ccxix. 262). The thallious chloride obtained from the flue-dust by precipitation with hydrochloric acid is mixed with acidulated water, and a few strips of zinc are immersed in the liquid, whereby, in the course of a few days, the entire quantity of thallious chloride is converted into a muddy deposit of metallic thallium, which is then washed and dissolved in dilute sulphuric acid. From this solution, pure thallious sulphate may be obtained by crystallisation, and this salt, when decomposed by the electric current, yields pure thallium.

Heat of Solution of Thallium-compounds.—The following determinations have been made by Thomsen (*J. pr. Chem.* [2], xix. 13):

	Grm. deg.		Grm. deg.
(TlCl, Aq) =	- 10100	Tl ₂ O, Aq =	- 3080

(TlI, Aq) =	- 17850		

Reactions.—1. Thallious chloride is very easily converted into *sulphate* by adding it to fused sodium-hydrogen sulphate, or to a solution of sodium sulphate of 3°–5° B. From the resulting solution, after slight acidulation, the thallium may be precipitated in the metallic state by zinc (Krause, *Dingl. pol. J.* ccxvii. 323).

2. When thallic oxide, Tl₂O₃, is mixed with about an eighth of its weight of *stannic sulphide* prepared in the dry way (massic gold), a mixture is obtained which, when rubbed with moderate force, or touched by an electric spark, takes fire and burns quickly without detonation (Böttger, *N. Rep. Pharm.* xxiv. 243).

3. According to Schöne (*Bull. Soc. Chim.* [2], xxix. 538), *hydrogen dioxide*, either liquid or gaseous, converts thallious oxide into a brown oxide insoluble in water. Consequently the brown coloration of an ozonoscope impregnated with thallium cannot be regarded as a proof of the presence of ozone, since former experiments of Schöne have shown that hydrogen dioxide is always present in the air.

Blowpipe Reaction.—Thallium salts, fused with borax and phosphorus salt, form colourless glasses, which become grey and opaque when heated for a short time in the reducing flame (E. J. Chapman, *Phil. Mag.* [5], ii. 397).

Estimation.—According to Phipson (*Compt. rend.* lxxviii. 563), thallium cannot be exactly estimated in the form of a thallic compound, but must first be reduced to the thallious form. For this purpose the solution of a thalliferous mineral in aqua regia is treated, after sufficient dilution, with hydrogen sulphide; the filtrate is heated to boiling, as far as possible out of contact with the air, to expel the excess of the reagent; then mixed with a slight excess of sodium carbonate, and quickly filtered; and the filtrate is treated with ammonium sulphide, which precipitates the thallium completely as thallious sulphide.

Nietzki (*Zeitschr. anal. Chem.* 1877, 422) estimates thallium by means of the insolubility of thallious iodide in a concentrated solution of potassium iodide. From dilute solutions the thallium is first precipitated by potassium iodide; the precipitate is collected on a filter, and treated with sulphuric acid till the whole of the iodine is expelled; and the concentrated solution thus obtained is titrated.

On the separation of Thallium from Vanadium, see VANADIUM.

Thallious Chloride, TlCl. Carnelley a. Williams, by the method already described (p. 941), found that this compound boils between 719° and 731°. At a lower temperature it melts to a pale yellow liquid, changing to cherry-red, and finally again to yellow.

The vapour-density was found by Roscoe (*Proc. Roy. Soc.* xxvii. 426) to be between 7.4 and 8.75, the calculated value for TlCl being 8.49.

Iodides. *Thallious Iodide*, TlI, boils, with slight decomposition, at 806°–814° (Carnelley a. Williams).

The following observations on the iodides of thallium have been made by Th. Knösel (*Ber.* vii. 576. 893). When yellow thallious iodide (v. 751), precipitated from a hot solution, is suspended in the liquid and exposed to direct sunshine, it turns green without change of composition, the yellow colour being, however, restored by various reagents, e.g. iodine-water or potassium iodide. The dry green substance, when heated, first turns yellow, then at a higher temperature orange-red, and by fusion and sublimation red transparent granules are obtained, which after some time become yellow. By contact with iodine, the green compound is converted into a black iodide containing, according to Knösel's analysis, 54.455 per cent. thallium, whence he deduces the formula Tl₂I₃. This, however, requires 51.71 per cent. thallium, and the experimental number agrees much better with Jörgensen's *thallosothallic iodide*, Tl₂I₄ (v. 1151), which requires 54.6 per cent.

Thallium Cyanides. See CYANIDES (p. 611); on Thallious Platinocyanide, p. 616.

Thallium-ethyl Sulphide, or **Thallium Mercaptide**, Tl₂S.C₂H₅, is formed on agitating a solution of thallium carbonate with mercaptan, as a yellow curdy precipitate which dissolves in water with alkaline reaction, oxidises on exposure to the air, slowly at ordinary temperatures, more quickly when heated, and is decomposed by acids, with evolution of mercaptan (Claesson, *J. pr. Chem.* [2], xv. 193).

Thallium-diethyl Compounds (F. C. Hartwig, *Ber.* vii. 298; *Liebig's An-*

nalen, clxxvi. 257). The *chloride*, $\text{Ti}(\text{C}^2\text{H}^3)^2\text{Cl}$, is produced when an ethereal solution of thallium trichloride, prepared by the action of chlorine on thallous chloride suspended in pure and dry ether, and freed by carbon dioxide from chlorine, hydrogen chloride, and the products of the action of chlorine on ether—is slowly added to zinc-ethyl mixed with twice its volume of ether; and by washing the product with water and crystallising it from boiling water, the pure chloride is obtained in beautiful shining scales. It is somewhat altered by exposure to light, and decomposes with slight detonation when heated to 190° , yielding thallous chloride and a combustible gas. The estimation of the thallium in this compound is best effected by mixing it in a beaker with nitric acid, neutralising with sodium carbonate, precipitating the concentrated solution with potassium iodide, washing the precipitated thallium iodide, and drying it at 100° .

The following salts were obtained by double decomposition between the chloride of thallium-diethyl in aqueous solution and the corresponding silver salts, except the iodide, which was prepared by mixing solutions of thallium-diethyl sulphate and barium iodide, the thallium-diethyl iodide being then extracted from the precipitate with boiling water.

The *sulphate*, $[\text{Ti}(\text{C}^2\text{H}^3)^2]^2\text{SO}_4$, forms needles grouped in stars, is very soluble, and explodes at 205° . The *phosphate*, $[\text{Ti}(\text{C}^2\text{H}^3)^2]^2\text{PO}_4$, forms needles which explode at 189° , and are easily soluble in water or alcohol, but less soluble in hot than in cold water. The *nitrate*, $\text{Ti}(\text{C}^2\text{H}^3)^2\text{NO}_3$, dissolves with difficulty, and explodes at 236° . The *acetate*, $\text{Ti}(\text{C}^2\text{H}^3)^2\text{C}^2\text{H}^3\text{O}_2$, is easily soluble in water or alcohol, and crystallises in hard, slender needles, melting at 212° , and distilling almost without decomposition at 245° ; when it explodes if rapidly heated. The *iodide*, $\text{Ti}(\text{C}^2\text{H}^3)^2\text{I}$, forms white, silky leaflets, which explode at 195° , and dissolve in 1,000 pts. of cold water.

The *hydrate of thallium-diethyl* was obtained in silky needles, by precipitating a solution of the sulphate with barium hydrate, and evaporating the filtrate. It explodes if rapidly heated to 211° , and dissolves more readily in cold than in hot water. The solution is alkaline, and on neutralisation with acids yields the salts already described; it does not, however, unite with carbonic acid.

Thallium-triethyl does not appear to be produced by the action of thallium trichloride on zinc-ethyl, even when an excess of the latter is employed, and the action of zinc-ethyl on thallium-diethyl chloride yields not thallium-triethyl, but metallic thallium, zinc chloride, and a gas, which is probably a mixture of ethylene and ethane. The iodide of thallium-diethyl reacts in a similar manner.

Thallium-salicylanilide, $\text{C}^6\text{H}^4(\text{OTl})\text{CO.NH.C}^6\text{H}^5$, formed by heating thallous hydrate with salicylanide, crystallises in faintly-yellowish shining laminae, sparingly soluble in water, more freely in alcohol, nearly insoluble in ether (Kupferberg, *J. pr. Chem.* [2], xvi. 424).

THAPSIA. The root-bark of *Thapsia garganica* and *Th. Silivium* has been analysed by Yvon (*Pharm. J. Trans.* [3], viii. 162), who found in the dry bark:

	Th. gargan.	Th. Silivium
Starch	22·510	26·124
Gum	5·179	5·421
Gum-resin	5·759	4·271
Resin	2·554	3·192
Albumin	1·354	0·624
Chalk	1·365	1·368
Magnesia	0·677	0·697
Iron	0·370	0·224
Alumina	0·338	0·508
Sulphuric acid	0·297	0·300
Phosphoric acid	1·468	1·919
Chlorine	0·219	0·420
Silica	2·715	0·707
	44·805	45·775

THAUMASITE. A mineral from the Areskustan mountain in Sweden, having, according to an analysis by G. Lindström, the composition $\text{CaSiO}_3, \text{CaSO}_3, \text{CaSO}_3, 14\text{H}^2\text{O}$ (A. E. Nordenskiöld, *Compt. rend.* lxxxvii. 313).

THEBAINE. This alkaloïd, treated with excess of *acetic anhydride*, yields an amorphous base, probably a polymerised body, which dissolves in ether, and forms an amorphous hydrochloride and platinochloride (Beckett a. Wright, *Chem. Soc. J.* xxix. 652)

Thebaine, treated with *sulphuric* and *iodic acids*, assumes a violet colour, which

however disappears on addition of sodium carbonate (Selmi, *Monit. Scientif.* 1878, 692).

On the Detection and Estimation of Thebaine in mixtures of Alkaloids, see PLANT-BASES (p. 1635).

THEOBROMIC ACID, $C^{64}H^{128}O^2$. This acid, the highest known member of the fatty series, has been obtained by Kingzett (*Chem. Soc. J.* xxxiii. 38) from cacao-butter by saponification and fractional crystallisation of the product. It melts at 72.2° , distils without decomposition at a higher temperature, and becomes electric by friction, a property likewise exhibited by its silver salt. Together with this acid there is obtained another fatty acid, having the composition of lauric acid, $C^{12}H^{24}O^2$; but it melts at 57.5° , whereas lauric acid melts at 43° : hence it is probably a mixture of an acid lower in the series than lauric acid with another of higher melting point than the latter.

THEOBROMINE, $C^7H^8N^4O^2$. For the separation of theobromine from cacao, G. Wolfram (*Dingl. pol. J.* ccxxx. 240; *Chem. Soc. J.* xxxvi. 406) recommends the use of sodium phosphotungstate. The aqueous infusion of the cacao is precipitated with a lead salt; the precipitate, after removal of the lead by hydrogen sulphide, is mixed with sodium phosphotungstate, and this last precipitate is mixed with baryta. According to Trojanowsky (*Dingl. pol. J.* ccxxiii. 650), the proportion of theobromine in cacao varies from 1.2 to 4.6 per cent.

On the Detection and Estimation of Theobromine in mixtures of Alkaloids, see PLANT-BASES (p. 1635).

THERMODYNAMICS. When heat is given to or taken from a body, there is caused in general a change of the temperature and volume of the body, and of the stress produced by it on the bodies with which it is in contact: in what follows, unless in special cases, this stress will be taken to be due to a uniform pressure over the whole of the bounding surface. The relation between the simultaneous changes in the three conditions mentioned can be expressed by help of three coefficients—namely, (i) The coefficient of expansion under constant pressure; (ii) The coefficient of increase of pressure at constant volume; (iii) The coefficient of volume-elasticity at constant temperature. These coefficients are defined as follows:

(i). Let v be the volume of unit-mass of substance at temperature t , and dv the increment of volume which takes place when the temperature is raised from t to $t + dt$, the pressure remaining constant; then the coefficient of expansion under constant pressure is:

$$\alpha = \frac{1}{v} \cdot \frac{dv}{dt} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

(ii). Similarly, let p be the pressure per unit of surface of the body at temperature t , and $p + dp$ the pressure per unit of surface when the temperature is $t + dt$, the volume remaining constant, then the coefficient of increase of pressure at constant volume is:

$$\beta = \frac{1}{p} \cdot \frac{dp}{dt} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

(iii). If the volume diminishes from v to $v - dv$ when the pressure per unit of surface increases from p to $p + dp$, the temperature remaining constant, the coefficient of volume-elasticity at constant temperature is:

$$\epsilon = -v \frac{dp}{dv} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

According to (1) the change of temperature accompanying an infinitesimal change of volume dv at constant pressure is $\frac{1}{\alpha} \frac{dv}{v}$; according to (2) the change of temperature accompanying an infinitesimal change of pressure dp at constant volume is $\frac{1}{\beta} \frac{dp}{p}$. Consequently, if both volume and pressure undergo infinitesimal changes without any alteration of temperature taking place at the same time, the alteration of temperature which would have resulted had volume only been changed must be equal and opposite to that which would have resulted from change of pressure only; that is, if the change is 'isothermal,'

$$\frac{dv}{\alpha v} + \frac{dp}{\beta p} = 0;$$

whence, by (3),

$$\beta = -\frac{\alpha v}{p} \cdot \frac{dp}{dv} = \frac{\alpha \epsilon}{p} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

The relation expressed by equation (4) is of importance, since the coefficient β is not accessible to direct experiment, except in the case of gases, whereas α and ϵ can both be found experimentally for solids, liquids, or gases.

In order to express the connection between the quantity of heat lost or gained by a body during given changes of its temperature, volume, and pressure, certain additional coefficients are required, which, to distinguish them from the three above defined, may be called calorimetrical coefficients. A change of temperature is in general determined when the simultaneous changes of volume and pressure are given; similarly, a change of volume is determined by the simultaneous changes of temperature and pressure, or a change of pressure by the simultaneous changes of temperature and volume. Hence a given alteration in the state of a body may be specified in terms of changes in any two of the three conditions in question. Thus, if an infinitely small quantity of heat dQ is imparted to unit-mass of a body occupying the volume v at temperature t and under pressure p , we may, by the use of appropriate coefficients, express the result either as a change of temperature and volume, as a change of temperature and pressure, or as a change of volume and pressure, as follows:

$$dQ = c dt + l dv \quad . \quad . \quad . \quad . \quad . \quad (5a)$$

$$= C dt + h dp \quad . \quad . \quad . \quad . \quad . \quad (5b)$$

$$= \kappa dp + \lambda dv \quad . \quad . \quad . \quad . \quad . \quad (5c)$$

Of the six coefficients here introduced, two, namely, c and C , are well known, the former under the name of the *specific heat at constant volume*, and the latter as the *specific heat under constant pressure*; l is sometimes called the *latent heat of expansion at constant temperature*. In like manner λ might be called the *heat of expansion under constant pressure*, h the *latent heat of increase of pressure at constant temperature*, and κ the *heat of increase of pressure at constant volume*. It is to be noted that all these coefficients are mathematically of the nature of partial differential coefficients. They are not really independent magnitudes, but, as will be shown further on, the six calorimetric coefficients defined by equations (5), together with the three previously defined, may be reduced to *three*, and can thus be expressed in terms of α , ϵ , and \bar{C} , the only ones which have hitherto been determined by direct experiment.

The science of Thermodynamics has reference, in the first place, to the mutual relations and reciprocal transformations of mechanical energy and heat, or thermal energy. But, since energy of every kind can be expressed in terms of mechanical energy, the conclusions of thermodynamics in the widest sense are applicable to electricity and other branches of physics which have not yet received a purely dynamical interpretation. Many results of the greatest scientific importance have indeed been arrived at by this extended application of thermodynamical principles, but in this article it is not proposed to discuss the relations between heat and any other form of energy than the mechanical. This restriction is to be borne in mind in considering some of the general statements that follow, which, if taken in the widest sense, would not be true without qualification.

In numerical statements as to quantities of work and energy, we shall adopt the system of absolute units based on the employment of the *Centimeter*, *Gram*, and *Second* as units of length, mass, and time respectively—the system known as the C.G.S. system. In accordance with this, the unit of *force* is the force which, by acting for a second upon one gram, can change its velocity by one centimeter per second. This force is called a *dyn*. The force with which a gram at the sea-level is urged towards the centre of the earth by the resultant effect of the earth's attraction and the centrifugal force due to the earth's diurnal rotation—in other words, the *weight* of a gram,—varies from 978.1 dynes at the equator to 983.1 dynes at the poles. One million dynes, called a *megadyne*, is roughly 2 per cent. more than the weight of a kilogram. The unit of *work*, founded upon the same fundamental units, is the work done when a force of one dyne acts through a distance of one centimeter. This amount of work is called an *erg*. One million ergs—otherwise a *megalerg* or *megerg*—is about 2 per cent. more than 1 kilogram-centimeter; 1 kilogram-meter is about 2 per cent. less than 1000 megalergs. The *energy* of any body or system of bodies is estimated numerically by the amount of work done *by* the body or system of bodies when the energy is expended, or that must have been done *upon* the body (or bodies) to impart to it the energy actually possessed by it. The *erg* is thus the unit for energy as well as for work. Accordingly, the systematic unit for the numerical expression of quantities of heat is the quantity capable of generating an erg, or which is produced by the expenditure of an erg; but, as the statement of quantities of heat in terms of this unit implies a knowledge of the so-called Mechanical Equivalent of Heat, we shall usually express quantities of heat by reference to the amount of heat needed to raise the temperature of 1 gram of water by 1 degree centigrade, and shall call this quantity 1 *gram-degree* of heat. Since, however, the specific heat of water is not constant, a

gram-degree is not a perfectly definite quantity of heat except at an assigned temperature. When the term is used without qualification, it may be taken to mean the quantity of heat needed to raise the temperature of a gram of water from 0°C . to 1°C .

The science of Thermodynamics is based upon two experimentally ascertained principles. The first of these may be stated in the following form:—

I. When mechanical work is done or mechanical energy is expended without producing mechanical energy numerically equal to itself, there is generated a quantity of heat which is proportional to the difference between the quantity of work done, or of energy expended, and the mechanical energy produced; and, conversely, when mechanical energy is produced or mechanical work is done without the expenditure of an equivalent amount of mechanical energy, a quantity of heat disappears which is proportional to the difference between the energy produced, or work done, and the energy expended. Moreover, in both cases the ratio of proportionality is the same; that is to say, the number expressing the ratio between the excess of mechanical energy expended over mechanical energy produced and the quantity of heat generated, in the one case, is the same as that which expresses the ratio of the excess of energy produced over the energy expended to the quantity of heat which disappears in the other case.

An example or two may make the exact meaning of the above statement more evident. Thus, if a body of mass m descends through a height h , the earth exerts upon it a vertical force, $=mg$, during the descent (if g stands for the intensity of gravity), and consequently a quantity of work, $=mgh$, is done upon the body. If the descent takes place by the body falling freely in a vacuum, it receives an increment of kinetic energy, $=\frac{1}{2}mv^2$ (where v^2 is the change in the square of its velocity), such that

$$\frac{1}{2}mv^2 = mgh.$$

In such a case, then, mechanical energy is produced, which is numerically equal to the work done in producing it, and accordingly there is no loss or gain of heat. If, however, the descent of the body, instead of being free, were impeded by friction—as, for example, when a stone slides down a rough plank—the body would not receive so great an increment of velocity as before, and hence its gain of energy would not be equal to the work done. Accordingly a quantity of heat, Q , would be generated, such that

$$JQ = mgh - \frac{1}{2}mv^2,$$

where v^2 is again the change in the square of the body's velocity, and J a numerical factor. Again, if a body is thrown upwards in a vacuum with velocity v , it rises to a height $h = \frac{v^2}{2g}$, and thus gains a quantity of potential energy, mgh , which is numerically equal to the kinetic energy, $\frac{1}{2}mv^2$, which it loses, and in this case no heat appears or disappears. But if a body is started with initial velocity v , along a rough level surface, it will, if no work is done upon it, lose kinetic energy without gaining potential energy; or, if work is done on the body so as to keep its velocity constant, there will be expenditure of work without gain of either kinetic or potential energy: in either case a quantity of heat is produced proportional to the loss of energy, or to the expenditure of work, respectively.

On the other hand, a steam-engine can do work, or produce mechanical energy, without any corresponding expenditure of mechanical energy, but while it is doing work a quantity of heat disappears which is in exact proportion to the work done or energy produced.

The facts that the destruction of a given quantity of mechanical energy involves the production of a definite quantity of heat, and that this same quantity of heat disappears when the same given quantity of mechanical energy is generated, is commonly expressed by saying that heat and mechanical energy are mutually convertible. When mechanical energy is destroyed, the number which expresses the ratio of the quantity destroyed to the quantity of heat that appears in its place, or, when mechanical energy is generated, the number expressing the ratio of the quantity generated to the quantity of heat that disappears, is called the **MECHANICAL EQUIVALENT OF HEAT**. This number naturally has different values according to the different units adopted for expressing quantities of mechanical energy or of heat, but the ratio represented by it is essentially constant.

II. The second fundamental principle of Thermodynamics has reference to the conditions which determine how much of a given quantity of heat can be converted into mechanical energy. In various ways it is possible for a body or system of bodies to go through a series of changes of pressure, volume, and temperature, being at the

end of the series in exactly the same condition in all these respects as it was in at the beginning, but so that, during the process, more work is done by the body or system against external forces than is done by external forces upon it. Work is done *by* the body or system when it undergoes a change of size or shape in opposition to external forces; and work is done *upon* the body or system when its size or shape is altered by yielding to external forces. But, since at the end of the process the volume and shape of the body are the same as at the beginning, it follows that the total distance through which the body has yielded to external forces is equal to the total distance through which it has overcome them. Consequently, for the work done by the body to exceed that done upon it, it follows further that the external forces overcome by the body must exceed those to which it yields. This is the same thing as the following shorter but more technical statement: *The stress during decrease of strain must be greater than the stress during increase of strain.* This implies that increase and decrease of strain take place at different temperatures, for the only known way of causing the stress of a body to change while the strain remains constant is to change its temperature; and, in order that this may be, heat must be supplied to the body during part of the series of processes gone through by it, and heat must be withdrawn during another part. If, as generally happens, increase of temperature causes increase of stress with constant strain—for example, increase of pressure with constant volume—heat must be supplied while strain diminishes—that is, while the body does work by changing size or shape in opposition to external forces; and heat must be withdrawn while strain increases—that is, while external forces do work upon the body by altering its size or shape. But if, as happens with water below 4°C , or with a mixture of ice and water, increase of temperature under constant strain causes decrease of stress, heat must be supplied during increase of strain and withdrawn during decrease of strain. In either case heat must be supplied while the temperature of the body is relatively high, and must be withdrawn while the temperature is relatively low. Moreover, the quantity of heat supplied must be greater than the quantity withdrawn, for, since during the whole series of processes the work done by the body exceeds the work done upon it, and since the final condition of the body is the same in all respects as its initial condition, a quantity of heat proportional to the excess of the former quantity of work over the latter must, in accordance with the First Principle of Thermodynamics, disappear. Now, the Second Fundamental Principle of Thermodynamics asserts that the greatest possible proportion which the quantity of heat so disappearing and converted into work can bear to the total quantity of heat supplied, depends only on the temperatures at which the supply and withdrawal of heat respectively take place, and is quite independent of the nature of the substance or substances which undergo the series of changes supposed.

This result is often referred to as 'Carnot's Principle,' it having been pointed out for the first time by Sadi Carnot (*Réflexions sur la puissance motrice de feu*, 1824), in a form which is substantially the same as that in which it is given above, though the mode of expression was adapted to the hypothesis of the indestructibility of heat.

In this article we have to point out some of the most important verifications which these two fundamental principles have received, and some of the chief results which have been deduced from them.

PRINCIPLE OF THE MUTUAL CONVERTIBILITY OF HEAT AND WORK.

Mechanical Equivalent of Heat.—For general evidence that heat and work are mutually convertible one into the other according to a constant numerical ratio, we may refer the reader to the article HEAT (iii. 125-129, and vi. 685-687 of this work). It may suffice in this place to give the results of two very important redeterminations of the value of this ratio which have been recently carried out.

The first of these redeterminations was made by Joule (*Phil. Trans.* 1878, 365-383; also abstract, stating final result, *Proc. Roy. Soc.* xxvii. 38), by a method essentially similar to that employed by him in 1850 in the experiments referred to in iii. 125-129. The measurement of the work expended was however effected by counting the number of turns of the paddle-wheel and at the same time observing the moment of the couple required to prevent the calorimeter from being carried round with it. This mode of measuring work is similar to that employed by Hirn in his determination of the mechanical equivalent of heat by the friction of water already referred to in vi. 685. Joule states his results in terms of the pound-degree, measured by the mercurial Fahrenheit thermometer, as unit of heat, and the foot-pound at 120 feet above sea-level, in latitude $53^{\circ} 28\frac{1}{2}'\text{N}$. (at Higher Broughton, Manchester), as unit of work. In five series of experiments he obtained the numbers given in the following table:

Mean temperature of calorimeter (Fahr.)	58°·5	54°·8	60°·0	58°·1	63°·1
Mean rise of " " "	3°·54	3°·77	3°·46	1°·11	5°·22
Mechanical equivalent	772·7	774·6	773·1	767·0	774·0

Taking these numbers as they stand, the mean result is 772·28 foot-pounds at Higher Broughton as the mechanical equivalent of 1 pound-degree at 58°·9 Fahrenheit. But, from circumstances connected with the separate series of experiments, Dr. Joule does not consider them as being all equally trustworthy. Giving to the separate results the relative weights which he assigns to them, the final result may be stated as follows: To raise the temperature of 1 pound of water weighed *in vacuo* from 61·19° to 62·19° of the mercurial Fahrenheit thermometer requires the expenditure of

772·53 foot-pounds

of work at Higher Broughton.

For the sea-level at the latitude of Greenwich, Dr. Joule himself gives as the final result of his experiments

772·55 foot-pounds,

this being the quantity of work required to raise the temperature of a pound of water, weighed *in vacuo*, from 60° to 61° F.

Since the publication of this result, Joule has compared the mercurial-thermometer used in his measurements with one the value of whose readings had been ascertained, in terms of the perfect air-thermometer, by Professor H. A. Rowland, of Baltimore. Applying the corrections calculated by Rowland for the difference between Joule's thermometer and the perfect air-thermometer, we must add 2·94 foot-pounds to the mean as given above, thus getting

775·47

as the corrected value for Manchester. To translate this number from Fahrenheit to Centigrade degrees, and from foot-pounds per pound-degree to centimeter-grams per gram-degree, we must multiply by $1·8 \times 30·48$, which gives

42545·4.

Lastly, to reduce the result to ergs, we must multiply by 981·32, the intensity of gravity in latitude 53° 58½' at 120 feet above sea-level. We thus get, for the absolute mechanical equivalent of a water-gram-degree at mean temperature 16·5° C.:

$4·175 \times 10^7$ ergs.

A second very remarkable series of experiments on the value of the mechanical equivalent of heat has been made by Professor Rowland (*Proceed. Amer. Acad. Arts and Sciences*, xv. [N. S. vii.], 75-200). His method was identical in principle with that employed by Joule, but by modifications in detail he was able to generate heat at a much more rapid rate, thus rendering the corrections for radiation and conduction less important, and to obtain much greater changes in the temperature of his calorimeter—in some experiments as much as 25° or 30° centigrade. His results are all reduced by him to degrees of the perfect air-thermometer, and they lead to the important conclusion that the specific heat of water decreases from temperatures near 0° C. to about 30° and then increases again. The following table gives his results for every fifth degree from 5° to 40°:

Temperature of water	Mechanical equivalent of 1 gram-degree in 10^7 ergs	Temperature of water	Mechanical equivalent of 1 gram-degree in 10^7 ergs
5° C.	4·212	25° C.	4·173
10	4·200	30	4·171
15	4·189	35	4·173
20	4·179	40	4·175

Application to Gases.—It is known experimentally in the case of the more difficultly condensable gases, that (1) at a constant temperature the product of pressure into volume is nearly constant; (2) for a given change of temperature, the ratio in which volume changes when pressure is kept constant is nearly the same as the ratio in which pressure changes when volume is constant, and that this ratio is nearly the same for all gases; (3) the specific heat under constant pressure is nearly independent of pressure or temperature; (4) no appreciable fall of temperature takes place when a gas expands into a vacuum without receiving heat—that is, no appreciable quantity

of work is done in separating the particles of a gas from each other. An ideal substance possessing in perfection the properties here enumerated as belonging approximately to actual gases is called a *perfect gas*. The discussion of the laws of a perfect gas as thus defined is useful as leading to results which are applicable with approximate accuracy to several known gases under ordinary conditions.

Values of the Thermal Coefficients for Perfect Gases.—The properties of a perfect gas in relation to pressure, temperature, and volume, are expressed by the equation

$$pv = R(a + t) \quad (6)$$

where v is the volume occupied by unit-mass of the gas under pressure p and at temperature t , R is a constant depending on the kind of gas, and a a constant depending on the position of the zero and the size of the degrees of the thermometric scale on which the temperature t is expressed. Since the expression $a + t$ occurs very often, it will be convenient to denote it by a single symbol T , writing (6) thus $pv = RT$. Differentiating we get

$$p dv + v dp = R dt \quad (7)$$

which, for the several cases in which dv , dp , or dt respectively = 0, gives

$$\frac{dp}{dt} = \frac{R}{v}, \quad \frac{dv}{dt} = \frac{R}{p}, \quad \frac{dp}{dv} = -\frac{p}{v}.$$

Substituting these values in equations (1), (2), and (3), whereby the coefficients α , β , and ϵ are defined, we get

$$\alpha = \frac{R}{pv} = \frac{1}{a + t}, \quad \beta = \frac{R}{pv} = \frac{1}{a + t}, \quad \epsilon = p.$$

Hence, for all perfect gases, we have

$$\alpha = \beta = \frac{1}{T}.$$

Again, if we equate the values of dQ given in (5a) and (5b), and make $dp = 0$,

$$l = (C - c) \frac{dt}{dv} = (C - c) \frac{p}{R}; \quad (8)$$

or, making $dv = 0$,

$$h = - (C - c) \frac{dt}{dp} = - (C - c) \frac{v}{R} \quad (9)$$

In like manner, (5b) and (5c) give, for $dp = 0$,

$$\lambda = C \frac{dt}{dv} = C \frac{p}{R} \quad (10)$$

and (5a) and (5c), when $dv = 0$, give

$$\kappa = c \frac{dt}{dp} = c \frac{v}{R} \quad (11)$$

The six calorimetric coefficients are thus reduced, in the case of perfect gases, to the two specific heats C and c ; the three forms of equation (5) may therefore be rewritten as follows:

$$dQ = c dt + \frac{C - c}{R} p dv \quad (12a)$$

$$= C dt - \frac{C - c}{R} v dp \quad (12b)$$

$$= \frac{c}{R} v dp + \frac{C}{R} p dv \quad (12c)$$

For the case in which there is no change of temperature, (12 a) gives

$$dQ = \frac{C - c}{R} p dv.$$

The factor $p dv$ in this last expression represents *work* done during the expansion of the gas against external pressure, and the whole quantity of heat dQ is spent in doing this amount of work, for we have supposed temperature to remain constant, and the substance being a perfect gas, no heat is used up in merely changing its volume. Accordingly, writing dW for $p dv$, we have for the ratio of dW to dQ —the ratio of a quantity of work to the heat expended in doing that work—the

mechanical equivalent of heat. Representing this, as is commonly done, by the symbol J , we get

$$J = \frac{dW}{dQ} = \frac{R}{C - c} \quad (13)$$

Equation (13) leads to several noteworthy conclusions. First, it shows that the specific heat at constant volume, c , is constant for the same gas, being independent of volume and temperature, for J , R , and C being all constants, c must be so likewise.

Secondly, the magnitude R , though constant for any one gas, varies for different gases inversely as their densities, so that the product of R for a given gas into the density ρ —or mass of unit-volume under standard pressure and temperature—of that gas, is the same for all perfect gases. Putting $C\rho = \Gamma$, and $c\rho = \gamma$, we have

$$\Gamma - \gamma = \frac{R\rho}{J},$$

where, everything on the right being constant, the left-hand member of the equation is constant also; or, the difference between the thermal capacity under constant pressure and the thermal capacity at constant volume, of so much of any perfect gas as occupies unit of volume under given conditions of pressure and temperature, is independent of the chemical nature of the gas.

Thirdly, since C and the factors which enter into the value of R are all directly measurable by experiment, a knowledge of c , the specific heat at constant volume, for any perfect gas, would enable us to determine the value of J , the mechanical equivalent of heat. We shall see immediately what principles are available for determining the value of c .

Fourthly, by substituting in (8) and (9) respectively the value of $\frac{C - c}{R}$ given by (13), namely, $\frac{1}{J}$, we get the following simple expressions for the coefficients l and h :

$$l = \frac{p}{J} \quad (8') \quad h = -\frac{v}{J} \quad (9')$$

Variation of Pressure, Volume, and Temperature without Gain or Loss of Heat; Adiabatic Changes.—Hitherto we have considered changes of pressure, volume, and temperature as resulting from the addition or removal of heat; but such changes may also take place without any loss or gain of heat. For example, under ordinary circumstances, increase of volume and rise of temperature are observed as the result of heat given to a body, and diminution of volume and fall of temperature as the result of the withdrawal of heat; but, in special cases, a rise of temperature may be exactly compensated by a diminution of volume, or a fall of temperature by an increase of volume, so that, on the whole, there is neither loss nor gain of heat. Changes which take place under such conditions are commonly called *adiabatic* changes, a term introduced by the late Professor Rankine. In general, any change of condition that takes place very rapidly may be considered as being adiabatic, since the quantity of heat that can be lost or gained in an indefinitely short time is itself indefinitely small. From the equations already established, it is easy to deduce expressions which connect the adiabatic changes of volume or of pressure respectively of a perfect gas with the simultaneous changes of temperature, or again which connect adiabatic changes of volume and pressure with each other. This is done by simply putting $dQ = 0$ in all the equations; for since dQ represents the quantity of heat lost or gained, the equation $dQ = 0$ expresses the condition that any given change is adiabatic.

Equations (12), when $\frac{p}{T}$ is written instead of R , by the characteristic equation of perfect gases (6), become

$$\begin{aligned} dQ &= c dt + (C - c) T \frac{dv}{v}, \\ &= C dt - (C - c) T \frac{dp}{p}, \\ &= \left(\frac{dp}{p} + C \frac{dv}{v} \right) T. \end{aligned}$$

If we combine with these expressions the adiabatic condition $dQ = 0$, the first one gives

$$c \frac{dt}{T} + (C - c) \frac{dv}{v} = 0$$

or, if we put k for the ratio of the two specific heats $\frac{C}{c}$,

$$\frac{dT}{T} + (k-1) \frac{dv}{v} = 0,$$

from which, by integration, we get

$$\left. \begin{aligned} \log_e T + (k-1) \log_e v &= \text{constant} \\ \text{or} \quad T v^{k-1} &= \text{constant} \end{aligned} \right\} (14)$$

Similarly, the second expression gives

$$\left. \begin{aligned} \log_e T - \frac{k-1}{k} \log_e p &= \text{constant} \\ \text{or} \quad T p^{\frac{-k-1}{k}} &= \text{constant} \end{aligned} \right\} (15)$$

and the third gives

$$\left. \begin{aligned} \log_e p + k \log_e v &= \text{constant} \\ \text{or} \quad p v^k &= \text{constant} \end{aligned} \right\} (16)$$

It is easily seen that the three equations, (14), (15), and (16), are not really independent, any one of them following as an immediate consequence from the other two. It may also be noted that any one of them, combined with the equation $p v = R t$, gives the other two.

Work done by the Expansion of a Gas.—If a gas under pressure p undergoes a small increment of volume, dv , it does a quantity of work $dW = p dv$. In general, however, pressure changes at the same time as volume, so that a second increment of volume dv takes place under a different pressure, say p' , the third similar increment under pressure p'' , and so on. Hence the whole amount of work done during a finite change from an initial volume v_0 to the final volume v is

$$W = p dv + p' dv + p'' dv + \dots = \int_{v_0}^v p dv.$$

That is to say, the work done during expansion depends not only on the change of volume and the initial pressure, but on the pressure at each stage of the process. We may consider three special cases:

1. Expansion under constant pressure. In this case we have obviously

$$W = p \int_{v_0}^v dv = p(v - v_0) \quad (17)$$

2. Expansion at constant temperature. In this case we have, by equation (6), $p = \frac{RT}{v}$, and therefore

$$W = RT \int_{v_0}^v \frac{dv}{v} = RT \log_e \frac{v}{v_0}, \text{ or } = RT \log \frac{p_0}{p} \quad (18)$$

3. Expansion without loss or gain of heat. According to (16), when a gas does not lose or gain heat, we have $p = N v^{-k}$, and therefore

$$W = N \int_{v_0}^v v^{-k} dv = \frac{N}{1-k} (v^{1-k} - v_0^{1-k}),$$

or, putting for N its value $p_0 v_0^k$,

$$W = \frac{p_0 v_0}{k-1} \left\{ 1 - \left(\frac{v_0}{v} \right)^{k-1} \right\} \quad (19a)$$

This, on transforming the last term by means of (16) and (14) respectively, gives

$$W = \frac{p_0 v_0}{k-1} \left\{ 1 - \left(\frac{p}{p_0} \right)^{\frac{k-1}{k}} \right\} \quad (19b)$$

and

$$W = \frac{p_0 v_0}{k-1} \left(1 - \frac{T}{T_0} \right) = \frac{R}{k-1} (T_0 - T) = J c (T_0 - T) \quad (19c)$$

Coefficients of Adiabatic and Isothermal Elasticity.—The definition of the coefficient

of volume-elasticity at constant temperature is given by equation (3), namely $\epsilon = -v \frac{dp}{dv}$, and we have already seen that for a perfect gas this becomes $\epsilon = p$. Elasticity of volume being the only kind of elasticity exhibited by gases, we may say generally that the elasticity of a perfect gas at constant temperature is measured by the pressure of the gas. This relation, however, no longer holds good if temperature is not constant. In general, the temperature of a gas varies while it is undergoing any change of volume, and the different ways in which it may vary are infinitely numerous. Hence the coefficient of elasticity of a gas may have an infinite number of different values, and has no definite meaning except under stated conditions. The coefficient corresponding to constant temperature, the value of which has just been given, is often called for distinction the coefficient of *isothermal* elasticity. Another special condition of much importance is that of no loss or gain of heat. The corresponding coefficient of elasticity is called the coefficient of *adiabatic* elasticity, and may be denoted by E . Its value for a perfect gas follows at once from equation (12c), which, with the condition that no heat is lost or gained, becomes

$$c \frac{v}{R} dp + C \frac{p}{R} dv = 0,$$

whence

$$E = -v \frac{dp}{dv} = \frac{C}{c} p. \quad (20)$$

Consequently the adiabatic elasticity of a perfect gas bears to the isothermal elasticity the same ratio as the specific heat under constant pressure bears to the specific heat at constant volume.

Experimental determination of the ratio k of the specific heat C under constant Pressure to the specific heat c at constant Volume.—First Method: A large volume of gas is suddenly compressed, so that its pressure rises from p_1 to p_2 . The process being very rapid, the compression may be considered as taking place without loss or gain of heat; hence, by (15), if the initial temperature be denoted by t_1 , the final temperature t_2 will be given by

$$(a + t_1)p_1^{\frac{1-k}{k}} = (a + t_2)p_2^{\frac{1-k}{k}}.$$

On now leaving the gas to itself without further change of volume, the heat due to the compression will be gradually dissipated, and, when the temperature has returned to the original value t_1 , the pressure will have attained a value, say p_3 , intermediate between p_1 and p_2 . To determine p_3 , we have to consider that p_2 and p_3 are the pressures of the same quantity of gas occupying the same volume at the temperatures t_2 and t_1 ; consequently $\frac{a + t_2}{a + t_1} = \frac{p_2}{p_3}$, and therefore

$$\frac{p_2}{p_3} = \left(\frac{p_2}{p_1} \right)^{\frac{k-1}{k}}$$

Taking logarithms of both sides, we get from this:

$$\log p_2 - \log p_3 = \frac{k-1}{k} (\log p_2 - \log p_1);$$

whence

$$k = \frac{C}{c} = \frac{\log p_2 - \log p_1}{\log p_3 - \log p_1}. \quad (21)$$

It is evident that a corresponding expression might be obtained as the result of an adiabatic rarefaction instead of an adiabatic compression.

Second Method.—The determination of the ratio $C : c$ by the method last given depends essentially on the relation between simultaneous changes of pressure and temperature during an adiabatic process. Another method may be founded on the relation between changes of pressure and changes of volume during a similar process. The measurement of velocity of sound in air affords the most accurate data for determining this relation, since the alternate compressions and rarefactions which constitute a train of sound-waves follow each other with such rapidity as to be almost strictly adiabatic. From dynamical principles it follows that the velocity with which a disturbance of

the character of a wave of sound is propagated in a medium of density ρ is $V = \sqrt{\frac{E}{\rho}}$

E standing for the adiabatic elasticity as above defined, whose value in the case of a perfect gas is by equation (20), $k p$. This gives for the ratio of the specific heats :

$$k = \frac{C}{c} = V^2 \frac{\rho}{p} . \quad (22)$$

Third Method.—Equation (13), namely $R = J(C - c)$, gives an expression for c in terms of C and the mechanical equivalent of heat : $c = C - \frac{R}{J}$. And as both these quantities can be found by direct experiment, the ratio of the two specific heats can be deduced from this expression.

Energy of a Body or System of Bodies.—The principle of the Conservation of Energy may be expressed in relation to the matters under discussion in this article by the equation :

$$J dQ = dI + dW ;$$

where $J dQ$ is the energy equivalent to the quantity of heat, dQ , received by a body or system, dI , the increment of energy within the body, and dW the energy given out (whether in the form of heat or of energy in any other form) to other bodies. The terms dI and dW may both be broken up in a manner corresponding to the various effects, internal or external, produced. For the present we will consider internal effects only, and write :

$$dI = J c dt + dM + dK + dP,$$

$c dt$ being the quantity of heat consumed in causing rise of temperature, dM the energy spent in producing molecular changes other than those showing themselves as changes of temperature, dK the increment of the kinetic energy of visible motion, and dP the increment of potential energy (due, for example, to increased height above the sea-level). With this notation we have :

$$J dQ = J c dt + dM + dK + dP + dW . \quad (23)$$

This equation allows us to draw some important conclusions with regard to the flow of fluids. At present we will apply it to the case of a gas forced, at constant pressure p_0 , through a narrow channel or porous plug, on the farther side of which there is a constant pressure p , without loss or gain of heat from external bodies, and without change of level or alteration of potential energy from any other cause. Then $dQ=0$, and $dP=0$; hence, if K_0, M_0, W_0 , and t_0 denote initial conditions, and K, M, W , and t the corresponding conditions of the gas after escaping, we have

$$K - K_0 + M - M_0 + W - W_0 + J \int_{t_0}^t c dt = 0.$$

For $K - K_0$ we may write $\frac{1}{2}(u^2 - u_0^2)$, and for $W - W_0$ we may put $p v - p_0 v_0$, where p_0 and p are the pressures on the two sides of the plug, and v_0 and v the corresponding volumes of the unit-mass. Therefore, since for gases c is constant, see (13), and $M - M_0 = 0$:

$$\frac{1}{2}(u^2 - u_0^2) = p_0 v_0 - p v + J c (t_0 - t).$$

Since $p v = R(a + t)$, and $R = J(C - c)$, this gives, if we put $u_0 = 0$:

$$\frac{1}{2}u^2 = J C (t_0 - t) . \quad (24)$$

to determine the velocity u with which a gas escapes from under pressure. To determine $t_0 - t$ in terms of the initial and final pressures, we have, by (15),

$$\frac{a + t_0}{a + t} = \left(\frac{p_0}{p} \right)^{\frac{k-1}{k}}, \text{ and therefore,}$$

$$\frac{1}{2}u^2 = J C (a + t_0) \left[1 - \left(\frac{p}{p_0} \right)^{\frac{k-1}{k}} \right] . \quad (25)$$

If the friction of the gas against the channel by which it escapes is so great as to make the final velocity $u = 0$, or if the velocity is destroyed by eddies, as happens in any case after a short time, we see by equation (24) that, for a perfect gas, the final temperature t is the same as the initial temperature t_0 . From (25) it appears that the velocity of efflux increases as the final pressure diminishes, becoming a maximum =

$$\sqrt{2 J C (a + t_0)} \quad \text{or} \quad \sqrt{\frac{2 k p_0 v_0}{k - 1}}$$

when the escape takes place into a vacuum ($p = 0$).

According to Carnot's conclusion, a proof of which will be given presently, the efficiency of such a cycle as the one just described is the same whatever the working substance; we may therefore, in order to determine the efficiency of the cycle, choose any material we please. The problem becomes simplest if we suppose the material to be a perfect gas. Then, the work done by the substance during operation 2 is, by (18),

$$W = R(a + t) \log \frac{v_3}{v_2},$$

and the heat taken in during the same operation is

$$Q = \frac{R(a + t)}{J} \log \frac{v_3}{v_2}.$$

The work done on the substance during the fourth operation is

$$W' = R(a + t') \log \frac{v_4}{v_1},$$

and the heat given out is

$$Q' = \frac{R(a + t')}{J} \log \frac{v_4}{v_1}.$$

The efficiency of the cycle is, therefore,

$$M = \frac{Q - Q'}{Q} = \frac{(a + t) \log \frac{v_3}{v_2} - (a + t') \log \frac{v_4}{v_1}}{(a + t) \log \frac{v_3}{v_2}};$$

but, since v_1 becomes v_2 as the result of an adiabatic compression during which temperature rises from t' to t , and v_3 becomes v_4 by an adiabatic expansion accompanied by fall of temperature from t to t' , we have, by (14),

$$\frac{v_1}{v_2} = \frac{v_4}{v_3}, \text{ and therefore } \frac{v_3}{v_2} = \frac{v_4}{v_1}.$$

It follows that the logarithms in the expression for M are all equal, and therefore that the expression reduces to

$$M = \frac{Q - Q'}{Q} = \frac{(a + t) - (a + t')}{a + t} = \frac{t - t'}{a + t}. \quad (27)$$

The result of (27) is, in words, that the efficiency of a cycle such as that described—known as a 'Carnot's cycle'—consisting of an adiabatic compression and an adiabatic expansion, alternating with an isothermal expansion and isothermal compression, is equal to the difference of the temperatures at which heat is taken in and given out respectively by the working substance (that is, the difference of the temperatures at which the two isothermal processes take place), divided by the temperature at which heat is taken in increased by the constant quantity a depending on the position of the zero-point of the thermometric scale employed. Before going further, it will be convenient to discuss a little more fully the physical significance of this constant.

It is implied in equation (6), $p v = R(a + t)$, which we have taken as the starting point for what has been said about the properties of perfect gases, that the thermometric scale is such that equal differences of temperature cause equal changes in the value of the product $p v$ for a constant quantity of a perfect gas. This is the same thing as saying that we agree to measure temperatures by a perfect gas thermometer, but it leaves us free to choose arbitrarily the size of the degrees and the zero-point of the scale. As to the former point, it is most convenient to define a degree of temperature as the one-hundredth part of the interval between the temperatures of melting ice and of saturated steam, both being under standard atmospheric pressure, and whenever the size of a degree comes into account in this article, this definition is to be understood. With regard to the position of the zero, it is evident that the natural zero of a perfect gas thermometer is the point at which the product $p v$ would vanish, that is, the point denoted by putting $t = -a$. From this it appears that the symbols T, T_1, T_2, \dots which we have hitherto used merely as abbreviations for $a + t, a + t_1, a + t_2, \dots$ may be interpreted as indicating the temperatures reckoned from the natural zero of the perfect gas thermometer which are respectively identical with those which, when reckoned from the arbitrary zero, are denoted by t, t_1, t_2, \dots . Consequently, expressing the temperatures at which heat is taken in and given out

Absolute Temperature.—Since, then, the efficiency of *any* reversible cycle is equal to the quotient of the difference between the temperatures at which heat is taken in and given out respectively divided by the temperature, counted from zero of the perfect gas thermometer, at which heat is taken in, the efficiencies of two cycles in which heat is received at the same temperature are to each other as the intervals of temperature occurring in the cycles. That is, if in two cycles heat is taken in at the same temperature T , and is given out in one cycle at T_1 and in the other at T_2 , we have:

$$\frac{T - T_1}{T - T_2} = \frac{M_1}{M_2}, \quad \text{or} \quad \frac{T_1 - T_2}{T - T_2} = \frac{M_2 - M_1}{M_2},$$

where M_1 and M_2 are the efficiencies of the respective cycles. If, however, W_1 and W_2 denote the amounts of work resulting from the reception of equal quantities of heat

by the working substances of the two cycles, $\frac{M_1}{M_2} = \frac{W_1}{W_2}$, and therefore

$$T_1 - T_2 = (T - T_2) \frac{W_2 - W_1}{W_2},$$

if we select arbitrarily two of the temperatures occurring in this formula, the third is defined by reference to them; moreover, since the formula contains only differences of temperature, it is equally applicable whatever the zero-point to which the temperatures are referred. Accordingly, if we take T to be the temperature of saturated steam under normal atmospheric pressure, and T_2 the temperature of melting ice under the same pressure, and agree that the numerical value of this interval shall be 100, we may write

$$T_1 - T_2 = 100 \frac{W_2 - W_1}{W_2}.$$

Lastly, if we take the temperature of melting ice as the zero-point of our scale, we have $T_2 = 0$, and therefore

$$T_1 = 100 \frac{W_2 - W_1}{W_2},$$

gives the temperature T_1 expressed by reference to what may be called the *absolute centigrade scale*. That is to say, the numerical value of the temperature T_1 is assigned relatively to the usual fixed points of the centigrade scale by means of the ratio of two quantities of work, a ratio which is expressible in terms of dynamical units (ergs), and does not involve a reference to the physical properties of any particular substance. The absolute scale of temperature thus arrived at was first proposed by Sir William Thomson. It is identical with the scale of the perfect gas thermometer, but the conception is of fundamental importance, since it affords a real method of comparing intervals of temperature by means of possible measurements with real substances, instead of a merely theoretical definition based on properties assigned to a hypothetical material.

Complex Cycles.—In the operations which constitute a Carnot's cycle, change of temperature and change of the quantity of heat in the working substance occur separately. But in ordinary circumstances both these changes take place together. It is evident, however, that a succession of very small changes of temperature, alternating with very small increments or decrements in the quantity of heat possessed by a body, may be made to resemble as closely as we please any reversible process wherein temperature and quantity of heat both change continuously and at the same time. Hence, in any case where such a process forms part of a cycle, it will not cause any finite difference in the result if we imagine it replaced by a sufficiently great number of sufficiently small alternate adiabatic and isothermal operations.

In a Carnot's cycle, taking a quantity of heat Q from a source at temperature T , and rejecting heat at T' , the amount transformed into work, namely $\frac{Q}{T}(T - T')$, is the same as the amount that would be transformed if the whole quantity of heat Q were subdivided into an infinite number of infinitely small parts, dQ , and each part were employed in a cycle worked between the same temperatures T and T' ; for the heat transformed into work by each such elementary cycle would be $\frac{dQ}{T}(T - T')$, and therefore

the amount transformed by all together would be $\int \frac{dQ}{T}(T - T') = \frac{Q}{T}(T - T')$. Again, if the interval of temperature $T - T'$ be subdivided into an infinite number of infinitely small parts, dT , the effect of the complete cycle will be the same as the combined

effect of an infinite number of cycles of infinitesimal range, the first of which takes in the quantity of heat Q at T , and gives out $Q_1 = Q \frac{T_1}{T}$ at T_1 , while the second takes in Q_1 at T_1 , and gives out $Q_2 = Q_1 \frac{T_2}{T_1}$ at T_2 ; the third takes in Q_2 at T_2 and gives out $Q_3 = Q_2 \frac{T_3}{T_2}$ at T_3 , and so on, the last one taking in Q_n at T_n and giving out $Q' = Q_n \frac{T'}{T_n}$ at T' where $T - T_1 = T_1 - T_2 = \dots = T_n - T' = dT$. The truth of this becomes apparent if we consider that the quantity of heat given out during any one elementary cycle is just equal to the quantity taken in during the elementary cycle next in order of temperature, so that the nett result of all the elementary cycles taken together is a quantity Q taken in at T , and a quantity Q' given out at T' , no heat being either taken in or given out on the whole at intermediate temperatures. It follows, therefore, that the difference between the quantities of heat Q and Q' has been converted into work, just as would be the result of the original cycle. This conclusion may also be arrived at by considering the quantities of heat transformed by the several elementary cycles, namely $\frac{Q}{T} dT, \frac{Q_1}{T_1} dT_1, \dots$ the total amount transformed being the sum of all these; but since $\frac{Q}{T} = \frac{Q_1}{T_1} = \dots = \frac{Q_n}{T_n}$, the sum becomes $\frac{Q}{T} \int dT = \frac{Q}{T} (T - T')$.

If we now suppose both kinds of subdivisions that have been considered to be carried out at the same time, we shall have, instead of the single cycle, during which the finite quantity of heat Q is received from the source, and worked between the temperatures T and T' , which have a finite difference, an infinite number of cycles each taking in an infinitesimal quantity of heat and working through an infinitesimal range of temperature; but the combined effect of the infinitely small cycles will be identical with that of the original finite cycle.

Similarly, any reversible cycle, even if including operations during which change of temperature and loss or gain of heat take place simultaneously, may be regarded as made up of an infinite number of infinitesimal Carnot's cycles, such that the temperatures at which heat is taken in and given out, and the nett quantities of heat taken in and given out at those temperatures, are the same for the combined infinitesimal cycles as for the single finite cycle.

General expression for Reversible Cycles.—It was shown above [equation (28)], that in a Carnot's cycle working between the absolute temperatures T and T' , a quantity of heat Q being taken in at the former temperature, and a quantity Q' given out at the latter, the following relation holds:

$$\frac{Q}{T} = \frac{Q'}{T'}$$

Or, reckoning heat given out as a negative quantity taken in:

$$\sum \left(\frac{Q}{T} \right) = 0.$$

We have now seen that any reversible cycle may be looked upon as built up from an infinite number of infinitesimal cycles. To each of these elementary cycles taken separately, the result just pointed out must apply, and therefore it must apply to all of them taken together. We may therefore write the following equation as applicable to every reversible cycle:

$$\int \frac{dQ}{T} = 0 \quad \dots \quad (29)$$

Condition of Maximum Efficiency of a Reversible Cycle.—The quantity of heat transformed into work in a complex cycle may be expressed by

$$Q_1 \frac{T_1 - T_1'}{T_1} + Q_2 \frac{T_2 - T_2'}{T_2} + Q_3 \frac{T_3 - T_3'}{T_3} + \dots$$

where the separate terms represent the quantities transformed by the several simple cycles, which together make up the complex cycle. If T and T' respectively represent the highest and lowest temperatures occurring during the cycle, it is evident that the sum of the above terms is less than $(Q_1 + Q_2 + \dots) \frac{T - T'}{T}$, which would express the quantity of heat transformed, if the whole quantity taken in during the cycle were taken in at the

highest temperature T , and if the whole quantity given out were given out at the lowest temperature T' .

From this it appears that, in order to get as much work as possible from a given quantity of heat supplied to a steam-engine, or other contrivance for transforming heat into work, the supply of heat should take place at as high a temperature, and the withdrawal of heat at as low a temperature, as possible.

APPLICATION OF THERMODYNAMIC PRINCIPLES.

Many important consequences may be deduced from the two fundamental principles discussed in the preceding paragraphs. The first principle tells us that, when heat is transformed into work, the work done bears a constant ratio to the quantity of heat that disappears; the second enables us to determine the proportion of a given quantity of heat which undergoes transformation under definite conditions. Combining the two, we are able, in relation to many physical processes to establish equations which exhibit on one side the work done during the processes expressed in terms of mechanical quantities, while on the other side we have equivalent expressions in terms of thermal quantities.

Relations between the Thermal Coefficients.—Of the nine coefficients introduced at the beginning of this article for the purpose of expressing the thermal relations of different bodies, only α , the coefficient of expansion, ϵ , the coefficient of elasticity, and C , the specific heat under constant pressure, have hitherto been made the subjects of direct experimental determination. It is therefore essential, if the formulæ in which these coefficients occur are to have any definite meaning, that their values should be known in terms of the three coefficients already mentioned. We proceed to show how this knowledge can be arrived at.

We recall in the first place the following relation between the coefficient of increase of pressure β , and the coefficients α and ϵ , equation (4), namely:

$$\beta = \frac{\alpha \epsilon}{p}.$$

Considering now an infinitesimal Carnot's cycle, we have as the thermal expression for the work done, $J \, dQ \frac{dT}{T}$, and as the mechanical expression for the same, $dp \, dv$; whence the equation

$$J \, dQ = \frac{T}{dT} dp \, dv.$$

But here dQ is the quantity of heat taken in during a small isothermal increase of volume dv at the temperature T : hence, by (5a), we have $dQ = l \, dv$. Also, to determine dp , the amount by which the pressure during expansion exceeds the pressure during compression, we have $dp = \frac{dp}{dT} dT$, where $\frac{dp}{dT}$ is the rate of change of pressure with temperature when volume is constant. Introducing these values into the above equation, we get:

$$J \, l \, dv = \frac{T}{dT} \cdot \frac{dp}{dT} \cdot dT \cdot dv$$

or

$$\begin{aligned} l &= \frac{T}{J} \cdot \frac{dp}{dT} \cdot \dots \dots \dots \bigg\} \\ \text{by (2)} \quad &= \frac{T}{J} p \beta = \frac{T}{J} \alpha \epsilon \dots \dots \dots \end{aligned} \quad (30)$$

Combining equations (5a) and (5b), and putting $dp = 0$, we have

$$\begin{aligned} C - c &= l \frac{dv}{dt} = l v \alpha \\ \text{by (30)} \quad &= \frac{T}{J} \frac{\alpha^2 \epsilon}{\rho} \dots \dots \dots \end{aligned} \quad (31)$$

if $\rho = \frac{1}{v}$ is put for the density (mass of unit volume) of the substance,

Putting $dt=0$, equations (5a) and (5b) give

$$\begin{aligned} h &= l \frac{dv}{dp} = -l \frac{v}{\epsilon} \\ &= -\frac{T}{J} \frac{\alpha}{\rho} \end{aligned} \quad (32)$$

In the same way (5a) and (5c) give

$$c dt + l dv = \kappa dp + \lambda dv;$$

whence, if $dv=0$,

$$\kappa = c \frac{dt}{dp} = \frac{c}{p \beta} = \frac{c}{\alpha \epsilon}$$

or, by (31),

$$\kappa = \frac{C}{\alpha \epsilon} - \frac{T}{J} \frac{\alpha}{\rho} \quad (33)$$

and (5b) and (5c), if $dp=0$, give

$$\lambda = C \frac{dt}{dv} = C \frac{1}{\alpha v} = C \frac{\rho}{\alpha} \quad (34)$$

Coefficient of Adiabatic Elasticity.—The coefficient of volume-elasticity of a substance is defined as $-v \frac{dp}{dv}$, but the ratio $dp:dv$ depends not only on the nature of the substance, but also, as already pointed out in the case of gases, upon the thermal conditions to which it is subject. If temperature remains constant, the above expression represents the coefficient of isothermal elasticity, ϵ . Its value is given by (5a) and (5b), which, if $dt=0$, yield

$$\epsilon = -v \frac{dp}{dv} = -v \frac{h}{\lambda}.$$

The coefficient of adiabatic elasticity E is given by (5c) on putting $dQ=0$, namely,

$$E = -v \frac{dp}{dv} = v \frac{\lambda}{\kappa}:$$

whence, on substituting the values of λ and κ from (34) and (33), becomes

$$E = \frac{\epsilon}{1 - \frac{T \alpha^2 \epsilon}{J C \rho}} \quad (35)$$

or, when the multiplier of ϵ in the denominator of this expression is a small quantity, as it usually is in the case of solids and liquids, we have approximately

$$E = \epsilon \left(1 + \frac{T \alpha^2}{J C \rho} \right) \quad (35')$$

Dividing (35) by ϵ , we get for the ratio of the coefficients of adiabatic and isothermal elasticity

$$\frac{E}{\epsilon} = \frac{1}{1 - \frac{T \alpha^2 \epsilon}{J C \rho}} \quad (36)$$

But it will be seen from equation (31) that this is the ratio of the specific heat under constant pressure to the specific heat at constant volume. Hence, for all bodies, the ratio of the two elasticities is equal to the ratio of the two specific heats, or

$$\frac{E}{\epsilon} = \frac{C}{c} \quad (37)$$

The various thermal coefficients, as well as the coefficient of adiabatic elasticity, have thus been expressed in terms of the three which can most easily be made the subject of direct measurement. The expressions now given are of general application, and include, as special cases, the formulæ given above (p. 1927) as applying to perfect gases. This follows at once from the relation $T\alpha=1$, α being the coefficient of expansion of a perfect gas.

Absolute Scale of Temperature.—As already explained, the temperatures denoted in the above formulæ are supposed to be measured by a perfect gas thermometer, and reckoned from the natural zero of such a scale. But, inasmuch as no known substance possesses the properties attributed to a perfect gas, a perfect gas thermometer can be

only an ideal instrument. If, however, we can ascertain how far the properties of a real gas differ from those of an ideal perfect gas, statements of temperature referred to a thermometer filled with this gas can be translated into the corresponding values referred to a thermometer constructed with a perfect gas. Experiments having this object in view have been carried out by Dr. Joule and Sir William Thomson (*Phil. Trans.* 1854, p. 321; 1862, p. 579). Their method was to force a gas in a continuous stream through a porous plug offering so much resistance to its passage that the gas escaped from the plug with only a negligible velocity, even when the difference of pressures on the two sides of the plug was considerable. If, during such an experiment, the gas does not lose or gain heat, it appears, from (24), that, in the case of a perfect gas, there would be no change of temperature—the final result being simply that the pressure of the gas is diminished and its volume increased by its passage from one side of the plug to the other. Accordingly, since no internal work is done during increase of volume of a perfect gas, no heat is used up and no change of temperature takes place. In the gases experimented upon, a slight change of temperature was always observed—namely, a fall of temperature in the case of air, nitrogen, oxygen, and carbonic acid, and a very slight rise in the case of hydrogen. The alteration of temperature for a given gas was found to be proportional to the change of pressure, and smaller at high temperatures than at low temperatures. By determining the ratio of the change of temperature to the change of pressure undergone by a gas under these circumstances, data were obtained by means of which, in conjunction with other data respecting the properties of gases derived chiefly from Regnault's observations, it is possible to give numerical statements of temperatures which do not depend upon the special properties of any particular substance. The following statement of the reasoning by which this result is arrived at is essentially abridged from Sir William Thomson's article *HEAT* in the *Encyclop. Britan.* 9th ed. xi.

Consider in the first place a series of four operations constituting a closed cycle performed on any substance as follows:—

'(1.) Alter the bulk or shape of the substance till it becomes warmer to any desired degree. (2.) Keeping it now at this higher temperature, alter bulk or shape further, and generate the heat which the substance takes to keep its temperature constant, by stirring water, or a portion of the substance itself if it is partly fluid, and measure the quantity of work spent in this stirring. (3.) Bring the substance back towards its original bulk and shape till it becomes cooled to its original temperature. (4.) Keeping it at this temperature, reduce it to its original bulk and shape, carrying off, by a large quantity of water, the heat which it must part with to prevent it becoming warmed. Find by a special experiment how much work must be done to give an equal amount of heat to an equal amount of water by stirring. Then the ratio of the first measured quantity of work to the second is the ratio of the higher temperature to the lower on the absolute thermodynamic scale.'

It will be seen that the definition of absolute temperature given in this paragraph agrees with that already given in this article, but that it is put in a more general form. If we suppose the changes of temperature taking place in operations (1) and (3) to be infinitely small, the corresponding changes of stress will also be infinitely small. If we suppose the stress upon the working substance to be a uniform pressure over the whole surface, and that its average amount during the second operation is p , its average value during the fourth operation will be $p \mp dp$, or infinitely near to its value during the second (the *plus* sign would apply in the case of substances such as water below 4° C., or a mixture of water and ice, whose temperature is *lowered* by *increase* of pressure); if, further, the change of bulk during the second operation is denoted by u , the work done during this operation will be $w = pu$, and it will exceed the work done during the fourth operation by an amount $dw = u dp$. This then is the amount by which the work done by the substance upon external bodies during the whole cycle exceeds the work done by them upon it. We may, therefore, in accordance with equation (28), write

$$\frac{dT}{T} = \frac{dw}{w} = \frac{u dp}{w},$$

or, multiplying numerator and denominator by p ,

$$\frac{dT}{T} = \frac{pu}{w} \cdot \frac{dp}{p} \quad . \quad . \quad . \quad . \quad . \quad . \quad (38)$$

The first factor on the right-hand side of this equation, called by Sir W. Thomson the 'work ratio,' expresses the ratio of the work done by the working substance upon external bodies during the second operation of the above cycle, to the total amount of work done upon it: the statement of the equation may therefore be put into words as follows:—

The ratio of the infinitesimal rise of temperature to the whole absolute temperature is equal to the work-ratio multiplied into the ratio of the infinitesimal increase of stress to the whole stress.

As a special example of the application of definition of absolute temperature in this form, consider any substance subject to uniform pressure in all directions. Let p and v be its pressure and volume, and let e be the energy which must be given to it to bring it from any conveniently defined zero condition, which we may call the condition (p_0, v_0) , to the given condition (p, v) . Let heat be communicated to the substance so as to cause its volume to increase by dv , the pressure being kept constant. The energy of the body will thus become greater by the amount $\frac{de}{dv} \cdot dv$. At the same time, the body in expanding and pressing out the matter around it does work to the extent $p \, dv$, and therefore the whole quantity of work required to generate the heat given to it must be $\left(\frac{de}{dv} + p\right)dv$.

Consequently the work-ratio is $\frac{p}{\frac{de}{dv} + p}$, and therefore by (38)

$$\frac{DT}{T} = \frac{dp}{p} \cdot \frac{p}{\frac{de}{dv} + p} = \frac{dp}{\frac{de}{dv} + p} \quad (39)$$

where DT denotes the change of temperature due to the increase of pressure dp , the substance being prevented the while from either losing or gaining heat. The last condition implies that the change of energy of the body is equal to the work done upon it by pressure from without, or

$$\frac{de}{dv} dv + \frac{de}{dp} dp = -p \, dv,$$

the negative sign on the right meaning that the change of volume dv is negative if the change of pressure dp is positive. Hence

$$dv = \frac{-\frac{de}{dp}}{\frac{de}{dv} + p} dp.$$

But

$$DT = \frac{dT}{dp} dp + \frac{dT}{dv} dv,$$

or, by the last equation,

$$DT = \left(\frac{dT}{dp} - \frac{\frac{dT}{dv} \cdot \frac{de}{dp}}{\frac{de}{dv} + p} \right) dp.$$

Eliminating $\frac{DT}{dp}$ from this by (39), we get

$$T = \left(p + \frac{de}{dv} \right) \frac{dT}{dp} - \frac{de}{dp} \cdot \frac{dT}{dv} \quad (40).$$

To connect this result with the experiments on the passage of fluids through a porous plug, we may proceed as follows:—Let $p + \delta p$ be the constant pressure on the fluid before passing the plug, and p the pressure on it beyond the plug. If, as is the case with common air, nitrogen, oxygen, carbonic acid, and no doubt many other gases, the fluid leaves the plug cooler than it enters it, let δw be the amount of work which, spent in stirring the fluid flowing from the plug, would restore unit-mass of it to the original temperature. If, on the other hand, the fluid is warmed by passing the plug, as is the case with hydrogen and all ordinary liquids, let δw denote the work that must be done in stirring water in order to warm it as much as it would be warmed if employed to cool unit-mass of the fluid on the second side of the plug to the temperature which it had on the first side. In this case δw is to be reckoned negative, as it is the mechanical equivalent of heat taken away from the fluid to restore its original temperature. Let v and $v + \delta v$, e and $e + \delta e$, respectively, represent the volume and energy of unit-mass of the fluid before and after passing the plug, the symbols in each case being understood as referring to the fluid in the tranquil parts of the stream

where it is unaffected by the rapids caused by the plug or by the eddies due to the stirring. Then the work done upon the fluid while approaching the plug, and done by it while flowing away from the plug, will be the same as if it were pressed towards the plug by a piston exerting a constant pressure $p + \delta p$ per unit of surface, and a piston exerting a constant pressure p were pushed forward by the escaping fluid. The work done by the first piston upon unit-mass of the fluid would be $(p + \delta p)(v + \delta v)$, and that done upon the second by the same quantity of fluid $p v$. The whole quantity of work done on unit-mass of the fluid therefore exceeds the work done by it by

$$(p + \delta p)(v + \delta v) - p v + \delta w = p \delta v + v \delta p + \delta w,$$

and this consequently must be the gain of energy by the fluid, or the amount by which e , the energy per unit-mass beyond the plug, exceeds $e + \delta e$, the energy per unit-mass of the fluid approaching the plug: that is,

$$-\delta e = p \delta v + v \delta p + \delta w. \quad (41)$$

Now the combined effect of the plug and the stirring is to make the temperature of the fluid the same, notwithstanding the change of pressure from $p + \delta p$ to p , and the change of volume from $v + \delta v$ to v ; in other words, the changes of temperature corresponding to the changes of pressure and of volume taken separately are such as to compensate each other, or

$$\delta T = \frac{dT}{dp} \delta p + \frac{dT}{dv} \delta v = 0;$$

that is,

$$\delta v = - \frac{dT}{dp} \div \frac{dT}{dv} \delta p,$$

and the change of energy may be written

$$\delta e = \frac{de}{dp} \delta p + \frac{de}{dv} \delta v.$$

Putting these values of δv and δe into equation (41), and at the same time dividing by δp , we get

$$\left(p + \frac{de}{dv}\right) \frac{dT}{dp} \div \frac{dT}{dv} - \frac{de}{dp} = v + \frac{\delta w}{\delta p}.$$

Combining this with (40), we have

$$T \div \frac{dT}{dv} = v + \frac{\delta w}{\delta p},$$

or, dividing by v and taking reciprocals of both members,

$$\frac{v}{T} \frac{dT}{dv} = \frac{1}{1 + \frac{1}{v} \frac{\delta w}{\delta p}} \quad (42)$$

This shows that if, for any one fluid, and for some one value of the pressure p , the heating or cooling effect due to passage through the porous plug were at all temperatures to be nothing, so that the work δw required to undo the change of temperature should vanish, then for this fluid

$$\frac{v}{T} \frac{dT}{dv} = 1$$

or, by integration,

$$T = B v \quad (43)$$

where B is an arbitrary constant. From this we infer that, with this particular fluid for thermometric substance, with the particular pressure of the experiment, and throughout the range of temperature for which the result $\delta w = 0$ has been obtained, absolute temperature is shown on a scale graduated and numbered in simple proportion to the whole volume of fluid.

Now Joule and Thomson's experiments showed that for pressures of from one to five or six atmospheres, hydrogen, air, nitrogen, oxygen, and carbonic acid, all somewhat nearly fulfil the condition of passing through a porous plug without change of temperature—hydrogen much more nearly, and carbonic acid much less nearly than any of the others. Hence we infer that absolute temperature is somewhat nearly proportional to the volume of the fluid, if any one of these gases is used in a constant-pressure thermometer. Further, since we know from the experiments of Regnault and others that the ratio in which volume changes under constant pressure, for a

given alteration of temperature, is nearly the same for these gases (at least, leaving out carbonic acid) as the ratio in which pressure changes at constant volume for the same alteration of temperature, we also infer that absolute temperatures are somewhat approximately shown by a thermometer graduated so as to show the pressure of one of these gases when kept at constant volume.

We see, then, that the assumption commonly made, that temperatures measured by an air or gas thermometer are approximately absolute temperatures, is justified.

To determine the degree of approximation that can be thus made, we must return to equation (42). The quantity of work, δw , required to undo the cooling effect can in practice be most accurately estimated by help of the specific heat of the fluid and the mechanical equivalent of heat. If C be the specific heat under constant pressure, and J the mechanical equivalent, we have

$$\delta w = J C \delta T,$$

and therefore (42) becomes

$$\frac{v}{T} \frac{dT}{dv} = \frac{1}{1 + \frac{J C}{v} \frac{\delta T}{\delta p}}. \quad (44)$$

It is to be noted here that the change of temperature δT can only be expressed in arbitrary measure, as we have not yet established a natural system of thermometry; it is, however, sufficient for our reasoning that J shall denote the dynamical equivalent of a water-gram-degree upon the same thermometer as that upon which the interval δT is measured.

The experiments showed δT to be simply proportional to δp , not only for infinitesimal differences of pressure, but for differences amounting to 5 or 6 atmospheres. In the case of hydrogen, the observed effect was an increase of temperature (δw therefore negative) amounting, on an average of the experiments at different temperatures, to 0.039 of a degree centigrade for a difference of pressure on the two sides of the plug equal to the pressure due to a column of ice-cold mercury 76 cm. in height.

Denoting this pressure by Π , we have then $\frac{\delta T}{\delta p} = -\frac{0.039}{\Pi}$, whence

$$\frac{v}{T} \frac{dT}{dv} = \frac{1}{1 - 0.039 \frac{J C}{\Pi v}}$$

Writing this

$$\frac{dT}{T} = \frac{dv}{v - 0.039 \frac{J C}{\Pi}}$$

we get by integration

$$T = B \left(v - 0.039 \frac{J C}{\Pi} \right). \quad (45)$$

Now let T_0 denote the absolute temperature corresponding to 0° C., T_{100} the absolute temperature corresponding to 100° C., and let v_0 and v_{100} be the volumes occupied by unit-mass of hydrogen at the same two temperatures when under any constant pressure (say, from 1 to 5 or 6 atmospheres) within the limits of Joule and Thomson's experiments, then (45) gives

$$T_0 = B \left(v_0 - 0.039 \frac{J C}{\Pi} \right) \text{ and } T_{100} = B \left(v_{100} - 0.039 \frac{J C}{\Pi} \right)$$

whence

$$\frac{T_{100} - T_0}{T_0} = \frac{v_{100} - v_0}{v_0 - 0.039 \frac{J C}{\Pi}}. \quad (46)$$

If we make $T_{100} - T_0 = 100$ and put H for $\frac{v_{100} - v_0}{v_0}$, the expansion of hydrogen under constant pressure, from 0° to 100° C. referred to the volume at 0° taken as unity, (46) gives

$$T_0 = \frac{100}{H} \left(1 - 0.039 \frac{J C}{\Pi v_0} \right).$$

If V_0 denote the volume of unit-mass of hydrogen under pressure Π instead of under the actual pressure p , this becomes

$$T_0 = \frac{100}{H} \left(1 - \frac{V_0}{v_0} 0.039 \frac{J C}{\Pi V_0} \right). \quad (47)$$

To obtain the numerical value of T_0 from (47), we have the following data:

H, for hydrogen under constant pressure of 1 atmosphere = .36613,

whence $\frac{100}{H} = 273.13$ (Regnault),

$C = 3.409$ (Regnault),

$J = 4.175 \times 10^7$ ergs. (Joule),

$\Pi V_0 = 1.1316 \times 10^{10}$ (Regnault).

Putting in these numbers, we get

$$T_0 = 273.13 \left(1 - 0.0004 \frac{V_0}{v_0} \right)$$

or, since the pressure under which expansion takes place is supposed to be atmospheric, and therefore $v_0 = V_0$,

$$T_0 = 273.00.$$

The experiments on air lead to almost an identical value for T_0 , and those on carbonic acid to one not very different. In each of these gases, passage through the porous plug caused a lowering of temperature, which was found to vary very nearly in the inverse proportion to the square of the temperature C , by mercury thermometer, with 273 added. Hence nearly enough for use in the small term of the denominator of (44)

$$\frac{\delta T}{\delta p} = A \left(\frac{273}{T} \right)^2 \frac{p}{\Pi} \quad (49)$$

where T denotes, as before, absolute temperature, and A the amount of the cooling effect per atmosphere difference of pressure on the two sides of the plug, at the temperature of melting ice. The values of A found for air and carbonic acid are 0.275 and 1.388 respectively. As the proper mean value to apply between 0° and 100° C., Sir W. Thomson calculates 0.756 A , which gives 0.208 for air, and 1.049 for carbonic acid, as the factors to be substituted for -0.039 in (47) to make it apply to these gases. As to the other data, we have

$$\begin{array}{llll} H = 0.36706 & \text{for air, } 0.3710 & \text{for carbonic acid} \\ C = .2375 & \text{,,} & .2006 & \text{(mean sp. ht. from } 0^\circ \text{ to } 100^\circ) \\ \Pi V_0 = 7.84 \times 10^8 & \text{,,} & 5.13 \times 10^8 & \text{,,} \end{array}$$

Using these numbers, and taking $v_0 = V_0$, we get

$$\begin{aligned} T_0 &= \frac{100}{.36706} (1 + .0026) = 272.44 \times 1.0026 \\ &= 273.14 \text{ (by air),} \end{aligned}$$

and

$$\begin{aligned} T_0 &= \frac{100}{.3710} (1 + .0171) = 269.5 \times 1.0171 \\ &= 274.15 * \text{ (by carbonic acid).} \end{aligned}$$

Of the three values thus arrived at for the absolute temperature of melting ice, Sir W. Thomson regards that derived from air as the most trustworthy on account of the greater ease, and therefore probably greater accuracy, with which the requisite numerical data can be determined in the case of air as compared with the other gases. The true temperature of melting ice may therefore be taken as 273.1 from absolute zero. The meaning of this result is that the ratio of the absolute temperature at which saturated water-vapour has a pressure equal to that of 76 cm. of ice-cold mercury to the absolute temperature of melting ice is 373.1 : 273.1.

Determination of Absolute Temperature by Observations with a Constant-Pressure Air Thermometer.—The temperature of melting ice being known, it is easy to deduce a formula to express the temperature in degrees of the absolute centigrade scale at which a quantity of air measuring v_0 c.c. at 0° C. occupies any observed volume v under the same pressure. For this purpose, we first generalise equation (45) by putting, instead of the numerical factor -0.039 applicable to hydrogen, the symbol m to stand for the mean cooling effect, corresponding to the range of temperature in question, produced in any gas when the difference of pressure on the two sides of the

* This number differs slightly from that calculated by Sir W. Thomson (*op. cit.* 573), namely 273.9. Thomson takes the mean cooling effect for carbonic acid as 1.105, which seems inconsistent with his own data, and finds 1.0163 for the final multiplier of $\frac{100}{.371}$.

plug is Π (1 atmosphere). m is to be reckoned negative when, as with hydrogen, the gas is heated by passing through the plug; its value at any temperature t reckoned from zero centigrade is nearly $m = \frac{1}{2} A \left[1 + \left(\frac{273}{273+t} \right)^2 \right]$ given by (49), the value of t being known, accurately enough for use in this formula, by a mercurial thermometer. We thus get

$$T = B \left(v + m \frac{J C}{\Pi} \right) \quad . \quad . \quad . \quad (50)$$

which gives, as in (46),

$$\frac{T - T_0}{T_0} = \frac{v - v_0}{v_0 + m \frac{J C}{\Pi}} = \frac{v - v_0}{v_0} \cdot \frac{1}{1 + m \frac{J C}{\Pi v_0}}$$

whence

$$t = T - T_0 = T_0 \frac{v - v_0}{v_0} \left(1 - m \frac{J C}{\Pi v_0} \cdot D \right) \quad . \quad . \quad (51)$$

where $D = \frac{V_0}{v_0}$ is the relative density of the gas at 0° C. referred to the density of the same gas at 0° and under atmospheric pressure, Π , taken as unity. Putting in numerical values and making Π one atmosphere, and therefore $D = 1$, we obtain from (51)

$$t = 273 \cdot 1 \frac{v - v_0}{v_0} (1 - 0 \cdot 0126 m).$$

This formula applies, with the proper value of m , to air, oxygen, hydrogen or nitrogen, the value of $\frac{C}{V}$, or the specific heat of the quantity of gas occupying unit-volume (1 c.c.) at 0° C., and under atmospheric pressure being nearly the same for all of these gases according to Regnault. For $t = 100^\circ$, the value of m is $-0 \cdot 039$ for hydrogen, $+0 \cdot 208$ for air, $+0 \cdot 253$ for oxygen, and $0 \cdot 249$ for nitrogen.

Another formula for use with a constant-pressure gas thermometer is easily derived from (51), namely,

$$t = 100 \frac{v - v_0}{v_{100} - v_0} \left[1 - \frac{J C}{\Pi V_0} D (m - m_{100}) \right]$$

$$= 100 \frac{v - v_0}{v_{100} - v_0} [1 - 0 \cdot 0126 D (m - m_{100})]$$

where v_{100} is the volume assumed by the gas at 100° C., m the mean cooling effect for the interval of temperature 0° C. to t , and m_{100} the value for the interval 0° to 100° C.

Hitherto the constant-pressure gas thermometer has not been constructed in a form convenient for practical use. Sir William Thomson, however, has designed and given a detailed description of such an instrument (*op. cit.* 575, 576), as to which he says, 'It seems probable that the constant-pressure hydrogen or nitrogen gas thermometer, which we have now described, may give even more accurate thermometry than Regnault's constant-volume air thermometers, and it seems certain that it will be much more easily used in practice.'

Constant-volume Air Thermometer.—A constant-volume air thermometer was employed by Prof. Rowland for reducing to absolute values the temperature-observations connected with his determination of the mechanical equivalent of heat (see above, p. 1926). If we put θ for the temperature directly indicated by the instrument itself without correction to the absolute scale—that is, if we make $\theta = 100 \frac{p - p_0}{p_{100} - p_0}$, where p_0 , p_{100} , and p are the pressures exerted by the constant volume of gas in the thermometer at 0° , 100° , and the temperature t to be determined respectively, the formula deduced by Rowland from Joule and Thomson's experiments may be written

$$t = T - T_0 = \theta - 0 \cdot 00088 \theta \frac{100 - \theta}{273 + \theta}.$$

By means of this formula, Rowland has calculated the following table for reducing the readings of the constant-volume air thermometer, containing air of normal density, to the equivalent temperatures on the absolute scale counted from 0° C.

Reading of air-thermometer θ	Absolute temperature above 0°C. $t = T - T_0$	Correction to air-thermometer readings $t - \theta$
0°	0°	0
10	99972	- 0.0028
20	199952	- .0048
30	299939	- .0061
40	399933	- .0067
50	499932	- .0068
60	599937	- .0063
70	699946	- .0054
80	799956	- .0044
90	899978	- .0022
100	100.000	0.0
200	200.037	+ 0.37
300	300.092	+ .092
400	400.157	+ .157
500	500.228	+ .228

Latent Heat.—The value of the coefficient that we have represented by the symbol l , or the ‘latent heat of expansion,’ is given by equation (80), as $\frac{T}{J} \cdot \frac{dp}{dT}$. Its physical meaning appears from (5a), namely $dQ = c dt + l dv$, and may be stated to be the *quantity of heat required to cause unit increase of volume* at constant temperature. The term latent heat, however, in its most usual sense means the quantity of heat that must be given to *unit-mass* of a substance to cause a change of condition at constant temperature and pressure. Let L stand for latent heat in this sense, and let u be the change of volume taking place during change of state of unit-mass. We then get immediately

$$L = ul.$$

or, by (30),

$$L = u \frac{T}{J} \frac{dp}{dT} \quad (52)$$

The value of u may evidently be written $u = s_2 - s_1$, if s_1 be put for the volume of unit-mass of the substance in its first state, and s_2 for the volume of unit-mass in the second state, that is, the state into which it is transformed by *receiving* heat.

Application to Water-vapour. The extent of agreement between this formula and the results of observation can be tested most satisfactorily in the case of water, as the data required for applying it are better known for water than for any other substance. Fairbairn & Tate's experiments (*Phil. Trans.* 1860; also iii. 97 of this work) give the value of s_s for saturated steam for a considerable range of temperature, and Regnault's experiments give the means of determining the values of $T \frac{dp}{dT}$. Tables of this latter quantity have been calculated from Regnault's results by Count P. de Saint-Robert (*Principes de Thermodynamique*, Turin, 1870), and his numbers are employed in the following comparison.

Latent Heat of Water-vapour.

Temperature	u	$T \frac{dp}{dT}$	L calculated	L Regnault
273 + 58·2	8274·3	2905·5	565·7	565·9
„ 68·5	5332·5	4455·9	557·8	558·7
„ 77·5	3714·1	6314·0	551·8	552·4
„ 86·8	2622·4	8854·1	546·3	545·8
„ 92·7	2148·5	10859·0	549·0	541·6
„ 117·2	942·1	23404·1	518·8	524·3
„ 139·2	496·2	42506·5	496·8	508·6
„ 144·7	432·1	48766·4	496·9	504·6

It will be seen that the agreement between the calculated and experimental values of

L is such as to afford a striking confirmation of the reasoning employed in deducing equation (52).

Internal Latent Heat.—In general, change of volume takes place during change of state of aggregation, and therefore work, equal in amount to the product of the change of volume into the average pressure under which it occurs, is done either by or upon the body, and the mechanical equivalent of this work is included in the value of L as given above, together with what may be called the internal or true latent heat, that is, the heat consumed in overcoming internal molecular forces. Accordingly, putting r for the internal latent heat,

$$r = L - \frac{1}{J} \int_0^u p \, du$$

Or, when the change takes place under constant pressure

$$r = L - \frac{p}{J} u.$$

From this expression we may eliminate either L or u by means of (52) and write either

$$\left. \begin{aligned} r &= \left(T \frac{dp}{dT} - p \right) \frac{u}{J} \\ \text{or} \quad r &= L \left(1 - \frac{p}{T \frac{dp}{dT}} \right) \end{aligned} \right\} \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad (53)$$

Latent heat of Dissociation.—The process of gradual decomposition with rise of temperature, or diminution of pressure, or both, to which the term ‘dissociation’ was applied by Deville (vi. 425, vii. 636, viii. 1009), is exactly analogous, from a physical point of view, to the process of evaporation, and equation (53) applies directly to these phenomena, r being the quantity of heat required to dissociate unit-mass of substance at absolute temperature T under pressure p , and u the difference between the volume at this temperature and pressure of the dissociated products and the volume of unit-mass of the original substance.

The quantity of heat r usually includes heat spent in causing change of physical state as well as that spent strictly in causing chemical decomposition. When the former quantity is known, the latter can be found by subtraction. For example, when aqueous vapour is formed from (say) dilute sulphuric acid, part of the heat required for its formation goes to cause vaporisation, and the remainder to cause dissociation of the water from the acid. Let r be the total internal latent heat required for the formation of 1 gram of water-vapour from dilute sulphuric acid at absolute temperature T , and let p be the maximum pressure of the vapour given off by the acid at this temperature, and u the volume occupied by 1 gram of vapour at temperature T and under pressure p ; also, let r_1 , p_1 , and u_1 have corresponding meanings in the case of pure water. Then we have

$$r = \left(T \frac{dp}{dT} - p \right) \frac{u}{J} \quad \text{and} \quad r_1 = \left(T \frac{dp_1}{dT} - p_1 \right) \frac{u_1}{J},$$

and therefore for the heat spent in causing purely chemical change

$$r - r_1 = \frac{1}{J} \left[\left(\frac{dp}{dT} - \frac{dp_1}{dT} \right) T - (pu - p_1u_1) \right]$$

In the particular case selected for illustration, p_1 is rather less than p , and u_1 rather greater than u ; hence, at any rate for any considerable degree of dilution, $pu - p_1u_1$ cannot differ much from zero, and we may write approximately

$$r - r_1 = \frac{T}{J} \left(\frac{dp}{dT} - \frac{dp_1}{dT} \right)$$

for the heat required to separate 1 gram of water from dilute sulphuric acid.

Specific Volume of saturated Vapour.—If the latent heat of vaporisation at a given temperature T is known by direct experiment, and also the values of $\frac{dp}{dT}$ at the same temperature, equation (52) gives

$$u = s_2 - s_1 = \frac{JL}{T} \cdot \frac{dT}{dp}$$

as the difference between the specific volume s_1 of the liquid and s_2 that of the vapour

at temperature T . The former being known by experiments on the expansion of the liquid, the latter can be at once calculated.

Limit of the Liquid State. Critical Temperature.—If s_1 be the specific volume of a liquid and s_2 that of the corresponding saturated vapour, s_1 continually increases (except in a few cases, such as that of water below 4°C.) and s_2 continually decreases as temperature rises. Hence at some sufficiently high temperature we must have $s_1 = s_2$. At this temperature we have $u = 0$, and therefore (equation 52) $L = 0$. Consequently the state of vapour is here continuous with the liquid state, inasmuch as the passage from one to the other takes place without change of density or the absorption of heat. The temperature at which this occurs is called by Dr. Andrews the 'critical temperature.'

Influence of Pressure on Melting-point.—Another application of the same fundamental formula (52) as that from which the last results are derived shows that in general the melting point of a solid body must change with the pressure to which it is subject. The factors J , L , and T being all positive, it follows that $\frac{dT}{dp}$ must be of

the same sign as u ; that is, when u is positive (specific volume of liquid greater than that of solid), dT must be of the same sign as dp , or the melting point must rise with increase of pressure; on the other hand, if u is negative (sp. volume of liquid less than that of solid), the melting point must fall with increase of pressure. This remarkable result was first pointed out by Professor James Thomson in 1849 in the case of ice, and was verified experimentally in the following year by Sir William Thomson (J. Thomson, *Edinb. Roy. Soc. Trans.* 1849, xvi. 1; W. Thomson, *Edinb. Roy. Soc. Proc.* February 1850; *Phil. Mag.* 1850, [3], xxxvii. 123).

If s_1 denote the specific volume of ice at 0°C. , s_2 the specific volume of water at the same temperature, and L the latent heat of fusion of ice, equation (52) gives

$$\frac{dT}{dp} = \frac{(s_2 - s_1)T}{JL} \quad \dots \quad (54)$$

According to Rossetti (vi. 672) the density of water at 0° compared with water at 4° is 0.999871, and according to W. H. Miller its absolute density at 4° is 1.000013. Hence for s_2 we have

$$s_2 = \frac{1}{1.000013 \times 0.999871} = 1.000116.$$

The value of s_1 is given by Bunsen's determination (vi. 681) of the relative density of ice at 0° , namely 0.91674, whence

$$s_1 = \frac{1}{1.000013 \times 0.91674} = 1.09080.$$

For L , Bunsen's experiments (*loc. cit.*) give 80.025. We have, therefore,

$$\frac{dT}{dp} = \frac{1.000116 - 1.09080 \times 273}{4.175 \times 10^7 \times 80.025} = -7.41 \times 10^{-9}.$$

This shows that an increase of pressure of 1 *dyne* per square centimeter should lower the melting point of ice by 7.41×10^{-9} degree centigrade. Taking 1 *megadyne* per square centimeter as unit of pressure, the result would be a lowering of temperature equal to 0.00741°C. Sir William Thomson found experimentally that, in two series of experiments in which the pressure was increased from 1 to 8.1 atmospheres, and from 1 to 16.8 respectively (1 atmosphere being equivalent to 1.014 megadyne per square centimeter), the temperature was lowered by 0.0586 and by 0.1289 of a degree. These numbers give

$$0.00725 \text{ and } 0.00757$$

respectively as the lowering of temperature due to a pressure of 1 megadyne per square centimeter, the mean being identical with the calculated number.

Experiments by Mousson in which much greater pressures were employed, whereby the melting point of ice was lowered to -18°C. , are described in the article HEAT (iii. 76).

In the case of substances whose specific volume is greater in the liquid than in the solid state, theory indicates that increase of pressure must raise the melting point, a conclusion which is verified by the results of experiments by Bunsen and by Hopkins, recorded vol. iii. 76.

Changes of Temperature resulting from the Adiabatic Compression of Solids or Liquids.—To find the change of temperature resulting from a given change of pressure

in a solid or liquid, we may start from equation (5b), namely, $dQ = C dt + h dp$. If there is no loss or gain of heat, or $dQ = 0$, and we get, on substituting the value of h from (32),

$$dT = \frac{T \alpha}{J C \rho} dp \quad (55)$$

An equivalent expression, giving the change of temperature in terms of the change of volume dv , is obtained by replacing $\frac{dp}{\rho}$ in (55) by $-E dv$, where E is the coefficient of adiabatic elasticity, and then putting for E its value from (35). This gives

$$dT = - \frac{C}{T \alpha \epsilon} \frac{dv}{J \rho} \quad (56)$$

Equation (55) has been verified by Joule (*Phil. Trans.* 1859, 133) by experiments on the effect of pressures suddenly applied to water and to oil. The results, with the data required for comparing them with the calculated values, are given in the following table, where ϖ denotes the pressure (in megadynes per square centimeter) and θ the rise of temperature (ϖ and θ here answer to dp and dT respectively in formula (55)). The value of J is taken throughout as 4.175×10^7 .

Thermal Effect of Compression of Water.

With oil the results given in the following table were obtained, showing that the heating effect at a given temperature is proportional to the pressure applied :

T	ϖ	θ	
		Experiment	Calculated
273 + 16	7.93	+ 0.079	+ 0.089
" + 17.29	15.86	.169	.176
" + 16.27	25.69	.266	.284

In consequence of practical difficulties no experiments have hitherto been made on the thermal effects of the adiabatic compression or extension of solid bodies by stresses acting equally in all directions. The only obvious way of exerting a uniform pressure over the whole surface of a solid is to immerse it in a fluid through which the pressure is transmitted ; but when this is done it becomes extremely difficult, if not impossible, to separate the thermal effect due to compression of the fluid from that due to compression of the solid. The changes of temperature produced by the sudden application or removal of forces tending to produce longitudinal extension or compression have, however, been studied in the case of uniform rods or wires of several materials by Joule (*Phil. Trans.* 1859, 91) and by Edlund (*Pogg. Ann.* 1861, cxiv. 1 ; 1865, cxvii. 539). In order that equations (55) and (56) may apply to such cases, we must modify them by introducing M , Young's modulus of elasticity, in place of ϵ , and must take ρ to stand for the mass of unit length of the rod, and α for the coefficient of linear expansion ; dv also in the latter formula must be taken as a change of length instead of as a change of volume. It should be noted further that the values of M or ϵ and ρ are certainly, and those of C and α probably, somewhat different, for solid bodies subjected to considerable stress, from the values of the same quantities for bodies not subject to stress : hence a very close agreement between the calculated and experimental results is not to be looked for in the case of such experiments. The following table, taken from Baynes's *Thermodynamics* (p. 152), gives the results of some of Joule's experiments on stretching reduced to absolute measure.

	T	$\frac{1}{\rho}$	α	JC	\mathcal{T}	θ	
						Calculated	Experiment
Iron . . .	273 + 13.3	0.429	1.220×10^{-5}	4.728	321.2	-0.102	-0.101
Hard steel . .	" + 1.7	.448	$1.362 \times$ "	4.255	321.2	- .127	- .162
Cast iron . .	" + 9.3	.525	$1.125 \times$ "	4.978	324.9	- .109	- .148
Copper . . .	" + 1.2	.377	$1.718 \times$ "	3.953	317.7	- .140	- .174
Lead . . .	+ 4.8	.075	$2.858 \times$ "	1.305	80.0	- .036	- .053

In this table \mathcal{T} denotes the elongating stress, or stretching force in megadynes per square centimeter of the cross section of the bars, and θ the change of temperature, which as indicated by the *minus* sign was a cooling effect. Joule also made numerous experiments on the effect of longitudinal compression upon metal rods. In these experiments a rise of temperature was observed, the results agreeing on the whole well with those calculated by equation (56) when modified in the way already pointed out, to make it suit the case of longitudinal stress.

Escape of Liquids from under Pressure.—If a liquid is forced by a piston through a narrow channel offering so much resistance to its passage that the liquid escapes with a negligible velocity, the temperature of the liquid is raised. This phenomenon was made by Hirn the basis of a method of determining the value of the mechanical equivalent of heat (vi. 686, 687). If the piston exerts a constant pressure p_1 per unit of surface, the work done by the piston in forcing through the channel unit-volume of a liquid is p_1 . Similarly, if p_2 is the pressure (say, that of the atmosphere) which tends to prevent the escape of the liquid, the work done against this, during the passage of as much liquid as occupies unit-volume while under the greater pressure, is $p_2(1 + \alpha \theta' + \frac{1}{E} \varpi)$, if α is the coefficient of expansion, E the coefficient of adiabatic elasticity, θ' the observed rise of temperature of the liquid, and $\varpi = p_1 - p_2$ the decrease of pressure. This last amount of work added to the mechanical equivalent of the heat produced must be equal to the work done by the first piston. Now the heat developed in the process may be written $C\rho\theta$, if ρ is the density, or mass of unit-volume, of the liquid while under the pressure p_1 , θ the true rise of temperature, and C the specific heat. Hence we have the equation,

$$JC\rho\theta = p_1 - p_2 \left(1 + \alpha \theta' + \frac{1}{E} \varpi\right) = \varpi + p_2 \left(\frac{\varpi}{E} + \alpha \theta'\right).$$

Hirn, treating θ and θ' as identical, and neglecting the last term, calculates the value of the mechanical equivalent as

$$J' = \frac{\varpi}{C\rho\theta'}$$

or, since he also takes $C\rho$ for water, the liquid experimented upon, as equal to unity, his formula becomes simply $J' = \frac{\varpi}{\theta'}$. The most important omission in this mode of

treating the result is that which consists in taking θ' , the observed heating effect, as the whole heating effect. According to the last section, a diminution of pressure must lower the temperature of water at any point above its temperature of maximum density, so that the total evolution of heat in Hirn's experiment must have been sufficient to neutralise the cooling due to decrease of pressure as well as to cause the observed rise of temperature. Neglecting, with Hirn, the small term $p_2 \left(\frac{\varpi}{E} + \alpha \theta'\right)$ representing external work done by the escaping liquid, we have by the last section

$$J = \frac{\varpi}{C\rho \left(\theta' + \frac{T\alpha\varpi}{JC\rho}\right)} = \frac{\varpi(1 - T\alpha)}{C\rho\theta'} = J'(1 - T\alpha)$$

if J' be taken as the approximate result calculated by Hirn's formula, and if $C\rho$ be put = 1, as is very nearly true for water. Hirn does not give the temperature of the water in his experiments, but only the observed change of temperature θ' . Consequently we cannot calculate the necessary correction, but assuming, for the sake of getting an idea of the possible magnitude of this correction, that the temperature of the water was 10°C. , we have α about = 0.000085, and therefore

$$J = J'(1 - \alpha T) = 433[1 - 0.000085 \times (273 + 10)] \\ = 423.7$$

as the value in meter-grams of 1 gram-degree of heat. Reduced to ergs, this becomes 4.156×10^7 , or about $\frac{1}{2}$ per cent. less than Joule's result, instead of 2 per cent. higher, as appears from the uncorrected value.

Specific Heat of Saturated Vapours.—We have already had occasion to distinguish between the specific heat of the same substance according as it is exposed to constant pressure or kept at the same volume. Another important case to consider is the case of a mixture of two portions of the same substance in different states of aggregation, say liquid and vapour, when the conditions are such that the quantity of matter existing in each state remains unaltered as temperature is changed. The substance is then said to be in a 'saturated' state. The specific heats of solids and liquids in the saturated state probably do not differ much from their specific heats under constant pressure; but, in the case of saturated vapours, the specific heat is often very different from that of the same vapour under constant pressure. The specific heat of a saturated vapour may be thus calculated. Let it be denoted by γ , and let the specific heat of the saturated liquid in contact with it be represented by C' . Also let v_1 be the volume of unit-mass of the liquid, and v_2 the volume of unit-mass of the vapour, and put $u = v_2 - v_1$. 1. Suppose unit-mass of liquid at T converted into saturated vapour at this temperature, and the vapour then heated to $T + dT$ while remaining saturated. The heat required for the evaporation of the liquid is L , of which an amount $\frac{p}{J}u$ is spent in doing external work, if p is the pressure of the saturated vapour. The heat needed to raise the temperature of the vapour is γdT , and of this, an amount $\frac{p}{J}dv_2$ does external work. Consequently, the total quantity of heat employed in doing internal work during the conversion of unit-mass of liquid at T into saturated vapour at $T + dT$ is

$$Q = L + \gamma dT - \frac{p}{J}(u + dv_2)$$

2. Next, let the same transformation be effected in a different way. Raise the temperature of the liquid from T to $T + dT$, and then convert unit-mass into saturated vapour at the higher temperature. The heat needed to raise the temperature of unit-mass is $C' dT$, of which an amount $\frac{p}{J}dv_1$ does external work. The heat needed for

the evaporation is $L + dL$, and of this a quantity $\frac{p + dp}{J}(u + du)$ is spent in external work. Hence the total quantity employed in doing internal work in this second case is

$$Q' = C' dT + L + dL - \frac{p}{J}dv_1 - \frac{p + dp}{J}(u + du).$$

But since in each case a gram of liquid at T has been converted into a gram of saturated vapour at $T + dT$, the expenditure of heat in internal work must be the same in both cases, or $Q = Q'$. Also we have $u = v_2 - v_1$, and $du = dv_2 - dv_1$. Consequently we get for the specific heat of the saturated vapour

$$\gamma = C' + \frac{dL}{dT} - \frac{u}{J} \frac{dp}{dT}$$

by (52)

$$= C' + \frac{dL}{dT} - \frac{L}{T} \quad \dots \quad (57)$$

We may get numerical results in the case of water-vapour as follows: Taking the specific heat of water under the pressure of saturated vapour as the same as the specific heat under constant pressure, we have, according to Münchhausen (Wüllner's *Compendium der Physik*, ii. 166):

$$C' = C = 1 + 0.000302(T - 273)$$

$$= 0.9176 + 0.000302 T$$

$$L = 607.2 - 0.718(T - 273) \text{ (see Wüllner, } op. cit. \text{ ii. 212)}$$

$$= 803.0 - 0.718 T$$

$$\frac{dL}{dT} = -0.718$$

$$\text{therefore } \gamma = 0.9176 + 0.000302 T - \frac{803}{T}.$$

This expression gives the subjoined numbers for the values of γ at the following temperatures—namely,

Temperature from absolute zero	300°	400°	700°	710°	800°
zero centigrade	27	127	427	437	527
γ	-1.669	-0.969	-0.081	0	+0.1554

Thus it appears that, below about 437° C., the specific heat of water-vapour is negative: that is to say, heat must be *taken from* it to keep it saturated as the temperature is raised. The physical interpretation of this, at first sight, rather contradictory result is, that a given quantity of water can evaporate completely in a smaller and smaller space as temperature rises; hence, to keep water-vapour saturated when its temperature is raised, it must be compressed into a smaller bulk, and the work done upon it by the compressing force is more than equivalent to the quantity of heat needed to cause the rise of temperature. This result was discovered independently and almost at the same time by Clausius and by Rankine in 1850.

[For a more complete treatment of the subject of Thermodynamics, readers may be referred to the following, among other works:—Rankine, *The Steam-Engine and other Prime Movers*; Clausius, *Mechanische Wärmetheorie* (or English translation by W. R. Browne); Verdet, *Théorie mécanique de la chaleur*; P. de Saint-Robert, *Principes de Thermodynamique*; Rühlmann, *Handbuch der mechanischen Wärmetheorie* (valuable for the completeness with which numerical data are given); Wüllner, *Die Lehre von der Wärme* (forms the third vol. of this author's *Lehrb. d. Experimental Physik*); Jamin a. Bouty, *Cours de Physique* (tome ii. fascicule 2); Maxwell, *Theory of Heat*; R. E. Baynes, *Lessons on Thermodynamics* (an excellent and comprehensive work in small compass). Most of the above works have been consulted more or less during the compilation of the foregoing article, but use has been chiefly made of Jamin and Bouty and of Baynes.]

G. C. F.

THERMONEUTRALITY. See HEAT (p. 985).

THETINES. This name is given to a series of sulphur-compounds analogous to betaine and its homologues, and represented by the general formula

$$\begin{array}{c} \text{CH}^2-\text{S}(\text{C}^2\text{H}^{2m+1})^2 \\ | \\ \text{CO}-\text{O} \end{array}$$

Only the methyl and ethyl terms are however at present known. See METHYLTHETINE (p. 1317).

TREVETOSIN. A glucoside obtained from the seeds of *Thevetia Yccali* D. C., a tree growing in Mexico, and there called *Joyote*. It crystallises in four-sided prisms, dissolves easily in alcohol, and is resolved by dilute sulphuric acid into glucose and a resinous body. It is very poisonous, acting as an emetic. The seeds also contain a non-drying oil, albuminoids, and extractive matters (Herrera, *Pharm. J. Trans.* [3], vii. 854).

THIACETAMIDE and THIACETANILIDE. See THIAMIDES.

THIACETIC ANHYDRIDE, or *Diacetyl Sulphide*, $(\text{C}^2\text{H}^3\text{O})_2\text{S}$. Barium dioxide acts violently on this compound in the dry state, producing incandescence; but if the anhydride be diluted with ether, the action begins after some time only, and is attended with only slight evolution of heat, the product being acetyl persulphide, $(\text{C}^2\text{H}^3\text{O})_2\text{S}^2$, probably formed according to the equation, $2(\text{C}^2\text{H}^3\text{O})_2\text{S} + \text{BaO}^2 = (\text{C}^2\text{H}^3\text{O})_2\text{S}^2 + (\text{C}^2\text{H}^3\text{O}^2)^2\text{Ba}$ (Beckmann, *J. pr. Chem.* [2], xvii. 439).

THIACETIC ETHERS. *Action of Permanganates.*—Thiethylic ether, or Acetyl-ethyl sulphide, $\text{C}^2\text{H}^3\text{O.S.C}^2\text{H}^5$, is but slightly attacked by potassium permanganate; but silver permanganate, even in very dilute solution, is quickly decolorised by it, with formation of acetic and ethylsulphonic acids. Isopentyl thiobenzoate, or benzoyl-isopentyl sulphide, $\text{C}^2\text{H}^5\text{O.S.C}^3\text{H}^{11}$, is but slightly attacked by the permanganates of potassium and silver, even at the heat of the water-bath. Ethyl thiobenzoate, on the other hand, is converted by silver permanganate in presence of sulphuric acid, even at ordinary temperatures, into benzoic and ethylsulphonic acids.

THIALDEHYDE, $\text{C}^2\text{H}^4\text{S}$. This compound is known only in polymeric modifications (H. Klinger, *Ber.* ix. 1893; xi. 1023). The oily liquid formed by passing hydrogen sulphide into aldehyde has, according to Pinner, the composition $\text{C}^2\text{H}^4\text{O.C}^2\text{H}^4\text{S}$, and when treated with acids, yields a precipitate of trithialdehyde or parathialdehyde, $\text{C}^6\text{H}^{12}\text{S}^3$, which compound may also be obtained directly by passing hydrogen sulphide into a strongly acidulated solution of aldehyde (vii. 37). Parathialdehyde thus obtained crystallises in white glistening needles, soluble in alcohol and ether; it begins to sublime at 45°, and may be volatilised without alteration. On adding silver nitrate to its solution in strong alcohol a crystalline compound is formed having the composition $\text{C}^6\text{H}^{12}\text{S}^3.2\text{AgNO}^3$.

With *chlorine* or *bromine* it forms chloride or bromide of sulphur, and chloride or bromide of ethylidene, together with more highly chlorinated or brominated products (Pinner, *Liebig's Annalen*, clxxix. 21). By oxidation with potassium permanganate, it yields potassium acetate, sulphuric acid, and potassium ethylenedisulphonate, $\text{CH}^3\text{CH}(\text{SO}^2\text{OK})^2$ (Guareschi, *Gazz. chim. ital.* 1879, 75).

When this parathialdehyde is heated on the water-bath with *acetic* or *benzoic chloride*, it is converted into a new modification (distinguished by Klinger as β -parathialdehyde) which has the same composition and vapour-density as that above described, and likewise crystallises in glistening needles, but melts at 125° , and boils with very slight decomposition at 245° – 248° . With silver nitrate, it forms two crystalline compounds, viz. $\text{C}^6\text{H}^5\text{S}^3\text{AgNO}^3$ (compact colourless needles) and $\text{C}^6\text{H}^5\text{S}^3\cdot 3\text{AgNO}^3$ (thin nacreous laminæ), which dissolve sparingly in boiling alcohol and detonate when heated.

A third modification, α -parathialdehyde, is produced by subjecting the compound $\text{C}^6\text{H}^5\text{O}\cdot\text{C}^2\text{H}^4\text{S}$, suspended in water, and frequently agitated, to the prolonged action of hydrogen sulphide. An oil is thereby obtained which yields only traces of ordinary parathialdehyde when treated with dilute acids, but on dissolving it in ether, drying the solution over calcium chloride, distilling off the portion which volatilises below 140° , and mixing the residue with a small portion of aldehyde, α -parathialdehyde is obtained. This modification crystallises from alcohol or glacial acetic acid in prisms, melts at 101° , boils between 246° and 247° , and forms with silver nitrate the compounds $\text{C}^6\text{H}^5\text{S}^3\cdot\text{AgNO}^3$ (concentric groups of dull white needles) and $\text{C}^6\text{H}^5\text{S}^3\cdot 3\text{AgNO}^3$ (microscopic prisms), both of which are permanent in the air, and are decomposed by alcohol only after prolonged boiling.

α -Parathialdehyde is converted by acetyl chloride into the β -modification, and the latter is also produced, instead of the α -modification, when the oil obtained as above mentioned for the preparation of the latter by means of hydrogen sulphide, is dissolved in strong sulphuric acid, and the solution is mixed with water, the β -modification then separating out. Both modifications may be crystallised from aldehyde without alteration, and yield the same products by oxidation with dilute nitric acid, viz. acetic acid, aldehyde, carbon dioxide, oxalic acid, sulphuric acid, and sulphur. When exposed to the vapours of fuming nitric acid, they yield sulphonic acids, in addition to the products just mentioned. They are but slowly oxidised by strong nitric acid.

The oil, formed as above described from the compound $\text{C}^2\text{H}^5\text{O}\cdot\text{C}^2\text{H}^4\text{S}$, is converted by ethyl iodide into triethylsulphine iodide, $(\text{C}^2\text{H}^5)^3\text{SI}$.

THIALDINE, $\text{C}^6\text{H}^5\text{NS}^2 = \text{CH}^3\cdot\text{CH} < \begin{smallmatrix} \text{S}\cdot\text{CH}(\text{CH}^3) \\ \text{S}\cdot\text{CH}(\text{CH}^3) \end{smallmatrix} > \text{NH}$ (v. 772). By oxidation in dilute solution with potassium permanganate, this base is converted into sulphuric, acetic, and syrupy ethylenedisulphonic acid, $\text{CH}^3\text{CH}(\text{SO}^2\text{H})^2$ (Guareschi, *Gazz. chim. ital.* 1879, 75).

THIAMIDES (Hofmann, *Ber.* xi. 338; Bernthsen, *ibid.* 503). These bodies may be conveniently prepared by the action of phosphorus sulphide (? penta-) on amides. When *formanilide*, $\text{H}\cdot\text{CO}\cdot\text{NH}(\text{C}^6\text{H}^5)$ (5 pts.), is triturated with phosphorus sulphide (3 pts.), the mixture heated for five to ten minutes on the water-bath, and then exhausted with dilute soda-ley, the filtrate, on acidulation with hydrochloric acid, immediately deposits white crystals of *thioformanilide*, $\text{H}\cdot\text{CS}\cdot\text{NH}(\text{C}^6\text{H}^5)$. Aniline formate may also be used in the preparation instead of formanilide, but it is less advantageous. In like manner, *thiacetanilide*, $\text{CH}^3\cdot\text{CS}\cdot\text{NH}(\text{C}^6\text{H}^5)$, may be prepared from acetanilide. *Thioformamide*, $\text{H}\cdot\text{CS}\cdot\text{NH}^2$, appears to be produced by the action of phosphorus sulphide on formamide. *Thiobenzanilide*, or *Benzothianilide*, is obtained in like manner, in very considerable quantity, from benzanilide (2 pts.) and phosphorus sulphide (1 pt.); and *Phenylthiacetamide* or *Thio-atolylamide*, $\text{C}^6\text{H}^5\cdot\text{CH}^2\cdot\text{CS}\cdot\text{NH}^2$, from phenylacetamide (3 pts.) and phosphorus sulphide (2 pts.)

Thiamides of fatty acids, $\text{C}^n\text{H}^{2n+1}\cdot\text{CS}\cdot\text{NH}^2$, are also produced by direct addition of hydrogen sulphide to nitrils, e.g. *acetothiamide*, or *thiacetamide*, $\text{CH}^3\cdot\text{CS}\cdot\text{NH}^2$, from acetonitril, $\text{CH}^3\cdot\text{CN}$. This compound crystallises, according to Bodewig, in the monoclinic system. Observed faces $\infty\text{P}\infty$, 0P , ∞P , $-\text{P}$, sometimes also $+\text{P}$; tabular according to $\infty\text{P}\infty$. Twins according to $\infty\text{P}\infty$. Angle $\infty\text{P}:\infty\text{P} = 94^\circ 47'$. Axial angle $80^\circ 55'$. The plane of the optic axes is perpendicular to the plane of symmetry. Thiacetamide melts at 108° . It dissolves readily in ether, differing therein from acetamide. Its solution gives with platinum chloride a precipitate of ammonium platinumchloride. It is an extremely unstable compound, and is resolved, both by acids and by alkalis into acetic acid, ammonia, and hydrogen sulphide. It is desulphurised by mercuric oxide, iodine solution, silver nitrate, cupric

nitrate, lead acetate, and mercuric nitrate, in some cases immediately, in others only on heating (Bernthsen, *Liebig's Annalen*, xcii. 1).

Aromatic Thiamides are produced: 1. From amides, as already mentioned, by the action of phosphorus sulphide.

2. By the action of hydrogen sulphide on imidoketonic chlorides: *e.g.* thiobenzanilide or benzothianilide from imidodiphenylketonic chloride:

(H. Leo, *Ber.* x. 2133).

3. By the action of hydrogen sulphide on the amidines of monobasic acids (p. 72). *Benzenylmonophenylamidine* thus treated at 130° yields simultaneously thiobenzamide or benzothiamide (m. p. 115°–116°), and thiobenzanilide (m. p. 95°–97°):

Benzenyldiphenylamidine (m. p. 144°), similarly treated, yields only one compound, *viz.* thiobenzanilide:

but its isomeride, *benzenyl-isodiphenylamidine* (m. p. 111°–112°), yields two compounds, *viz.* thiobenzamide and benzodiphenylthiamide, $\text{C}^6\text{H}^5.\text{CS.N}(\text{C}^6\text{H}^5)^2$:

Methenyldiphenylamidine in like manner yields formothianilide or thioformanilide:

Benzenylmonophenylamidine, heated at 100°–120° with carbon sulphide, yields thiobenzanilide and thiocyanic acid:

(Bernthsen, *Ber.* x. 1238).

Thiobenzanilide, $\text{C}^{13}\text{H}^{11}\text{NS}$, crystallises in sulphur-yellow tablets melting at 97°. It is not acted upon by iodine. When heated, it gives off hydrogen sulphide, and leaves a body having the composition $\text{C}^{12}\text{H}^{10}\text{N}^2\text{S}^2$. Heated with hydrochloric acid it yields benzoic acid, with evolution of hydrogen sulphide. Heated with potash-ley in a sealed tube at 150°, or with lead oxide, it is converted into benzanilide, $\text{C}^{13}\text{H}^{11}\text{NO}$. Fused with *aniline hydrochloride*, it yields benzenyldiphenylamidine:

(Leo, *Ber.* x. 2135).

Thiobenzotoluide, or *Benzothiotoluide*, $\text{C}^{14}\text{H}^{13}\text{NS}$, is prepared by the action of hydrogen sulphide on imidotolylphenyl-ketonic chloride:

It melts at 123.5°–129.5°.

Thiacetanilide, $\text{CH}^3.\text{CS.NH}(\text{C}^6\text{H}^5)$, prepared in like manner from imidophenyl-methyl-ketonic chloride, crystallises in light yellow needles melting at 74.5°–76°.

Thiamides containing both fatty and aromatic radicles are formed by the action of haloïd ethers (alkyl haloïds) on the sodium-derivatives of aromatic thiamides. Thus sodium-thiacetanilide (which forms compact crystals) and ethyl bromide act upon one another even at temperatures below 100°, forming thiobutyrylanilide, $\text{C}^{10}\text{H}^{13}\text{SN}$:

The best mode of proceeding is to bring together 2 mol. thiacetanilide, 1 mol. sodium and 2 mol. ethyl bromide in alcoholic solution, and, after the action is over and the

cyanic acids. It dissolves in 145 pts. of boiling water. By hot concentrated hydrochloric acid, it is resolved into hydrogen sulphide, ammonium chloride, and cyanuric acid. Nitric acid oxidises it to ammeline nitrate. Heated with ammonia it yields a body having the properties of melamine. Thiammeline dissolves in acids and in alkalis, and gives precipitates with salts of the heavy metals (Ponomareff, *Compt. rend.* lxxx. 1384).

THIANILINE, or **THIOANILINE**, $C^{12}H^{12}N^2S = (C^6H^4.NH^2)^2S$. This compound, which Merz a. Weith obtained by boiling aniline with sulphur (vii. 1154), is also produced: α . By reduction of nitrophenyl sulphide, $(C^6H^4.NO^2)^2S$ (p. 1546). β . By the action of sulphur iodide [S^2I^2] on aniline at 160° – 170° , in small quantity however, and mixed with a large amount of resinous products. The thianiline obtained by both these processes melts at 105° – 106° , agreeing therein closely with Merz a. Weith's product, which melted at 104° – 105° . With aniline and sulphur chloride a product was obtained melting at 108° – 109° , and agreeing in all other respects with the preceding (E. Schmidt, *Ber.* ix. 1050; xi. 1168).* Thianiline is also found in the mother-liquor obtained in the preparation of α -triphenylguanidine by the action of thiocarbonyl chloride in ethereal solution on aniline (Rathke, *Liebig's Annalen*, clxvii. 211).

Dithianiline, $C^{12}H^{10}N^2S^2 = (C^6H^3)^2S^2(NH^2)^2$ (E. B. Schmidt, *Ber.* xi. 1168).—This compound is formed, together with monothianiline and resinous sulphuretted products, by the action of sulphur bromide on aniline. Its *sulphate* is obtained by heating dithiacetanilide (*infra*) with dilute sulphuric acid, and when purified by recrystallisation from water, forms small white slender needles or warty masses which acquire a reddish tint on exposure to the air. It contains 2 mol. water of crystallisation. Dithiacetanilide heated with hydrochloric acid yields, not the corresponding hydrochloride of dithianiline, but a free bisulphuretted base, $C^{12}H^{12}N^2S^2$, designated by Schmidt as *pseudodithianiline*. This base crystallises from water in long thin greenish needles having a vitreous lustre; it melts at 79° , dissolves readily in alcohol, ether, and chloroform, sparingly in benzene, ligroin, and carbon bisulphide. Schmidt represents the two so-called dithianilines by the following formulæ:

Dithiacetanilide, $(C^6H^4.NH.C^2H^3O)^2S^2$, and **Trithiacetanilide**, $(C^6H^4.NH.C^2H^3O)^2S^2$, are formed by the action of sulphur chloride on acetanilide at 100° , and are separated by their different degrees of solubility in glacial acetic acid. **Dithiacetanilide** is easily soluble in glacial acetic acid and in alcohol, and crystallises from the former in large greyish-white laminae, from the latter in pointed shining needles; in other solvents it is either insoluble or very sparingly soluble. It melts at 215° – 217° . By sulphuric or hydrochloric acid it is resolved into acetic acid and dithianiline.

Trithiacetanilide is but sparingly soluble in glacial acetic acid, and crystallises therefrom in nacreous laminae melting at 213° – 214.5° . It is moderately soluble in warm alcohol, from which it separates in stellate groups of small crystals. It is decomposed by sulphuric or hydrochloric acid into acetic acid and trithianiline (Schmidt).

THIOBENZALDEHYDE, $C^6H^5.CHS$ (H. Klinger, *Ber.* ix. 1893; x. 1877). This compound is formed by passing hydrogen sulphide into an alcoholic solution of bitter almond oil, and is obtained, according to the concentration of the solution, either in amorphous reddish flocks, or as a quickly solidifying oil (α -modification). It softens at 83° – 85° , decomposes at a higher temperature, dissolves very readily in benzene and in chloroform, somewhat slowly in hot alcohol. By treatment with acid chlorides, it is converted into a modification (β) which forms white shining needles, melting with decomposition at 225° – 226° , easily soluble in hot glacial acetic acid, less easily in alcohol, benzene, and chloroform. The amorphous modification, heated with finely divided copper, yields $C^{14}H^{12}$.

On adding a very small quantity of iodine to a solution of the amorphous (α) thiobenzaldehyde in benzene, crystalline needles separate in a short time consisting of a compound of β -thiobenzaldehyde (m. p. 225°), with *benzene*, $C^6H^5.CHS.C^6H^5$, which gives off the benzene at 125° – 130° . 36 pts. of α -thiobenzaldehyde thus treated yield 9 pts. of the β -modification. The latter heated with finely-divided copper yields so

* J. Roorda Smit (*Ber.* viii. 1445), by acting on aniline with sulphur chloride, obtained a body which he calls *thianilide*, having the same composition as thianiline, but differing from the latter altogether in its physical properties, being a yellow oil at ordinary temperatures, and boiling at 230° – 240° . Its *diacetyl* derivative melts at 125° – 126° ; the *dibenzoyl*-derivative at 150° .

large an amount of stilbene ($\frac{2}{3}$ of its weight) that this method may be advantageously used for the preparation of stilbene (p. 676).

β -Thiobenzaldehyde is converted by oxidation with nitric acid into benzaldehyde and benzoic acid; by heating with lead oxide into lead sulphide and benzaldehyde, together with small quantities of stilbene and high-boiling sulphur-compounds (Klinger). Treated with strong potash-ley it yields a mixture of benzyl hydro-sulphide, benzyl bisulphide, and benzoic acid (Böttiger, *Ber.* xii. 1053).

The thiobenzaldehyde (m. p. 78° – 80°) which Cahours and Fleischer obtained by the action of potassium hydrosulphide on benzylene chloride, $C^6H^4Cl^2$, in alcoholic solution (vi. 329), is regarded by Klinger as a third modification (γ). It is not converted into the β -modification either by acetyl chloride or by iodine.

THIOBENZAMIDE, $C^6H^5.CS.NH^2$. The action of iodine on this body gives rise, as already mentioned (vi. 258), to the compound $C^{14}H^{10}N^2S$, which crystallises from hot alcohol in long needles melting at 90° .

Amidothiobenzamide, $C^6H^4(NH^2).CS.NH^2$, is acted upon by iodine (both in alcoholic solution) in the same manner, and on evaporating the resulting liquid, there remains a brownish resinous substance, from which, by repeated boiling with water, a body is extracted which separates from the hot filtrate in white slender needles, and when purified by recrystallisation from water has the composition

This compound melts between 128° and 129° ; dissolves in alcohol, ether, carbon sulphide, chloroform, and benzene; exhibits marked basic properties; and forms a crystalline sulphate and hydrochloride, also a yellowish bulky platinum salt, with addition of 2 mol. of acid (R. Wanstrat, *Ber.* vi. 332).

THIOBENZANILIDE, $C^6H^5.CS.NH(C^6H^5)$. See **THIAMIDES** (p. 1924).

THIOBENZOIC ETHERS. *Isopentyl* or *Amyl Thiobenzoate*, or *Benzoyl-isopentyl Sulphide*, $C^6H^5.O.(CH^3)_2CH(CH^3)_2$, is but slightly acted on by the permanganates of potassium and silver even at the heat of the water-bath. The *ethylic ether*, on the other hand, is converted by silver permanganate in presence of sulphuric acid, even at ordinary temperatures, into benzoic and ethylsulphonic acids (Beckmann, *Ber.* xi. 1687).

THIOBENZOPHENONE, or *Diphenyl Thioketone*, $C^6H^5.CS.C^6H^5$, is formed by the action of potassium sulphide on diphenylketonic chloride (benzophenone chloride):

It is also formed as a secondary product in the preparation of thiobenzpinacone (*infra*), and remains in the mother-liquors. It crystallises in small white needles melting at 146.5° , is not attacked in alcoholic solution by copper. By hydrogen sulphide, especially in the nascent state, it is converted in alcoholic solution into the thiopinacone (C. Engler, *Ber.* xi. 922).

THIOBENZPINACONE, $C^{10}H^{12}S^2 = (C^6H^5)_2(HS)C-C(SH)(C^6H^5)_2$, is formed by the action of ammonium-hydrogen sulphide on benzophenone (Engler, *Ber.* xi. 922); also, together with thiobenzophenone, by the action of potassium-hydrogen sulphide on benzophenone chloride (Behr, *Ber.* vi. 970). It melts at 151° , and is converted in alcoholic solution by finely divided copper into tetraphenylethane, $(C^6H^5)_2HC-CH(C^6H^5)_2$ (p. 1916).

THIOCARBACETO-ACETATE, **ETHYLIC**, $CH^3.CO.C \begin{smallmatrix} CS \\ COOC^2H^5 \end{smallmatrix}$.

This ether is formed, together with small quantities of carbon oxide and lead sulphide, when ethylic acetoacetate (p. 12) is heated at 100° in a sealed tube with carbon sulphide and lead oxide, and may be extracted from the product by alcohol. It crystallises in straw-yellow needles, melting at 156° – 162° (Norton a. Oppenheim, *Ber.* x. 701).

THIOCARBAMATES. On the action of Ammonium Thiocarbamate on Aldehydes, see p. 387.

Potassium Phenylthiocarbamate is formed by the action of carbon bisulphide and potassium hydroxide on aniline:

The actual product of the reaction is always however the acid potassium salt, $C^6H^5NS^2K.C^6H^5NS^2$; and this salt is most conveniently prepared by heating an alcoholic solution of aniline and potassium xanthate in molecular proportions for three or four hours, the liquid on cooling first depositing diphenylthiocarbamide and then the acid potassium salt, while a thiocarbamate remains in solution. The acid potassium salt recrystallised from lukewarm water, forms golden-yellow, transparent, monoclinic crystals, which when crushed by pressure, yield a white powder, turning yellowish again at about 30° . Between 60° and 70° the crystals melt in their water of crystallisation; at ordinary temperatures they dissolve in less than their own weight of water. The solution decomposes when heated, yielding diphenylthiocarbamide and phenylthiocarbimide, $C^6H^5.NCS$. The salt when exposed to the air decomposes into phenylthiocarbimide and potassium dithionate, a small quantity of diphenylthiocarbamide being formed at the same time. It is decomposed by salts of heavy metals with formation of phenylthiocarbimide and a metallic sulphide. The potassium salt when heated yields water and diphenylthiocarbamide, and is resolved by acids into aniline and carbon bisulphide. Its solution takes up large quantities of aniline, and if subsequently heated gives off hydrogen sulphide, and deposits diphenylthiocarbamide. The dissolved potassium salt is resolved by *aniline salts* into diphenylthiocarbamide, aniline, carbon bisulphide, and hydrogen sulphide; by *ammonium salts* into diphenylthiocarbamide, ammonia, carbon bisulphide, and ammonium sulphide (B. Rathke, *Ber.* xi. 988).

THIOCARBAMIDE, $NH^2.CS.NH^2$. *Sulphurea* (Bernthsen a. Klinger, *Ber.* xi. 492). This body (p. 395) unites with *alcoholic iodides* (alkyl iodides), forming strongly basic compounds, which exhibit the characters of sulphine-compounds. *Methiodide thiocarbamide*, $N^2H^4CS.CH^3I$, crystallises in prisms which melt at 177° , and dissolve readily in water and in alcohol. On agitating its aqueous solution with silver chloride, the iodine is replaced by chlorine. On adding silver oxide to the aqueous solution of the iodide, silver iodide is formed, together with a strong base which has not been isolated: its solution, neutralised with hydrochloric acid and mixed with platinum chloride, yields the *platinochloride*, $(N^2H^4CSCH^3Cl)_2PtCl_4 + H^2O$, which crystallises in groups of small prisms, efflorescing on exposure to the air, and giving off the whole of their water at 110° . The solution of the base gives a characteristic precipitate with metallic salts, and when left to evaporate deposits crystals which after a while cease to exhibit basic reaction. On agitating the aqueous solution of the methiodide-thiocarbamide with *mercuric oxide*, cyanamide, or dicyanodiamide, is produced, together with a yellow flocculent substance resolved by heat into mercuric iodide and methyl sulphide.

The *hydriodide of methylthiocarbamide*, $NH^2.CS.NH(CH^3).HI$, metameric with the compound just described, crystallises in large laminæ, melts below 100° , and yields a platinochloride which crystallises in concentric groups of bent and branched needles. Silver nitrate added to its solution throws down silver iodide and a silver compound of methylthiocarbamide, whereas the solution of the metameric compound, when similarly treated, deposits nothing but silver iodide. The hydriodide of methylthiocarbamide is immediately desulphurised by silver oxide, and converted into methylcyanamide.

Ethiodide thiocarbamide acts just like the methyl-compound, excepting that when treated with silver oxide it is very easily converted into cyanamide. These addition-products are decomposed when somewhat strongly heated, yielding hydrocyanic acid and products not yet examined, partly amorphous, partly crystalline, the latter being converted into the former by heat.

Thiocarbamide unites also very readily with *benzyl chloride*, forming the compound $CSN^2H^4C^6H^5Cl$, which may be purified by washing with ether, crystallises from water and from alcohol in small needles, and melts at 166° – 168° . On evaporating its solution in hydrochloric acid, decomposition takes place to a very slight extent, attended with the formation of white bulky needles, while the greater quantity crystallises in large colourless prisms having the same melting point as the crude product. The corresponding *platinochloride* crystallises in yellow prisms. The *free base*, $C^6H^5N^2S$, is separated from the solution of the hydrochloride by ammonia or sodium hydrate in the form of a very bulky white precipitate. It is somewhat sparingly soluble in water, and crystallises from ether, alcohol, or best from benzene, in white felted needles; its solutions decompose very readily when heated, the aqueous solution becoming turbid in consequence of the formation of benzyl hydrosulphide. The base melts at 71° – 72° , and is resolved at a slightly higher temperature into benzyl hydrosulphide and dicyanodiamide. It dissolves readily in acids, the hydrochloride thus formed being identical with that above described (Bernthsen a. Klinger, *Ber.* xii. 574).

Thiocarbamide, heated with *thiocarbonyl chloride*, CSCl_2 , yields the hydrochloride of thiodicyanodiamine, $\text{C}^2\text{H}^4\text{N}^2\text{S}\cdot\text{HCl}$ (p. 1930).

On the reaction of thiocarbamide with *œnanthyl*, see *œNANTHYLENE THIOCARBIMIDE (infra)*.

Diethyl-thiocarbamide, $\text{CS}(\text{NHC}^2\text{H}^5)^2$, is formed, together with ethyl thio carbamide, ethylammonium iodide, carbon bisulphide, and free sulphur, by the action of iodine on ethylthiocarbamate of ethylamine:

Diethylthiocarbamide treated with *iodine* yields sulphur and hydrogen iodide, but no ethylthiocarbimide (Rudneff, *Ber.* xi. 977).

Phenylthiocarbamides.—Mono- and di-phenylthiocarbamide—and likewise phenyl-xanthamide, $\text{C}^6\text{H}^5\text{S}\cdot\text{CO}\cdot\text{NH}^2$ —dissolve in aqueous potash and soda (not in ammonia), and are precipitated from the solution by acids, even by carbonic acid. In these alkaline solutions the two thiocarbamides are easily and completely desulphurised by lead oxide, yielding respectively phenyl cyanamide, $\text{CN}^2\text{H}(\text{C}^6\text{H}^5)$, and diphenylguanidine, $\text{CN}^2\text{H}^2(\text{C}^6\text{H}^5)^2$. The phenylthiocarbamides also dissolve with moderate facility in concentrated hydrochloric acid, the solution of monophenylthiocarbamide being very permanent even at the boiling heat, whereas diphenylthiocarbamide heated with hydrochloric acid is converted into carbamiliide, $\text{CO}(\text{NHC}^6\text{H}^5)^2$.

The desulphuration of monophenylthiocarbamide dissolved in alcoholic ammonia produces monophenylguanidine (Rathke a. Feuerlein, *Ber.* xi. 772, 1602).

THIOCARBIMIDES, or ISOTHIOCYANATES (ALCOHOLIC), $\text{R}-\text{N}=\text{CS}$. *Mustard-oils. Action of Chlorine and Bromine.* **Ethyl-thiocarbimide**, $\text{C}^2\text{H}^5\text{N}=\text{CS}$ (p. 761), is energetically attacked by dry chlorine, with formation of sulphur chloride and other products of further decomposition; but on passing dry chlorine through a cooled mixture of ethylthiocarbimide and anhydrous ether in equal volumes, the liquid soon solidifies to a thick yellowish pulp, which, when left for a day or two under the air-pump, is converted into an unstable yellowish-white powder. On drenching this powder with soda-ley, a small quantity of sulphur separates, and a heavy brown oil is produced, which after some time solidifies to a crystalline mass; and on pressing this mass between filter paper and dissolving it in a small quantity of alcohol, the solution deposits splendid colourless tablets and prisms, a centimeter long, consisting of a compound of 2 mol. ethylthiocarbimide and 1 at. oxygen, $(\text{C}^2\text{H}^5\text{NCS})^2\text{O}$. The crystals melt at 42° , are insoluble in water, but dissolve easily in alcohol; are oxidised by strong nitric acid, with emission of red fumes; and form with platinic chloride a red non-crystalline compound. On treating their solution with ammonium sulphide, sulphur immediately separates, and the filtrate yields on evaporation fine crystals which melt at about 60° , and therefore do not consist of ethylcarbamide as might have been expected (E. Sell, *Ber.* vi. 322).

On the *Thiocarbimides of Butyl* (primary and secondary), and on *Butenyl- or Crotonyl-thiocarbimide*, $\text{C}^4\text{H}^7\text{NCS}$, see p. 607.

Pentenyl- or Angelyl-thiocarbimide, $\text{C}^5\text{H}^9\text{N}=\text{CS}$, is prepared, like the butyl-compounds, from the volatile mixture of primary and secondary monamines and diamines resulting from the action of ammonia on the dibromide obtained from commercial amylene and bromine. It boils at 190° , and unites directly with ammonia, forming the compound $\text{C}^5\text{H}^9\text{NCS}\cdot\text{NH}^3$, which crystallises in needles and melts at 103° (Hofmann, *Ber.* viii. 105).

Heptylene- or œnanthylene-thiocarbimide, $\text{C}^7\text{H}^{11}(\text{NCS})^2$. Thiocarbamide and œnanthal, dissolved together in alcohol, react on addition of a drop of hydrochloric acid, forming œnanthylene-disulphureid, $\text{C}^7\text{H}^{11}(\text{NH}\cdot\text{CS}\cdot\text{NH}^2)^2$; and on mixing the resulting solution with a larger quantity of hydrochloric acid, sal-ammoniac separates out, and œnanthylene-thiocarbimide remains dissolved:

œNanthylene-thiocarbimide is an oily liquid having an extremely repulsive odour. By treatment with ammonia, it is reconverted into the above-mentioned *œnanthylene-disulphureid*, which forms with œnanthal a vitreous polymeride (H. Schiff, *Ber.* xi. 830).

Phenylthiocarbimide, $\text{C}^6\text{H}^5-\text{N}=\text{CS}$, is converted by *chlorine* into the chloride of phenyl-isocyanide or phenyl-carbamine, $\text{C}^6\text{H}^5\text{N}=\text{CCl}^2$, which is a heavy yellowish liquid having an extremely unpleasant and pungent odour, and boiling at $211^\circ-212^\circ$. *Bromine* acts differently. On mixing phenylthiocarbimide diluted with 3 vol. chloro-

form with an equal weight of bromine, likewise diluted with 3 vol. chloroform, the mixture after a few hours deposits a deep orange-red body having the composition

This orange-red body is decomposed by water at 100°, with evolution of carbon dioxide and hydrogen sulphide, and formation of the hydrobromides of aniline and a base $\text{C}^6\text{H}^5\text{NO}$, which also separates in the free state as a resinous body, and may be obtained by crystallisation from alcohol in long white needles melting at 156°, slightly soluble in hot water, dissolved with difficulty by strong hydrochloric acid, and precipitated from the solution by alkalis. With platinic chloride it forms a well-crystallised double salt.

When the original orange-coloured product is boiled with alcohol, hydrogen bromide and ethyl bromide are evolved, and the liquid on cooling deposits sulphur-yellow crystals of the compound $\text{C}^{14}\text{H}^{10}\text{N}^2\text{S}^2 = \text{C}^6\text{H}^5\text{N}=\text{C}-\text{S}-\text{S}-\text{C}=\text{NC}^6\text{H}^5$, while

the base $\text{C}^6\text{H}^5\text{NO}$ remains in the mother-liquor. These crystals, which are also produced by the action of glacial acetic acid on the orange-red body, are insoluble in water, sparingly soluble in cold, easily in hot alcohol, and melt at 152°. When digested for some time in alcohol, they give off hydrogen sulphide and sulphur dioxide; heated at 200° with strong *hydrochloric acid*, they yield CO^2 , SO^2 , SH^2 , and aniline. Treated in alcoholic solution with *nascent hydrogen*, they yield mercaptan, aniline and a resin. Heated with finely divided *copper*, they are partly converted into phenylthiocarbimide, but at the same time phenylisocyanide and crystals of unknown composition are formed. When digested with alkaline *lead hydroxide*, they yield CO^2 , SO^2 , and diphenylcarbamide. The yellow body is not formed by treating phenylthiocarbimide with sulphur, or carbodiphenylimide with sulphur or carbon bisulphide (Proskauer a. Sell, *Ber.* ix, 1262).

Phenylthiocarbimide, treated at ordinary temperatures with *hydrogen sulphide*, yields thiocarbaniide and carbon bisulphide (Proskauer a. Sell).

When vapour of *sulphur trioxide* is passed over phenylthiocarbimide, sulphur dioxide is given off, and a compound, $\text{C}^6\text{H}^5\text{NS}^2\text{O}^2$, is formed, which dissolves in benzene, and separates therefrom in crystals melting at 180°–183°. It is insoluble in water, alcohol, ether, and glacial acetic acid, but dissolves in boiling benzene, also in chloroform and nitrobenzene. By water at 100° under pressure, it is resolved into carbon dioxide, hydrogen sulphide, and sulphanilic acid, whence its constitution may probably

be represented by the formula $\text{C}^6\text{H}^5 \begin{array}{l} \text{NH.CS} \\ \diagup \text{SO}^2.\text{O} \end{array}$ (Magatti, *Ber.* xi. 2267).

Phenylthiocarbimide and *phosphorus pentachloride*, heated together in a sealed tube for five or six hours at 160°, form phosphorus trichloride, phosphorus thiochloride, PSCl^3 , isocyanphenyl chloride or phenylcarbimide chloride, $\text{C}^6\text{H}^5\text{N}=\text{CCl}^2$, and products of higher boiling point. At the same time there are formed large yellow crystals of the *hydrochloride of chlorophenylthiocarbimide*, $\text{C}^6\text{H}^5\text{Cl.NCS.HCl}$, which dissolve but sparingly in benzene and chloroform, but readily and with decomposition in water and in alcohol. Water separates chlorophenylthiocarbimide, a strongly refractive oil which may be dried over calcium chloride; it has an aromatic odour, boils at 248°, dissolves readily in alcohol, but is insoluble in water; unites with dry hydrogen chloride, forming a crystalline mass, probably having the composition above specified. According to its chemical reactions, however, this body does not appear to be a true thiocarbimide, not being attacked by alcohol and ammonia even at 100°, and therefore differing from the chlorophenylthiocarbimide previously known.

Water, especially in presence of acids, converts the so-called chlorophenylthiocarbimide at a somewhat higher temperature into the corresponding *hydroxyl-compound*, $\text{C}^6\text{H}^5\text{NS(OH)}$, which may be conveniently prepared by heating the crude hydrochloride with alcohol till dilute alkalis no longer separate an oil from it. Hydrochloric acid added to the solution throws down the hydroxyl-compound, which quickly solidifies, and may be obtained by solution in hot alcohol, in well-defined crystals melting at 136°. It is insoluble in water and ammonia, soluble in ether and the fixed alkalis, and is precipitated from the latter by acids (A. W. Hofmann, *Ber.* xii. 1126).

The true *hydroxyphenylthiocarbimide*, $\text{C}^6\text{H}^5\text{(OH).NCS}$, is obtained: *a.* By boiling

an alcoholic solution of orthamidophenol with carbon bisulphide in a stream of hydrogen:

The boiling must be continued as long as hydrogen sulphide continues to escape, and on recrystallising the yellowish-grey crusts thus produced from alcohol and boiling water, the hydroxythiocarbamide is obtained in broad nearly colourless needles melting at 196°. It does not volatilise with vapour of water; chars when heated above its melting point; dissolves readily in ammonia, and crystallises out unaltered. On adding silver nitrate to the ammoniacal solution, white flocks are precipitated which do not blacken when boiled. Boiling aniline decomposes the hydroxyphenylthiocarbimide, with evolution of hydrogen sulphide. Hydrochloric acid at 170° decomposes it into CO², H²S, and amidophenol (J. Dünner, *Ber.* ix. 465).

The same hydroxyphenylthiocarbimide is formed by the action of a high temperature on ortho-hydroxyphenylthiocarbamide, C⁶H⁴(OH).NH.CS.NH² (J. Bendix, *ibid.* xi. 2262).

***o*-Tolyl-thiocarbimide**, C⁶H⁴(CH³)NCS. The action of chlorine on this compound diluted with chloroform, gives rise to a dichloride, C⁶H³Cl²NCS², which boils at 218°, is insoluble in water, and is energetically decomposed by alcohol, glacial acetic acid, and potash-ley. Alcoholic potash converts it into *o*-tolylethyl-urethane, C⁶H³.NH.CO²H², which melts at 46°, and volatilises with vapour of water, and *o*-ditolyl-carbamide, N²H²(C⁶H³)²CO, which melts at 250°, and does not volatilise with water-vapour (G. Lachmann, *Ber.* xii. 1349).

Cymyl-thiocarbimide, C¹⁰H¹³.NCS (or *Cumyl-thiocarbimide*), is formed from dicymyl-thiocarbamide by the action of phosphoric anhydride (which abstracts cymylamine):

It is a colourless liquid having an odour of mustard-oil, faint at ordinary temperatures, but becoming distinct on heating, and distils, with partial decomposition, between 245° and 270°. It unites after some time with ammonia, forming cymyl-thiocarbamide or cymyl-thiosinamine, (C¹⁰H¹³)H²N²CS, which crystallises in needles, and with *cymylamine* immediately, forming dicymyl-thiocarbamide, (C¹⁰H¹³)²H²N²CS, which crystallises from dilute alcohol in white needles having a satiny lustre, and melting at 128° (A. Raab, *Ber.* x. 52).

THIOCARBONIC ETHERS (F. Salomon, *J. pr. Chem.* [2], vi. 433; vii. 252; viii. 114). Of these ethers, the following are theoretically possible, taking the ethyl-compounds as examples:

CO $\begin{smallmatrix} \text{SEt} \\ \text{OEt} \end{smallmatrix}$	Carbonyloxythiodiethyl
CS $\begin{smallmatrix} \text{OEt} \\ \text{OEt} \end{smallmatrix}$	Thiocarbonyldioxydiethyl
CO $\begin{smallmatrix} \text{SEt} \\ \text{SEt} \end{smallmatrix}$	Carbonyldithiodiethyl
CS $\begin{smallmatrix} \text{OEt} \\ \text{SEt} \end{smallmatrix}$	Thiocarbonyloxythiodiethyl
CS $\begin{smallmatrix} \text{SEt} \\ \text{SEt} \end{smallmatrix}$	Thiocarbonyldithiodiethyl

1. *Carbonyloxythiodiethyl* is readily obtained by the action of ethyl chlorocarbonate on sodium mercaptide. A mixture of mercaptan with about twice its volume of ether is introduced into a flask surrounded with a freezing mixture, an equivalent quantity of sodium is added, and then ethyl chlorocarbonate by drops. When the reaction is completed, the mass is diluted with about twice its volume of water, and the ethereal layer which rises to the surface is decanted and submitted to fractional distillation. The carbonyloxythiodiethyl then passes over between 150° and 156°. It is a colourless strongly refractive liquid, having an aromatic taste and a peculiar odour like that of rotten fruit. When heated in the air, it burns with a faintly luminous flame, emitting a large quantity of sulphurous acid. It is insoluble in water, but dissolves in alcohol and common ether. Sp. gr. = 1.0285 at 18°. Boiling point 156°. Its reactions with alcoholic potash, alcoholic ammonia, and water are represented by the following equations:

Carbonyloxythiodiethyl is also produced by the action of ethyl bromide on the salt $\text{CO}(\text{OEt})\text{SK}$, produced by the action of alcoholic potash solution on ethyl xanthate, $\text{CS}(\text{OEt})(\text{SEt})$, or by passing carbon oxysulphide, COS , into alcoholic potash.

2. *Thiocarbonyl-dioxydiethyl*, $\text{CS}(\text{OEt})^2$.—This ether (*ethylic monosulpho-carbonate*) was discovered by Debus, who obtained it by dry distillation of the compound $(\text{C}^2\text{H}^5\text{O})^2\text{CS}^2$ (v. 497, 499). Salomon finds that it exhibits the properties described by Debus, but is difficult to purify. It exhibits the following reactions:

3. *Carbonyl-dithiodiethyl*, $\text{CO}(\text{SEt})^2$, was obtained by the action of strong sulphuric acid on ethyl thiocyanate (Schmitt a. Glutz's method, vi. 413):

and by that of carbonyl chloride (phosgene) on sodium mercaptide:

the latter method yielding it in theoretical quantity. It is a nearly colourless strongly refracting liquid, easily soluble in alcohol, ether, and strong sulphuric acid. Alcoholic potash decomposes it into carbon dioxide and mercaptan; with alcoholic ammonia it yields carbamide and mercaptan. When heated with water at 160° , or treated with alcoholic potash, it is resolved into carbon dioxide and mercaptan:

With alcoholic ammonia it yields mercaptan and carbamide (urea):

4. *Carbonyl-oxythiodiethyl*, or *Ethyl Xanthate*, $\text{CS}(\text{OEt})(\text{SEt})$, is best prepared by the action of ethyl bromide on potassium xanthate, the action being then completed in a quarter of an hour, whereas when ethyl chloride is employed (Debus's method) it takes a week.

5. *Thiocarbonyl-dithiodiethyl*, or *Ethyl Trithiocarbonate*, $\text{CS}(\text{SEt})^2$, is also conveniently prepared by the action of bromethyl on the corresponding potassium salt, the action at ordinary temperatures being completed in about twenty minutes. The action of potassium hydroxide and ammonia on this ether is represented by the following equations:

The following table exhibits a comparison of the boiling points of the thiocarbonic ethers above described:

	B. p.	
$\text{CO}^{\text{OC}^2\text{H}^5}_{\text{OC}^2\text{H}^5}$	125°	} Diff. 31°
$\text{CO}^{\text{OC}^2\text{H}^5}_{\text{SC}^2\text{H}^5}$	156°	
$\text{CS}^{\text{OC}^2\text{H}^5}_{\text{OC}^2\text{H}^5}$	161°	} Diff. 5°
$\text{CO}^{\text{SC}^2\text{H}^5}_{\text{SC}^2\text{H}^5}$	196°	
$\text{CS}^{\text{OC}^2\text{H}^5}_{\text{SC}^2\text{H}^5}$	200°	} Diff. 4°
$\text{CS}^{\text{SC}^2\text{H}^5}_{\text{SC}^2\text{H}^5}$	240°	
		} Diff. 40°
		} Diff. 39°

Hence it appears that: 1. The introduction of an atom of sulphur into the ethylated radicle is accompanied by a rise of 40° , except in the case of the first two members of the series, in which the difference is only 31° .

2. The introduction of sulphur into the carbonyl group is attended by a rise of 4° – 5° in the boiling point.

The specific gravities of these isomeric ethers are nearly equal, as shown in the following table, in which they are given for the temperature of 19°:

$\text{CO} \begin{smallmatrix} \text{OC}^2\text{H}^3 \\ \text{OC}^2\text{H}^3 \end{smallmatrix} = 0.975$	$\text{CO} \begin{smallmatrix} \text{SC}^2\text{H}^3 \\ \text{SC}^2\text{H}^3 \end{smallmatrix} = 1.035$
$\text{CO} \begin{smallmatrix} \text{OC}^2\text{H}^3 \\ \text{SC}^2\text{H}^3 \end{smallmatrix} = 1.0285$	$\text{CS} \begin{smallmatrix} \text{OC}^2\text{H}^3 \\ \text{SC}^2\text{H}^3 \end{smallmatrix} = 1.035$
$\text{CS} \begin{smallmatrix} \text{OC}^2\text{H}^3 \\ \text{OC}^2\text{H}^3 \end{smallmatrix} = 1.0325 ?$	$\text{CS} \begin{smallmatrix} \text{SC}^2\text{H}^3 \\ \text{SC}^2\text{H}^3 \end{smallmatrix} = 1.152$

Carbonyl-thioethyl Chloride, $\text{CO}(\text{SC}^2\text{H}^3)\text{Cl}$, is formed by the action of carbonyl chloride on mercaptan. On saturating mercaptan with the gas and leaving it at rest, the evolution of hydrogen chloride begins after a few hours, and continues till the following day; and the liquid, on subsequent distillation, yields considerable quantities of carbonyl-thioethyl chloride. The formation of this compound is represented by the equation:

Carbonyl-thioethyl chloride is a colourless strongly refracting liquid, which emits a tear-exciting vapour. It has a density of 1.154 at 16°, and boils at 136°. Treated with *potassium ethylate*, it yields carbonyl-oxythiodiethyl. With aqueous or alcoholic ammonia it forms a crystalline non-sulphuretted body, not yet examined; but when a strong current of gaseous ammonia is passed over the chloride, it solidifies to a crystalline mass, separable by ether into sal-ammoniac, which remains undissolved, and a body which dissolves in the ether and separates therefrom in large dazzling white tablets. This body is thio-ethyl carbamate, $\text{C}^2\text{H}^3\text{NSO} = \text{CO}(\text{SC}^2\text{H}^3)\text{NH}^2$. It is readily soluble in alcohol, ether, and hot water, insoluble in cold water. Heated with potash-ley, it is resolved into carbon dioxide, ammonia, and mercaptan; by prolonged contact with alcoholic ammonia into mercaptan and carbamide.

The boiling point of carbonyl-thioethyl chloride (136°) differs from that of carbonyl-oxyethyl chloride or ethyl chlorocarbonate, $\text{CO}(\text{OC}^2\text{H}^3)\text{Cl}$ (94°), by nearly the same amount as that which exists between the boiling points of the above-described thiocarbonic ethers and the corresponding carbonic ethers (p. 1961), viz. 42°. The specific gravities of thio- and oxychlorides also differ by the same amount as those of the corresponding thio- and oxycarbonic ethers, viz. by about 0.05 (Salomon, *J. pr. Chem.* [2], vii. 252).

The following methylic and ethyl-methylic thiocarbonates have been prepared by Salomon a. Manitz (*J. pr. Chem.* [2], viii. 114):

1. *Thiocarbonyl-oxyethylthiethyl*, $\text{CS} \begin{smallmatrix} \text{OCH}^3 \\ \text{SC}^2\text{H}^3 \end{smallmatrix}$, obtained by the action of ethyl iodide on potassium methylxanthate, $\text{CS}(\text{OCH}^3)\text{SK}$, is a liquid closely resembling ordinary xanthic ether in colour and odour, boiling at 184°, and having a density of 1.12 at 18°. With alcoholic potash it is resolved into methylxanthamide (m. p. 45°) and mercaptan:

On adding potassium ethylate (2 vol.) to the ether (1 vol.) diluted with alcohol, the potassium salt, $\text{CO} \begin{smallmatrix} \text{OC}^2\text{H}^3 \\ \text{SK} \end{smallmatrix}$, separates in slender needles. The decomposition is represented by the following equation:

2. The isomeric ether, $\text{CS} \begin{smallmatrix} \text{OC}^2\text{H}^3 \\ \text{SCH}^3 \end{smallmatrix}$, formed by the action of methyl iodide on potassium ethylxanthate, resembles the preceding in all its physical properties, and is decomposed in the same manner by potassium ethylate, yielding the salt $\text{CO}(\text{OC}^2\text{H}^3)\text{SK}$. By alcoholic ammonia, on the other hand, it is converted into xanthamide, $\text{CS}(\text{OC}^2\text{H}^3)\text{NH}^2$, and methyl mercaptan:

3. *Thiocarbonyl-oxyethyl-thiomethyl*, or *Dimethyl Xanthate*, $\text{CS} \begin{smallmatrix} \text{OCH}^3 \\ \text{SCH}^3 \end{smallmatrix}$, produced by the action of methyl iodide on potassium methylxanthate, is a faintly coloured, somewhat strongly refractive liquid, having a density of 1.176 at 18°

and boiling at 167°–168°. With ammonia it yields methyl-xanthamide, $\text{CS}(\text{OCH}^3)\text{NH}^2$ (m. p. 43°); with potassium ethylate, the ethyl compound $\text{CO}(\text{OC}^2\text{H}^5)\text{SK}$.

The peculiar action of potassium ethylate on these ethers, leading in all cases to the formation of an ethyl-compound as final product, is repeated in the action of potassium methylate on the ethylic ethers $\text{CS}(\text{OC}^2\text{H}^5)(\text{SC}^2\text{H}^5)$ and $\text{CS}(\text{OC}^2\text{H}^5)(\text{SCH}^3)$, whereby in each case the salt $\text{CO}(\text{OCH}^3)\text{SK}$ is obtained in tufts of needles having a vitreous lustre:

the ethyl in the group OC^2H^5 being replaced by methyl. Hot alcohol also acts in a similar manner, converting the last-mentioned salt $\text{CO} \begin{smallmatrix} \text{OCH}^3 \\ \text{SK} \end{smallmatrix}$ into $\text{CO} \begin{smallmatrix} \text{OC}^2\text{H}^5 \\ \text{SK} \end{smallmatrix}$, whereas with methyl alcohol the reverse action is not produced (Salomon).

Carbonyl-dithio-dipseudopropyl or *Dithiopseudopropyl Carbonate*, $\text{CO}[\text{SCH}(\text{CH}^3)^2]^2$, formed by the action of strong sulphuric acid on pseudopropyl mercaptan, is a liquid having a repulsive alliaceous odour, and converted by hydrogen sulphide into *perthiopseudopropylurethane*, $\text{CS}(\text{SC}^3\text{H}^7)\text{NH}^2$, which crystallises from alcohol and ether in laminae having a splendid silky lustre and melting at 97° (Gerlich, *Ber.* viii. 650).

THIOCUMYLAMIDE, or THIOCUMINAMIDE,

$\text{C}^{20}\text{H}^{13}\text{NS} = \text{C}^6\text{H}^{11}\text{CS.NH}^2$. This compound is acted upon by iodine in the same manner as thiobenzamide (vi. 358). On mixing the two substances in alcoholic solution, decoloration immediately takes place, sulphur is separated, and hydriodic acid is formed; and if the addition of iodine be continued till an excess of it is indicated by addition of starch-solution, and the alcohol be then distilled off, there remains a brownish oil, which, when washed with ammoniacal water, decanted from the latter, and stirred for some time with a glass rod, solidifies to a white amorphous mass, contaminated with sulphur, which is difficult to separate. When freed from this impurity by a somewhat circuitous process, the product is obtained in the form of transparent colourless prisms several lines long, and melting at 45°. It has the composition

and its formation is represented by the equation:

It is insoluble in water, soluble in ether, alcohol, chloroform, carbon sulphide, benzene, and strong sulphuric acid, and is separated from the last-mentioned solvent by water in its original state. By prolonged boiling with strong potash- or soda-ley, it is resolved into sulphur and cumonitril, $\text{C}^6\text{H}^{11}\text{N}$, which latter, by assumption of the elements of water, is converted into ammonia and cumic acid. Thiocumylamide is not attacked by dilute alkalis or by lead oxide (R. Wanstrat, *Ber.* vi. 332).

THIOCYANATES, CN.S.R. See pp. 602–606. On the preparation of Metallic Thiocyanates on the large scale, see Tcherniak a. Grünzburg (*Jahresb. f. Chem.* 1878, 1123).

On Alcoholic Isothiocyanates or Thiocarbimides, $\text{CS}=\text{N.R.}$, see pp. 606–608, and 1958–1960.

THIOCYMENE, $\text{C}^{10}\text{H}^{13}\text{SH.}$ See CYMENE-MERCAPTAN (p. 623).

THIODICYANODIAMINE, $\text{C}^2\text{H}^6\text{N}^4\text{S} = \text{NH}^2.\text{CS.NH.C}(\text{NH})\text{NH}^2$. This compound is formed by the action of thiocarbonyl chloride, CSCl^2 , or of phosphorus pentachloride, on thiocarbamide. The reaction with PCl^5 is represented by the equation:

Thiodicyanodiamine is a base forming transparent monoclinic crystals, which dissolve in water, sparingly in alcohol, and yield a strongly alkaline solution. When heated above 100°, it melts and is completely transformed into the isomeric guanidine thiocyanate, $\text{HN}=\text{C}(\text{NH}^2)^2.\text{HCNS.}$

The *hydrochloride*, $\text{C}^2\text{H}^6\text{N}^4\text{S.HCl}$, forms fine transparent rhombic crystals, which dissolve freely in water and alcohol. The *platinochloride* is an amorphous dark-coloured salt. The *oxalate*, $\text{C}^2\text{H}^6\text{N}^4\text{S.C}^2\text{H}^2\text{O}^4 + \frac{1}{2}\text{H}^2\text{O}$, forms small granular crystals, sparingly soluble in water. Both salts have an acid reaction (Rathe, *Ber.* xi. 962).

THIODIETHYLOXAMIDE, $C^6H^{12}N^2S^2 = (C^2H^5)HN(CS)^2NH(C^2H^5)$ (Wallach & Pirath, *Ber.* xii. 1063). When diethyloxamide is mixed with phosphorus pentachloride, the mixture first liquefies, and if it be then gently warmed, gives off a large quantity of hydrogen chloride. If now the operation be interrupted at the first stage, and hydrogen sulphide be passed into the well-cooled liquid diluted with benzene, till hydrogen chloride ceases to be given off, thiodiethyloxamide will be formed, and will separate, as the benzene evaporates, in large, reddish-yellow, transparent plates. In the formation of this compound the oxygen of the diethyl-oxamide is first replaced by chlorine, and the resulting amidochloride is then decomposed by the hydrogen sulphide, as represented by the equation:

Thiodiethyloxamide melts at 54° . Treated with sodium ethylate and ethyl bromide it yields an oily liquid, which boils at a temperature above 250° , and probably has the composition $(C^2H^5)N=(CSC^2H^5)^2=N(C^2H^5)$, but it has not been obtained in the pure state.

By treating the product of the action of phosphorus pentachloride on *oxanilide* with hydrogen sulphide, a compound is obtained which crystallises from ethereal solution in golden-yellow plates.

THIODIGLYCOLLIC ACID, $C^4H^6SO^4$ (*infra*).

THIOFORMANILIDE, $C^6H^7NS = C^6H^5.NH.CSH$, is produced: 1. By the action of phosphorus pentasulphide on formanilide or aniline formate. 2. By the action of dry hydrogen sulphide on phenyl-carbimide, $C^6H^5.NC + H^2S = C^6H^5.NH.CSH$. 3. Together with large quantities of methenyldiphenyl-diamine, $C^6H^{12}N^2$ (p. 1302), when a saturated alcoholic solution of potassium hydrosulphide is added to a well-cooled alcoholic solution of aniline (1 mol.), chloroform (1 mol.), and potassium hydroxide (3 mol.) The liquid, after standing for a few hours, is mixed with water, the golden-yellow oil thereby separated (consisting of thioformanilide-methenyldiphenyldiamine, phenylcarbimide, aniline, and chloroform) is treated with hydrochloric acid; and after the chloroform has been evaporated by exposure to the air, the mass, which has now become crystalline, together with the crystals obtained from the mother-liquor of the oil after supersaturation with hydrochloric acid, is recrystallised as quickly as possible from boiling water. The filtered liquid on cooling deposits thioformanilide in thin laminæ, while methenyldiphenyldiamine hydrate remains in the mother-liquor. The thioformanilide is purified by dissolving it in boiling alcohol, and adding hot water to the solution till it begins to show turbidity. The liquid on cooling deposits the thioformanilide in long white needles which melt at 137.5° , decomposing at the same time into phenylcarbimide and hydrogen sulphide. Its solutions taste intensely bitter. It dissolves without alteration in cold potash-ley, and is precipitated therefrom by acids; but hot potash-ley decomposes it into formic acid, aniline, and hydrogen sulphide (A. W. Hofmann, *Ber.* x. 1095).

THIOGLYCOLLIC ACID, $C^2H^4O^2S = CH^2(SH).COOH$. This acid, already described (p. 884), is one of the products of the action of phosphorus pentachloride on sulphacetic acid (R. Siemens, *Ber.* vi. 659).

Thiodiglycollic Acid, $C^4H^6SO^4 = S \begin{smallmatrix} CH^2.COOH \\ CH^2.COOH \end{smallmatrix}$ [v. 776]. The calcium salt of this acid is produced by the action of recently prepared calcium sulphhydrate on monochloroacetic acid [perhaps thus:

After the two solutions have been boiled together in a reflux apparatus for eight hours, while a slow stream of hydrogen sulphide is passed through the liquid, the excess of calcium sulphhydrate is decomposed by carbonic acid, the filtrate evaporated to the crystallising point, and the separated crystalline mass is freed from calcium chloride by means of hot strong alcohol, and recrystallised from water. The calcium salt thus obtained, $C^4H^4SO^4Ca$, dissolves in 48.6 pts. water at 21° , somewhat more readily in boiling water. Its solution is not precipitated by barium chloride. With *lead acetate* it gives a white precipitate which dissolves on boiling, and is also soluble in nitric acid; with *silver nitrate* a white precipitate, which is easily soluble in nitric acid and in ammonia, and does not turn perceptibly brown when boiled with water; but on adding a little ammonia to the water, the odour of ammonium sulphide becomes perceptible and silver sulphide is separated. *Mercuric chloride* also gives with the solution of the calcium salt a white precipitate which does not dissolve on boiling. The mother-liquor obtained in the preparation of the calcium salt contains calcium thioglycollate (C. Schreiber, *J. pr. Chem.* [2], xiii. 436).

According to Böttiger (*Ber.* xi. 1899), the action of hydrogen sulphide on glyoxylic acid in presence of silver oxide, produces simultaneously thioglycollic and thiodiglycollic acids, which may be separated by converting them into ethylic ethers, and fractionally distilling the product, whereupon one portion passes over at 160° and the other at 260°.

Diethyllic Thiodiglycollate, $S(CH_2.CO^2C^2H^3)^2$, is formed by the action of methyl sulphide on ethyl iodacetate, which appears to take place by two stages, thus:

(Letts a. Collie, *Edinb. Roy. Soc. Trans.* xxviii. pt. 2, p. 583).

Thiodiglycollamide, $S[CHNH^2.COOH]^2$, crystallises in acute square pyramids with very distinct basal cleavage (Arzruni, *Zeitschr. Kryst.* i. 447).

Nitrosothiohydantoïn, $C^3H^3(NO)N^2OS$, may be prepared by treating thiohydantoïn with nitric acid of sp. gr. 1.2, or by passing nitrous gas through a mixture of thiohydantoïn and water. It separates out as a crystalline powder, and may be obtained in microscopic pyramids by recrystallisation from a large quantity of boiling water. It is soluble in alkalis, but insoluble in alcohol, ether, carbon sulphide, and hydrocarbons. With 1 equiv. of an alkali it yields a red solution, but if 2 equiv. of alkali are used, a yellow solution is formed which turns red on addition of an acid.

When *barium chloride* is added to a solution of nitrosothiohydantoïn in ammonia, glistening yellow hexagonal and rhombic plates separate out, having the composition $C^3H^3(NO)N^2OS.BaH^2O^2.H^2O$. This compound is but very slightly soluble in cold water, and is partly decomposed by recrystallisation from hot water. On the addition of an acid it yields a red barium-compound, which is soluble in water, but has not been obtained in the pure state. The red solution gives a yellowish-red precipitate with lead acetate, orange-coloured with zinc chloride and mercuric chloride, dark-red with silver nitrate. On adding silver nitrate to an ammoniacal solution of nitrosohydantoïn slightly acidulated with acetic acid, the compound $C^3H^2(NO)AgN^2OS.Ag^2O$ separates as a dark reddish-brown precipitate. A similar compound is formed with ferrous salts (R. Maly, *Ber.* xii. 967).

THIOHYDROBENZOIC ACID. Syn. with THIOBENZOIC ACID, $C^6H^4(SH).COOH$. See BENZOIC ACIDS (p. 297).

THIOLACTIC ACID, $C^3H^5SO^2 = C^3H^4(SH).COOH$ (C. Böttiger, *Ber.* ix. 404, 804, and 1061; xi. 1561). This acid is formed: 1. By decomposing the silver salt of α -chloropropionic acid with hydrogen sulphide:

This reaction determines the constitution of the acid.

2. By similar treatment of silver pyroracemate. The pyroracemate suspended in water is decomposed by hydrogen sulphide, and the liquid, when saturated with the gas, is left to itself for a week, then filtered, and the filtrate is concentrated by distillation. Acetic acid then passes over, and the remaining liquid, freed from precipitated silver and silver sulphide, is repeatedly agitated with ether. The oily ether-residue spread out in a thin layer, changes in the course of a fortnight into a crystalline crust of thiolactic acid, greasy to the touch, which may be purified by repeated crystallisation.

Thiolactic acid crystallises from aqueous solution in groups of transparent rectangular plates. It dissolves with extraordinary facility in hot water, much less easily in cold water, very sparingly in dilute sulphuric acid, and crystallises therefrom in prismatic needles melting at 141°. These properties, however, are considerably modified by the smallest quantities of impurities, the melting point even by the presence of moisture. The solution of the acid nearly neutralised with ammonia gives with *lead acetate* and *mercuric chloride* precipitates which are quite insoluble in water, but soluble in acids; the dilute solution of the free acid gives a similar precipitate with *mercury nitrate*; with *lead acetate* and *mercuric chloride* it gives either no precipitate, or precipitates which after a while are redissolved. When the acid is oxidised by dilute *chromic acid*, a small quantity of sulphur is precipitated on gentle heating, and on boiling the liquid, sulphuric, acetic, and carbonic acids are formed.

When hydrogen sulphide is passed into pure pyroracemic acid, a compound of

lactic and thiolactic acids is produced, and in such quantity that the whole solidifies to a thick white pulp. This compound, when washed with ether and dried in the exsiccator, has the composition $C^6H^8SO^3 = C^2H^4O^3 + C^4H^4SO^2$. It begins to melt at 87° , decomposing at the same time, the portion which remains solid being somewhat sparingly soluble in cold water. The compound when kept in a tightly-closed bottle is converted within a week into an oil, with evolution of hydrogen sulphide. If the precipitate formed by hydrogen sulphide in pyroracemic acid be left for some time in contact with the liquid, or if the passage of the gas be prolonged, the precipitate redissolves, being probably converted into thiolactic acid, which however is more readily produced from the solid body by heating with hydriodic acid.

THIONESSAL, C^2H^2S (vi. 1087). This compound is formed, together with others, by the action of heat on benzyl sulphide, and is easily separated from the portion of the product which passes over between 360° and 460° , by fractional distillation, and crystallisation from absolute alcohol of the fraction which distils between 440° and 460° . It forms closely felted groups of white brittle needles, melts at 184° , sublimes in needles without alteration, and boils at about 460° . It dissolves with moderate facility in ether and carbon sulphide, less easily in ligroin, very sparingly in alcohol. Its ethereal solution is not precipitated by bromine, and on evaporating the ether, needle-shaped crystals remain having the original melting point. When treated with chromic acid mixture, it blackens and yields carbonic and benzoic acids. It is not altered by boiling with alcoholic potash (C. Forst, *Liebig's Annalen*. clxxviii. 370).

THIONYL CHLORIDE, $SOCl_2$. Syn. with SULPHUROUS CHLORIDE (vii. 1131).

THIOPHENOL, $C^6H^5.SH$. *Phenyl Hydrosulphide* or *Phenyl-mercaptan* (p. 1546). This compound, treated with *sulphuric hydroxychloride*, is converted into phenyl disulphide:

(Beckurts a. Otto, *Ber.* xi. 2065).

Treated with *acetyl chloride*, it yields phenyl thiacetate, $C^6H^5.S.C^2H^3O$, a colourless liquid having an intensely mercaptan-like and at the same time ethereal odour, and boiling at 218° – 220° (corr. 227° – 229°). It sinks in water, and is at the same time slowly decomposed thereby, with formation of thiophenol. By boiling with strong potash-ley it is completely resolved into thiophenol and acetic acid. With *benzoyl chloride*, thiophenol forms a compound which crystallises in fine white prisms (Michler, *Ber.* vii. 1312).

THIOPHTHALIC ACIDS, $C^6H^4(COSH)(COOH)$. See PHTHALIC ACIDS (p. 1617).

THIOPRUSSIAMIC ACIDS. This name is given by Claus a. Seippel (*Ber.* vii. 233; *Liebig's Annalen*, clxxix. 184) to certain sulphuretted compounds, which are formed by the action of heat on ammonium thiocyanate, and may be regarded as products of decomposition intermediate between thiocarbamide and melam. The compounds which have been investigated are—a *dithioprussiamic acid*, $(NH^2)_2Cy^3.NH.Cy^3(SH)^2$, a *monothiodiaprussiamic acid*, and a *dithiotriprussiamic acid*, $NH^2.Cy^3.NH^2.NH.NH^2.Cy^3.NH.SHCy^3(SNH^4)$. The first of these acids gives no coloration with ferric chloride, the other two give the thiocyanate reaction. The precipitates formed in their concentrated solutions by *lead acetate* are soluble in boiling water, a property by which these acids are especially distinguished from other thiocyanogen compounds. With dilute hydrochloric or nitric acid all the three acids are resolved, even at ordinary temperatures, into melamine and a sulphuretted body (or several) not yet examined.

THIOQUINOL, $C^6H^4(SH)^2$ [1 : 4]. This compound is obtained by the action of tin and hydrochloric acid on benzeneparadisulphonic acid (p. 251), in the form of a crystalline sublimate consisting of shining hexagonal laminae; it separates also in the same form from boiling alcohol, in which it is slightly soluble. It smells somewhat like tropeolum, and melts at 98° . When exposed to the air it gradually oxidises to a yellow powder. Its lead-compound is an orange-red precipitate (Körner a. Monselise, *Gazz. chim. ital.* 1876, 133).

THIORESORCINOL, $C^6H^4(SH)^2$ [1 : 3], obtained in like manner from benzene-meta-disulphonic acid, exhibits the properties described by Patzschke (vii. 1156). It smells like the leaves of some kinds of geranium, melts at 27° , and boils at 240° (Körner a. Monselise, *loc. cit.*)

THIORUFIC ACID, $C^{10}H^{14}.S^2O^4$ (Norton a. Oppenheim, *Ber.* x. 685). An acid formed by the action of carbon bisulphide on the mixture of sodium ethylate and

ethyl acetosodacetate obtained by treating ethyl acetate with sodium (p. 11). The product, after washing with water, is a light yellow acid substance, nearly insoluble in water, and crystallising in scales having a dark orange-red colour and nacreous lustre. On evaporating its solution in alcohol or acetic ether, it is decomposed. Its *calcium salt*, $(C^6H^5S^2O^4)^2Ca$, crystallises in cherry-red needles. The *mercury, lead, and zinc salts* are orange-coloured; the *iron salt* brown, the *silver salt* red, the *copper salt* black.

The formation of the acid may be explained by supposing that the acetylated thiomalonic acid and sodium hydrosulphide, which might be expected to form in the first instance, separate out, and that the residues unite, thus:

THIOSULPHURIC ACID. See SULPHUR, ACIDS OF (p. 1879).

THIO- α -TOLYLAMIDE, $C^6H^5NS = C^6H^5 \cdot CH_2 \cdot CS \cdot NH_2$. See THIAMIDES (p. 1954).

THOMSONITE. This mineral, from the Palle Rabbiose, Monte Monzoni, has been analysed by Doelter a. John (*Vcrh. geol. Reichsanst.* 1875, 295, 304). The needle-shaped crystals analysed were intimately mixed with calcite, to the amount of 19 per cent., after deduction of which their analysis gave:

SiO ²	Al ² O ³	CaO	MgO	NaO	K ² O	H ² O
39.24	27.90	12.45	trace	7.95	0.60	11.86 = 100

THORIUM. This metal is not isomorphous with any other known element. A number of its compounds have lately been examined by P. T. Cleve (*Bull. Soc. Chim.* 1874, xxi, 116). The atomic weight was found, from the mean of six analyses of the anhydrous sulphate, to be 233.8; from the analyses of the oxalate, 233.97.

Thorium Oxide, or *Thoria*, obtained by ignition of the hydroxide, is insoluble in dilute acids, soluble in warm strong sulphuric acid. When the oxide obtained by ignition of the oxalate is heated with excess of nitric or hydrochloric acid, and the excess of the acid—which does not appear to dissolve or act in any way on the oxide—is expelled by heating on the water-bath, a residue is obtained which dissolves completely in water, the solution appearing white in reflected light, like milk and water or a solution of glycogen, and yielding, on addition of a little acid or salt solution, a curdy precipitate which redissolves in pure water. With ammonia the solution gives a bulky precipitate, which resembles thorium hydroxide, but is insoluble in acids even at the boiling heat. When hydrochloric acid is used for the preparation of the soluble body (in which case a certain quantity of the normal chloride is also produced), the precipitate formed by ammonia has the composition $Th^4O^7(OH)^2$. The normal hydroxide dried at 100° contains $Th(OH)^4$.

Thorium Chloride, $ThCl^4 \cdot 8H^2O$, obtained by decomposing the sulphate with barium chloride, forms white very deliquescent needles. *Thorium-potassium chloride*, $2ThCl^4 \cdot KCl \cdot 18H^2O$, forms colourless crystals easily soluble in water. The *platinochloride* has the composition $ThCl^4 \cdot PtCl^4 \cdot 12H^2O$.

Thorium Silicofluoride, obtained by treating the hydroxide with silicofluoric acid, is a crystalline semi-transparent mass, insoluble in excess of silicofluoric acid; when left over sulphuric acid, it gives off hydrogen fluoride and silicon fluoride.

Thorium Platinocyanide, $ThPt^2Cy^6 \cdot 16H^2O$, crystallises in yellowish-green well-defined orthorhombic prisms, very soluble in hot, sparingly in cold water; gives off $14H^2O$ at 100° or over sulphuric acid. The *ferrocyanide*, $ThFeCy^6 \cdot 4H^2O$, is a white powder. The *thiocyanate* is obtained as a viscid mass by evaporating a solution of thorium hydroxide in thiocyanic acid. Its solution gives with mercuric cyanide an amorphous precipitate consisting of $Th(OH)^2SCy \cdot HgCy^2 \cdot H^2O$, and the filtrate on cooling deposits nacreous scales of the salt $Th(OH)(SCy)^3 \cdot 3HgCy^2 \cdot 12H^2O$.

Thorium Nitrate, $Th(NO^3)^4 \cdot 12H^2O$, forms large, transparent, very hygroscopic tablets, which give off $8H^2O$ over sulphuric acid. The *chlorate* and *perchlorate* are hygroscopic soapy masses. The solution of the *bromate* decomposes when evaporated in a vacuum. The *iodate*, $Th(IO^3)^4$, is a white amorphous precipitate.

Thorium-sodium Carbonate, $Th(CO^3)^2 \cdot 3Na^2CO^3 \cdot 12H^2O$, is a white amorphous precipitate.

Thorium Sulphate, $\text{Th}(\text{SO}_4)_2 \cdot 9\text{H}_2\text{O}$, forms monoclinic crystals very slightly soluble in water, insoluble in alcohol; gives off $7\text{H}_2\text{O}$ over sulphuric acid. Sulphates have also been obtained containing 8 and 3 mol. H_2O . *Thorium-sodium sulphate*, $\text{Th}(\text{SO}_4)_2 \cdot \text{Na}_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$, forms thin needles. *Thorium-ammonium sulphate*, $\text{Th}(\text{SO}_4)_2 \cdot (\text{NH}_4)_2\text{SO}_4$, prisms soluble in water and in ammonium sulphate. *Thorium sulphite* has the composition $\text{Th}(\text{SO}_3)_2 \cdot \text{H}_2\text{O}$.

Thorium Selenate, $\text{Th}(\text{SeO}_4)_2 \cdot 9\text{H}_2\text{O}$, forms bulky crystals permanent in the air, giving off $8\text{H}_2\text{O}$ at 120° . The *selenite*, $\text{Th}(\text{SeO}_3)_2 \cdot \text{H}_2\text{O}$, is a white amorphous precipitate insoluble in water.

Phosphates.—The *orthophosphates*, $\text{ThH}_2(\text{PO}_4)_2 \cdot \text{H}_2\text{O}$ and $\text{ThH}_2(\text{PO}_4)_2 \cdot 4\text{H}_2\text{O}$, are bulky precipitates. The *pyrophosphate* has the composition $\text{ThP}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$. *Thorium-sodium pyrophosphate*, $\text{ThNa}_4(\text{P}_2\text{O}_7)_2$, crystallises with 2 mol. H_2O .

Thorium Formate, $\text{Th}(\text{CHO}_2)_4 \cdot 3\text{H}_2\text{O}$, forms flat well-defined prisms which give off $2\text{H}_2\text{O}$ over sulphuric acid, and $3\text{H}_2\text{O}$ at 100° . The *acetate* forms microscopic needles. The *oxalate*, $\text{Th}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$, is insoluble in water. *Thorium-sodium oxalate*, $\text{Th}(\text{C}_2\text{O}_4)_2 \cdot 2\text{K}_2\text{C}_2\text{O}_4 \cdot 4\text{H}_2\text{O}$, is decomposed by water. *Thorium tartrate*, $(\text{C}_4\text{H}_4\text{O}_4)_4 \cdot \text{Th}^2(\text{OH})_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, is a white powder which gives off all its water at 100° . *Thorium-potassium tartrate* has the composition $\text{ThK}_2(\text{C}_4\text{H}_4\text{O}_6)_3$.

THYMOHYDROXYCUMIC ACID, $\text{C}^{10}\text{H}^{12}\text{O}^3$ (L. Barth, *Ber.* xi. 567, 1571). This acid is formed, together with others, by fusing thymol with potassium hydroxide. On dissolving the melt in water, acidulating with sulphuric acid, extracting with ether, and distilling the residue with water, acetic acid passes over with the steam, and the residue of the distillation deposits on cooling crystals (mixed with a little tar) which, by repeated crystallisation from water, may be resolved, though not completely, into: (1) hydroxyterephthalic acid, very slightly soluble even in hot water; (2) thymohydroxycumic acid, moderately soluble in hot, very sparingly in cold water; and (3), an easily soluble portion, consisting of substances precipitable by lead acetate, together with a small quantity of hydroxybenzoic acid.

Thymohydroxycumic acid, after repeated crystallisation with animal charcoal, forms long, thin, colourless, somewhat fragile needles melting at 143° , or sometimes at 141° ; very soluble in ether, alcohol, chloroform, and benzene; dissolving also in water as above stated. The aqueous solution is not perceptibly coloured by ferric chloride, and gives no precipitate with lead acetate. The normal salts have a slight acid reaction. The *normal sodium salt*, $\text{C}^{10}\text{H}^{11}\text{O}^3\text{Na}$, $2-2\frac{1}{2}\text{H}_2\text{O}$, crystallises in broadly laminar masses, sometimes also in well-formed plates. It is very efflorescent and very soluble in water. The *basic sodium salt*, $\text{C}^{10}\text{H}^{10}\text{O}^3\text{Na}^2$, is a very deliquescent crystalline mass composed of microscopic needles. After drying in a vacuum over sulphuric acid, it still retains $1\frac{1}{2}\text{H}_2\text{O}$. The *barium salt*, $(\text{C}^{10}\text{H}^{10}\text{O}^3)_2\text{Ba}$ (at 130°), is easily soluble in water and separates from its solution, when concentrated, in granulo-crystalline masses, seldom in small prisms. The *cadmium salt*, $(\text{C}^{10}\text{H}^{10}\text{O}^3)_2\text{Cd}$, forms microscopic plates, rarely prisms, and generally contains 1 mol., sometimes 3 mol., water; it is moderately soluble in alcohol and in ether. The *ethyl ether*, $\text{C}^{10}\text{H}^{11}\text{O}^3 \cdot \text{C}_2\text{H}_5$, prepared with alcohol and gaseous hydrogen chloride, is at first liquid, but subsequently solidifies and then melts at $73^\circ-75^\circ$. From dilute alcohol it separates first in oily drops, afterwards in long prisms.

Thymohydroxycumic acid is not at all or but slightly attacked by strong hydrochloric acid at $200^\circ-250^\circ$, but at 250° further action takes place. The acid heated by itself above 300° partly volatilises undecomposed, and is partly resolved into water and the anhydride $\text{C}^{10}\text{H}^{22}\text{O}^5$, which remains as a mass resembling colophony, and likewise separates in the amorphous state from solution in alcohol. The acid heated with quick lime yields phenolic and anisöilic products, but neither propyl-phenol nor methyl-ethyl-phenol. By the further action of melting potash it is converted into hydroxyterephthalic acid, together with an easily soluble acid which gives a red coloration with ferric chloride, and is precipitated by acetate of lead.

The constitution of thymohydroxycumic acid has not been definitely established, but it may be represented either by the formula $\text{C}^6\text{H}^3(\text{CO}^2\text{H})(\text{OH})(\text{C}^4\text{H}^4)$, or by $\text{C}^6\text{H}^3(\text{CH}^1)(\text{OH})(\text{C}^4\text{H}^4\text{O}^2)$.

Dibromthymohydroxycumic acid, $\text{C}^{10}\text{H}^{10}\text{Br}^2\text{O}^3$, the chief product of the action of bromine on thymohydroxycumic acid, melts under water, dissolves but sparingly therein; is very soluble in alcohol, even when dilute, and separates therefrom as an oil which solidifies in the crystalline form only after the solvent has been completely expelled by evaporation. The further action of bromine gives rise to bromophenol.

THYMOL, $C^{10}H^{14}O = C^6H^3(OH)(C^3H^7)(CH^5)$. See PHENOLS (p. 1544).

On the Violet Dye produced by the action of Nitrous Acid on Thymol, see DYE-STUFFS (p. 698).

THYMOQUINONE, $C^{10}H^{12}O^2$ (vii. 1156). This compound is formed by oxidising methyl-thymol dissolved in acetic acid with chromic acid mixture:

(Paternò, *Ber.* viii. 440). It may be advantageously prepared by distilling amidothymol (from nitrosothymol) with ferric chloride, the yield exceeding 50 per cent. (Armstrong, *Ber.* x. 297).

Thymoquinone is acted upon by normal potassium sulphite at 60°, the liquid on cooling solidifying to a mass of splendid crystals, which must be separated from the now strongly alkaline liquid, washed with a small quantity of ice-cold water, and quickly dried by pressure. The air-dried salt has the composition $C^{10}H^{12}O^5K$, and is formed according to the equation:

Its rational formula is either

(potassium hydrothymoquinonesulphonate), the latter being the more probable of the two. *Ferric chloride* colours the aqueous solution first emerald-green, then golden-yellow. *Lead acetate* forms with it a white flocculent precipitate insoluble in acetic acid, soluble in nitric acid; *silver nitrate*, a white precipitate, which soon turns black, and forms a silver speculum when heated. The salt boiled with hydrochloric acid yields sulphuric acid and thymoquinol:

Caustic alkalis induce the absorption of oxygen from the air, whereby hydroxythymoquinone is produced:

Polythymoquinone. Thymoquinone, when exposed to light, especially in thin layers, is converted into a polymeric modification, which dissolves but sparingly in all solvents, especially in ether. From alcohol it crystallises in long light yellow inodorous silky needles, which greatly resemble anthraquinone, and melt at 200°–201°. Strong sulphuric acid dissolves it without alteration at ordinary temperatures, but acts upon it at higher temperatures in the same manner as on thymoquinone. Bromine dissolved in water or in acetic acid attacks it but slightly even when heated; water, aqueous sulphurous acid, and acetic anhydride do not act upon it even at 180°. Fuming nitric acid dissolves it, but does not decompose it even at the boiling heat. By boiling it with hydriodic acid (sp. gr. 1.7) and red phosphorus, it is converted into thymoquinone; also by addition of hydrochloric acid and zinc-dust to its boiling alcoholic solution (Armstrong, *Ber.* x. 297).

Hydroxythymoquinone, $C^{10}H^{11}(OH)O^2$, is formed, as above mentioned, by the action of atmospheric oxygen on an alkaline solution of thymoquinone; also, together with dihydroxythymoquinone, by reduction of ethyl-dinitrothymol with tin and hydrochloric acid. To separate it, the tin is precipitated by hydrogen sulphide, the filtrate evaporated, and the residue crystallised from strong hydrochloric acid. The crystals, freed as far as possible from hydrochloric acid, yield by distillation with a dilute aqueous solution of ferric chloride in a current of steam, a product of oxidation which collects in the receiver, and is found to consist of hydroxythymoquinone, melting at 169°–172° (Ladenburg a. Engelbrecht, *Ber.* x. 1218).

Carstanjen, who first obtained hydroxythymoquinone by the process above mentioned, and found its melting point to be 187°, is of opinion that the differences of melting point observed by himself and by Ladenburg may be due to the formation of two isomeric compounds in the above reaction. These compounds may indeed be separated to a certain extent by sublimation, the product thereby obtained consisting partly of light orange-coloured needles melting at 169°–175° (or even at 165°–166°), partly of red needles which do not melt below 183° or even 221° (*J. pr. Chem.* [2], xv. 398). Ladenburg, on the other hand (*Ber.* x. 49), ascribes the observed differences of melting point to contamination of the monohydroxythymoquinone with the dihydroxy-compound, or perhaps to the existence of a polymeric modification analogous to that of thymoquinone itself (*supra*).

Chlorohydroxythymoquinone, $C^{10}H^{10}(OH)ClO^2$, is prepared by acting on

dinitrothymol with phosphorus pentachloride, reducing the product with tin and hydrochloric acid, and oxidising the resulting amido-compound with chromic acid. 20 to 25 g. dinitrothymol are mixed in a beaker with twice the quantity of phosphorus pentachloride, and the mixture is gradually heated to 115°-120° till the reaction begins; the heating is then discontinued as long as the reaction goes on briskly without it; and the process is terminated by renewed heating, finally to the boiling point. The phosphorus oxychloride thereby produced is distilled off in an oil-bath; the residue is poured into water; and the precipitated viscid mass, after being washed with sodium carbonate and with water, is several times crystallised from alcohol with addition of animal charcoal. The dinitrochlorocymene, $C^{10}H^{11}(NO_2)_2Cl$, thus obtained (light yellow prisms melting at 100°-101°), is reduced by tin and hydrochloric acid, in small quantities at a time, and at the lowest possible temperature; and the resulting hydrochloride of diamidochlorocymene, after being freed from tin, and evaporated to dryness, is oxidised with a mixture of 2 pts. potassium dichromate and 3 pts. strong sulphuric acid,—about 3 g. of the amido-compound dissolved in a large quantity of water being distilled with the oxidising mixture, likewise diluted with a large quantity of water. The substance which then separates from the water in the receiver may be separated by fractional crystallisation into hydroxythymoquinone and an easily soluble chlorinated body, which latter may be purified by long-continued sublimation on the water-bath in watch-glasses covered with inverted beakers. The first sublimates thus obtained are nearly free from chlorine; and on continuing the sublimation till the sublimate and residue are found to melt at the same temperature (120°-122°), and crystallising the residue from alcohol, chlorohydroxythymoquinone is obtained, nearly pure, in lemon-yellow prisms, easily soluble in alcohol and ether, melting at 122°, and easily sublimable (Ladenburg a. Engelbrecht, *Ber.* x. 1218).

Dihydroxythymoquinone, $C^{10}H^{10}(OH)_2O^2$, is produced by boiling a solution of chlorohydroxythymoquinone in potash, and is obtained by treating the solution with excess of hydrochloric acid, and repeatedly crystallising the resulting precipitate from alcohol, in cherry-red prisms. It melts at 220°, sublimes undecomposed, is sparingly soluble in alcohol, very sparingly in water. Ammonia and potash dissolve it with violet colour. The dilute ammoniacal solution is not precipitated by barium chloride, nor the potash-solution by alum (Ladenburg a. Engelbrecht, *loc. cit.*)

The same *dihydroxythymoquinone* is formed as a bye-product in the preparation of monohydroxythymoquinone (*supra*), and is also formed by treating the mono-derivative successively with ethyl iodide and potash; or better by boiling a concentrated solution of the mono-derivative with potash till the original violet colour of the solution is completely changed to brown-red, then precipitating with hydrochloric acid, and crystallising the precipitate from alcohol (Ladenburg a. Engelbrecht),

TIGLIC ACID, $C^8H^8O^2$. The supposition of Geuther a. Fröhlich (vii. 395) that this acid—one of the products of the saponification of croton oil—is identical with methyl-crotonic acid, $CH^3.CH=C(CH^3).COOH$, has been confirmed by the experiments of E. Schmidt (*Ber.* x. 835). The two acids agree in crystalline form and optical properties, melt at 64°, and boil between 196° and 197°; their barium and calcium salts also agree in character. Both acids fused with potassium hydroxide yield propionic and acetic acids. Bromine converts them both into dibromovaleric acid; with hydriodic acid they yield iodovaleric acid. According to Schmidt a. Berendes (*Liebig's Annalen*, xcvi. 94), *barium tiglate* forms nodular groups of small laminar crystals, but sometimes crystallises in more compact form; it has the composition $(C^8H^7O^2)^2Ba.4H^2O$, and effloresces easily. The *calcium salt*, $(C^8H^7O^2)^2Ca.3H^2O$, forms laminae or stellate groups of small white opaque needles, and is less soluble in water than the barium salt.

In the portions of croton-oil boiling at higher temperatures than tiglic acid, Schmidt found a liquid having the composition $C^8H^{10}O^2$. The portion of the oil boiling between 174°-175° gave with lime a crystallised salt, consisting of a compound of valerate and tiglate of calcium.

Tiglic acid is also produced, together with angelic acid, by saponification of Roman chamomile oil, and, as observed by Demarçay (p. 86), by the action of heat or of strong sulphuric acid on angelic acid. The acid obtained from Roman chamomile oil melts at 64.5°, and boils at 198.5°. Its *calcium salt*, $(C^8H^7O^2)^2Ca.3H^2O$, crystallises in white laminae, which dissolve sparingly in cold and freely in boiling water. The *barium salt*, $(C^8H^7O^2)^2Ba.4H^2O$, is more soluble than the calcium salt, but much less soluble than the corresponding salt of angelic acid. It forms small hard prismatic crystals. The *silver salt* is less soluble than that of angelic acid, but may be crystallised from boiling water in small white feathery groups. The *potassium salt* crystallises readily in tufts of small needles which are not deliquescent (H. Kopp, *Liebig's Annalen*, ccxv. 81).

TIMBO. The root bark of the Timbo tree (*Paullinia pennata*, Linn.) contains starch, a resin, a volatile oil, tannin, an organic acid, traces of grape-sugar, and an alkaloid called *timbonine*, the sulphate of which crystallises in white needles (Martin, *Pharm. J. Trans.* [3], vii, 1020).

TIN. *Occurrence.*—Lockyer has observed in the solar spectrum a line indicating the presence of tin in the sun (*Proc. Roy. Soc.* xxvii, 279). Metallic tin in small laminae has been found by Frenzel (*Jahrb. f. Min.* 1873, 802) in bismuth-spar from Mexico.

In the form of stannic oxide, SnO_2 , tin occurs in various lithia-micas, as in the lepidolite of Paris in the State of Maine, and of Rozena in Moravia, the silica of these minerals being partly replaced by the stannic oxide (Sandberger, *Jahrb. f. Min.* 1878, 291, 657).

Stannic oxide (tinstone) occurs in the kaolins of the Department Allier in France. The levigated sand contains 18·3 per cent. SnO_2 , together with a small quantity of titanic iron; the unlevigated sand 0·05 per cent. Moreover, the rocks from which the kaolin has been formed contain tin; thus a quartz-like rock occurring in veins was found to contain 0·02 per cent., and a hornblende rock 0·04 per cent. tin (De Gouvenain, *Compt. rend.* lxxviii, 1032).

Two samples of tinstone from the mines of Lampiglia in Tuscany, which were worked by the ancient Etruscans, and have lately been reopened, have been analysed by C. Blanchard (*Dingl. pol. J.* ccxxiv, 653) with the following results:

SnO_2	Fe_2O_3	CaCO_3
92·40	3·49	3·34 = 99·23
75·18	4·00	19·64 = 98·82

A rich deposit of tin-ore occurs at Mount Bischoff in Tasmania (Ulrich, *Jahrb. f. Min.* 1877, 494). The occurrence of tin-ore in Australia is described by Gregory a. Ulrich (*Geol. Soc. Qu. J.* xxix, 1, 5; *Sill. Am. J.* [3], v, 137).

Extraction.—A report by Th. Goldschmidt, on the extraction of tin from its ores, is given in Hofmann's *Entwicklung der Chemischen Industrie*, p. 986.

Methods of obtaining tin in the pure state appear to have been known to the ancient Egyptians, as a white metal found in the wrappings of an Egyptian mummy of the age of at least 600 or 700 years B.C. was found to consist of pure tin (Church, *Chem. News*, xxxvi, 168).

Banca tin contains only very small quantities of foreign substances. Vlandereen (*Dingl. pol. J.* ccxix, 276) found in samples obtained from various districts, at most 0·175 per cent. iron, and 0·0099 sulphur, no arsenic, and mere traces of carbon; traces of lead were found only in the tin from the district of Djeboes.

Recovery of Tin from Tin-plate cuttings.—Moulin a. Dolé (*Ber.* vi, 1138) extract the tin from these cuttings by passing gaseous hydrogen chloride into chambers loosely filled with them. As soon as the iron begins to be attacked, the stream of gas is interrupted, the tin chloride produced is dissolved out by water, and the tin is precipitated from the solution by zinc or iron. The precipitated powder, after being washed with dilute sulphuric acid and water, is dried and melted.

Two other methods of effecting the extraction are described by E. Kopp (*Amer. Chemist*, v, 292). (1). The cuttings are boiled in soda-ley, and litharge is added by successive portions, whereby the tin is dissolved, and lead is precipitated, according to the equation:

If care be taken that the solution finally retains a small quantity of lead oxide, the whole of the tin may be separated from the iron. The residual mixture of iron and spongy lead is levigated, and the lead thereby separated is re-oxidised in iron pans. The plumbiferous solution of sodium stannate is finally made to act on a fresh portion of tin-plate cuttings, whereby it is completely freed from lead. It is then evaporated down, and the sodium stannate thus obtained is sold for use in dye-works. (2). The tin is subjected to the action of chlorine gas, whereby it is volatilised as stannic chloride even at ordinary temperatures, while the iron remains unaltered.

S. Keith effects the separation of the tin by immersing the cuttings in an alkaline liquid, and making them serve as the positive electrode of a dynamo-electric circuit (*Deutsche Industrie-Zeitung*, 1877, 455).

On the Purification of melted Tin by Filtration, see Carter (*Dingl. pol. J.* ccxv, 469; *Jahresb. f. Chem.* 1875, 1016).

A method of obtaining Crystals of Tin by Electrolytic action is described by F. Stolba (*Ber. d. Königl.-böhm. Gesellsch. d. Wissensch.* 7 Nov. 1873; *Jahresb. f. Chem.* 1873, 282).

Grey and Brittle Modification of Tin.—The conversion of ordinary tin into this modification, noticed by Fritzsche and Oudemanns (vii. 1157), has also been observed in the pyrotechnic laboratory at Spandau, where considerable quantities of tin in sheet and blocks became brittle and more easy to pulverise and more soluble in hydrochloric acid than ordinary tin. This tin contained only traces of foreign metals, and was quite free from stannic oxide, and from sulphur and phosphorus (*Ann. Phys. Chem.* [2], ii. 304; *Phil. Mag.* [5], iv. 158). The same alteration has been observed by A. Schertel (*J. pr. Chem.* xix. 322) in a tin medal and some rings, which had been kept for some centuries in a wooden box in the cathedral of Freiberg. The altered metal, which consists of nearly pure tin free from lead and containing only traces of iron and sulphur, has a reddish-grey colour, and is so brittle that it may be crushed between the finger-nails; but on drenching the pieces with hot water, they immediately acquire a lighter colour and much stronger cohesion; strong pressure or a heavy blow likewise brings out immediately a whiter colour. The specific gravity of the altered metal was only 5.8, but increased to 7.3 when the lumps were immersed in hot water. A specimen of disintegrated Banca tin, received from Fritzsche, exhibited nearly the same behaviour; its sp. gr. was 6.0, and increased on immersion in boiling water to 7.25. A further peculiarity in this latter specimen was the greater facility with which it passed from the grey into the white modification, heating for an hour and a half in ether-vapour, being sufficient to effect the conversion, whereas the Freiberg tin under these circumstances remained unaltered even after three hours, and did not acquire the density of 7.3 till it had been heated to 5.9° (in vapour of acetone). The grey modification is electro-negative to the white in dilute potash-solution, positive in dilute nitric acid.

Estimation and Separation.—Pellet a. Allart (*Bull. Soc. Chim.* xxvii. 438) estimate tin volumetrically by means of standard solutions of ferric or cupric chloride.

For the assay of tin ores, A. E. Arnold (*Chem. News*, xxxvi. 238) reduces the stannic oxide with hydrogen at a moderate red heat, and determines the loss of weight. The metallic tin is dissolved in ferric chloride, and the amount of ferrous oxide thereby formed is determined by titration.

Separation from Arsenic and Antimony.—Tin is completely precipitated from solution in aqua regia by sulphuric acid, phosphoric acid, ammonia, alkaline carbonates, and potassium cyanide, whereas solutions of antimonious acid, if prepared with tartaric acid, give no precipitate with either of these reagents. For quantitative separation, however, the only suitable reagent is *potassium cyanide*, as it is the only one which precipitates the tin completely as stannic oxide without at the same time throwing down part of the antimony. The precipitated stannic oxide is difficult to filter, but the filtration may be facilitated by addition of calcium chloride, in such quantity that the calcium carbonate subsequently precipitated by potassium carbonate may amount to about fifteen times the quantity of the stannic oxide. The following mode of conducting the process is given by Cl. Winckler (*Zeitschr. anal. Chem.* 1875, 156): The compound to be analysed, if an alloy, is dissolved in aqua regia, with addition of tartaric acid, or if it contains the metals in the form of sulphide, it is dissolved in dilute potash-ley; bromine is added in slight excess; the solution is neutralised with hydrochloric acid, and diluted to 300–400 c.c.; the necessary quantity of calcium carbonate is then added; and the solution is neutralised with potassium carbonate, mixed with potassium cyanide, and finally with a slight excess of potassium carbonate in order to complete the precipitation of calcium, after which the liquid is heated to boiling, and passed through a filter without previous stirring up of the precipitate. This last operation is once repeated with fresh water, and the precipitate which remains in the beaker is dissolved in a small quantity of strong hydrochloric acid, and again precipitated with cyanide and carbonate of potassium. By this treatment, the whole of the antimony and arsenic are obtained in the filtrate, while the precipitate—after being well washed and dried (the filter being burnt), and very strongly ignited in a porcelain crucible—contains the stannic oxide in the insoluble form, together with calcium carbonate, which may be easily separated from the stannic oxide by treatment with dilute nitric acid.

From arsenic alone tin may be separated by precipitating the two metals with hydrogen sulphide, and boiling the precipitate with water, whereby the sulphides are converted into oxides, of which that of arsenic is soluble, while the tin oxide is insoluble. Care must be taken that the mixed sulphides, immediately after precipitation, are completely freed from adhering acid by washing with water. They are then to be boiled in a flask with a large quantity of water as long as hydrogen sulphide continues to escape; or the operation may be accelerated by using a retort, through which a stream of air is passed. The same method may be applied to the quantitative separation of arsenic from all the other metals which are precipitated by hydrogen sulphide (De Clermont a. Frommel, *Compt. rend.* lxxxvi. 828).

Alloys. The arsenide of tin, Sn^3S_3 , formed by fusing the two metals together under boric oxide, is brittle, crystalline, and has a density of 6.56 (Descamps, *Compt. rend.* lxxxvi. 1065).

On the physical properties and composition of alloys of Tin and Copper, see pp. 563-566.

Tin and Lead.—The action of distilled water, vinegar, and solution of common salt on these alloys has been examined by F. Knapp (*Dingl. pol. J.* cxxx. 446), who finds, in accordance with former investigators, that the alloy composed of 4 pts. tin and 9 lead withstands the action of these liquids better than alloys containing larger proportions of tin. In general, the quantities of metal dissolved out from these alloys, even under unfavourable conditions of experiment, were quite insignificant, so that there is really nothing to fear from the use of culinary vessels made of them. On the action of Water and Saline Solutions on these Alloys, see also Bessnou (p. 1167). R. Weber (*Dingl. pol. J.* cxxxii. 153, 264; *Chem. Soc. J.* 36, 390) finds that when alloys of lead and tin, or of lead, tin, and antimony, are treated with vinegar, the quantities of metal dissolved decrease rapidly as the proportion of tin in the alloy increases. In treating the alloys with vinegar a second time, the total quantity of metal dissolved is less, but it contains a larger proportion of tin, because a portion of the lead dissolved in the first instance is precipitated by the action of the alloy on the metalliferous vinegar.

Stannic Bromide, SnBr_4 (v. 806). Carnelley a. O'Shea (*Chem. News*, xxxvi. 264) prepare this compound by acting on tin in a W-shaped tube with bromine. When purified by distillation, it forms a colourless liquid which solidifies to a mass of colourless crystals. It melts at 30° , boils without decomposition at 201° , does not fume, but slowly decomposes in contact with the air; dissolves in water without immediate decomposition. Its vapour-density, determined by Dumas' method, agrees with the molecular formula SnBr_4 (*Chem. Soc. J.* xxxiii. 55).

The double salt, $\text{SnBr}_4 \cdot 2\text{NH}_4\text{Br}$, crystallises in combinations of the cube and octohedron. Sp. gr. = 3.505 (Topsoë, *Wien. Akad. Ber.* [2 Abth.], lxi. 261).

Chlorides. The vapour-density of stannous chloride was found by Rieth (*Ber.* iii. 668) in two determinations to be 7.47 and 6.88 [$H = 1$], agreeing nearly with the molecular formula SnCl_2 , which requires 6.58. V. and C. Meyer, on the other hand (*Ber.* xii. 1195), find it to be 12.85 at 619°C . and 13.08 at 697° , leading to the formula Sn^2Cl_4 , which requires 13.06. They are of opinion that the lower numbers obtained by Rieth were due to the circumstance that he employed too high a temperature, at which the stannous chloride underwent dissociation; they find, indeed, that it gives off chlorine at a bright red heat. Carnelley, on the other hand (*Chem. Soc. J.* xxxvi. 1014), considers that the results obtained by V. and C. Meyer are not quite conclusive as to the vapour-density of the compound, inasmuch as they were made at temperatures too near its boiling point, 617° - 628° .

Double Salts of Stannic Chloride.— $2\text{NaCl} \cdot \text{SnCl}_4 \cdot 6\text{H}_2\text{O}$ is obtained by adding the calculated quantity of sodium chloride to an aqueous solution of stannic chloride, and separates in ill-defined crystals with dull striated faces. A salt, represented by the formula $2[\text{Na}^{10}(\text{NH}_4)^{10}\text{Cl}] \cdot \text{SnCl}_4$, was obtained by adding sodium chloride to a solution of tin in aqua regia, the ammonia being formed by the action of the nitric acid on the tin. $\text{CaCl}_2 \cdot \text{SnCl}_4 \cdot 8\text{H}_2\text{O}$ forms large, transparent, extremely deliquescent rhombohedrons. $\text{SnCl}_4 \cdot 8\text{H}_2\text{O}$, striated needles or channelled prisms without definitely bounded faces (Topsoë, *Wien. Akad. Ber.* [2 Abth.], lxi. 261).

The following salts, prepared by Cleve (*Bull. Soc. Chim.* [2], xxxi. 197), are exactly analogous in constitution to the corresponding platinochlorides. The *lanthanum salt* has the composition $2\text{La}^2\text{Cl}_6 \cdot 5\text{SnCl}_4 \cdot 45\text{H}_2\text{O}$; the *cerium salt* is $\text{Ce}^2\text{Cl}_6 \cdot 2\text{SnCl}_4 \cdot 18\text{H}_2\text{O}$. The *didymium salt*, $\text{Di}^{12}\text{Cl}_6 \cdot 2\text{SnCl}_4 \cdot 21\text{H}_2\text{O}$, forms large red crystals; the *yttrium salt* contains $\text{Y}^2\text{Cl}_6 \cdot 2\text{SnCl}_4 \cdot 16\text{H}_2\text{O}$.

Oxides. *Stannous oxide*, SnO , is obtained in the form of a violet-black crystalline powder, when the precipitate formed by adding potassium cyanide to a solution of a stannous salt is boiled for several days with solution of potassium cyanide (L. Varenne, *Compt. rend.* lxxxix. 360).

Stannic Oxide, SnO_2 —The crystalline form of native stannic oxide (tin stone) has been examined by F. Becke (*Jahrb. f. Min.* 1878, 76), who finds that the ratio of the principal to the secondary axes is 1 : 0.67232. Microscopic examination of a specimen of *wood-tin* enclosed in quartz showed that the needle-shaped crystals, which were arranged in groups, agrees in form with needle-tin ore. A tin-stone from Schlackenwald gave by analysis 98.74 per cent. SnO_2 , 0.19 FeO , 0.12 Fe_2O_3 , and 0.41 CaO (= 99.46). According to A. E. Arnold (*Chem. News*, xl. 25), both the native oxide and the strongly ignited artificial oxide are soluble in strong hydrochloric acid.

Chlorostannic Acid.—J. W. Mallet (*Chem. Soc. J.* xxxv. 524) observed in a moderately concentrated solution of stannous chloride which had been kept for a year or two in a bottle not very well closed, a layer of a translucent yellow gelatinous substance, which, when purified by washing with water and dried, had the composition SnO^2HCl , and probably the constitution of chlorostannic acid, $\text{O}=\text{Sn}(\text{OH})\text{Cl}$. When heated, and even when left in a vacuum, it splits up into SnO^2 and HCl . Its acid character is shown by its behaviour to soda and ammonia. By the former it is resolved into sodium chloride and stannic hydrate, which slowly dissolves in the excess of alkali; with ammonia, on the other hand, it forms a salt having the composition $\text{SnO}(\text{ONH}^4)\text{Cl}$.

Organic Compounds of Tin.

On *Ferrocyanides of Tin*, see CYANIDES (p. 613); *Mercaptides* (p. 1276).

The crystalline forms of the stannomethyl compounds and their homologues are described by Hiortvaahl (*Compt. rend.* lxxxviii. 584; *Chem. Soc. J.* xxxvi. 518).

Stannopropyl-compounds. Some of these compounds, prepared by Cahours, have been already described (vii. 1085). The following have been obtained by Cahours a. Demarçay (*Compt. rend.* lxxxviii. 1112).

Stannodipropyl Diiodide, or *Stannic Diiododipropide*, $\text{Sn}(\text{C}^3\text{H}^7)^2\text{I}^2$, is obtained by the action of pure tin on propyl iodide, whereas that of an alloy of tin with 10 per cent. sodium gives rise to stannotripropyl iodide, $\text{Sn}(\text{C}^3\text{H}^7)^3\text{I}$. The diiodide, separated from the other products of the reaction by distillation in a vacuum, is a colourless strongly refractive liquid boiling at $270^\circ\text{--}273^\circ$. Alkalis convert it into the corresponding oxide, which is a white amorphous substance insoluble in water, alcohol, and ether, and this, when treated with hydrochloric acid, yields the dichloride, $\text{Sn}(\text{C}^3\text{H}^7)^2\text{Cl}^2$, which melts at $80^\circ\text{--}81^\circ$.

Stannotripropyl Iodide, or *Stannic Iodotripropide*, $\text{Sn}(\text{C}^3\text{H}^7)^3\text{I}$, formed, as above mentioned, by the action of sodium stannide on propyl iodide, may be dissolved out of the product by ether, and is obtained on distilling the residue left after the evaporation of the ether, as a colourless mobile liquid having a very pungent odour and boiling at $260^\circ\text{--}262^\circ$. It is decomposed by silver salts, yielding corresponding salts of stannotripropyl, and is converted by distillation with potash into a crystalline hydroxide, $\text{Sn}(\text{C}^3\text{H}^7)^3\text{OH}$, which unites with acids forming crystalline salts.

Isopropyl iodide, similarly treated, yields a series of tin-compounds analogous to those just described. Like other isopropyl-compounds, they are more fusible and volatile than the corresponding compounds of normal propyl. The *di-iodide* boils at $265^\circ\text{--}268^\circ$; the *dichloride* at $56.5^\circ\text{--}57.5^\circ$. *Stannic iodotriisopropide*, $\text{Sn}[\text{CH}(\text{CH}^3)^2]^3\text{I}$, boils at $256^\circ\text{--}268^\circ$.

Stannobutyl and Stannamyl Iodides (Cahours a. Demarçay, *Compt. rend.* lxxxix. 68). *Stannic di-iodo-diisobutide*, $\text{Sn}(\text{C}^4\text{H}^9)^2\text{I}^2$, is a colourless liquid, boiling at $290^\circ\text{--}295^\circ$, obtained by heating tinfoil and isobutyl iodide at $120^\circ\text{--}125^\circ$ in a sealed tube for several hours. Ammonia and potash give a white amorphous precipitate of the hydroxide, which yields crystalline compounds with acids. The corresponding chlorine compound, $\text{Sn}(\text{C}^4\text{H}^9)^2\text{Cl}^2$, prepared by the action of hydrochloric acid on the iodo-derivative, is a colourless, mobile, heavy liquid, boiling at $260^\circ\text{--}262^\circ$ and solidifying at $5^\circ\text{--}6^\circ$ to a mass of silky needles resembling asbestos. *Stannic iodotributide*, $\text{Sn}(\text{C}^4\text{H}^9)^3\text{I}$, a colourless liquid, having an irritating odour, is obtained by heating a finely powdered alloy of tin and sodium containing 8 to 10 per cent. of the latter, metal with an excess of isobutyl iodide, and exhausting the solidified mass with ether. It boils at $284^\circ\text{--}286^\circ$, and when heated with potash gives the corresponding hydroxide, which boils at $311^\circ\text{--}314^\circ$, and forms crystalline compounds with formic and acetic acids.

The action of isopentyl or amyl iodide on tin appears to yield a mixture of *stannic di-iodo-diisopentide* and *stannic iodo-triisopentide*, which decomposes on distillation, and when treated with ammonia gives a white flocculent precipitate of the two hydroxides, which may be separated by means of ether, and yield crystalline compounds with acids. When an alloy of sodium and tin is employed, the main product of the reaction is *stannic iodo-triisopentide*, $\text{Sn}(\text{C}^5\text{H}^{11})^3\text{I}$, an almost colourless liquid, having a feebly irritating odour and boiling at $302^\circ\text{--}305^\circ$. The action of potash yields the hydroxide $\text{Sn}(\text{C}^5\text{H}^{11})^3\text{OH}$, a colourless, limpid, heavy liquid, which boils at $335^\circ\text{--}338^\circ$ with partial decomposition, and forms crystalline compounds with formic and acetic acids.

From the stannic methides to the stannic pentides, the stability of the compounds gradually decreases and their odour becomes less irritating.

Stannophenyl Compounds (Aronheim, *Ber.* x. 2228; xi. 2285; *Liebig's Annalen*, xciv. 145). These compounds are prepared by the mutual action of mercury-diphenyl and stannic chloride in boiling ligroin, the liquid after twelve hours being filtered and distilled in a paraffin-bath at a temperature not exceeding 150° – 160° . On pouring the residue into water which is kept cool, the ligroin separates out, while stannic chloride, hydrochloric acid, and stannic diphenylchloride remain in solution. On heating this solution, the stannic diphenylchloride or dichlorophenide, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{Cl}_2$, is precipitated as an oily liquid, and the liquid decanted from it deposits, on further warming, sticky pulverulent substances which, after being heated for two hours, may be collected on separate filters. The first portion (m. p. 175°) consists of stannic diphenylchloride and the corresponding hydroxychloride; the second (175° – 187°) of the nearly pure hydroxychloride; the third of an infusible mixture of oxychloride, stannic diphenyloxide and stannic oxide. By washing with alcohol and prolonged suspension in water, the second portion is converted into perfectly pure stannic diphenylhydroxychloride, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{ClOH}$, melting at 187° .

Stannic Diphenylchloride, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{Cl}_2$, crystallises in colourless triclinic prisms, in which, according to Arzruni's measurements, $\alpha = 62^{\circ} 47'$; $\beta = 76^{\circ} 48'$; $\gamma = 94^{\circ} 3'$; $a : b : c = 0.5877 : 1 : 1.0666$. Observed forms: $\infty \bar{P} \infty$, $\infty \bar{P} \infty$, $0P$, $\bar{P} \infty$, ∞P , $\infty P/4$. Measured angles: $\infty \bar{P} \infty : \infty \bar{P} \infty = 87^{\circ} 45'$; $\infty \bar{P} \infty : \bar{P} \infty = 77^{\circ} 14'$; $\infty \bar{P} \infty : 0P = 62^{\circ} 55'$; $\bar{P} \infty : \infty \bar{P} \infty = 56^{\circ} 40'$. The chloride distils with partial decomposition at 338° – 337° , the oily distillate remaining liquid for several weeks. It dissolves easily in ether, alcohol, and ligroin, less easily and with partial decomposition in water. It crystallises best from ligroin; the prisms effloresce very easily on some of their faces. By moisture the chloride is converted into the hydroxychloride; by alkalis into the oxide; by hydriodic and hydrobromic acids into the chloriodide and chlorobromide respectively. Sodium-amalgam converts the chloride dissolved in ether into stannic triphenylchloride, $\text{Sn}(\text{C}^6\text{H}_5)_3\text{Cl}$, melting at 106° . Concentrated acids split up the chloride into benzene and inorganic tin-salts or stannic acid.

Stannic Diphenylhydroxychloride, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{ClOH}$, is an amorphous powder which does not dissolve in the ordinary solvents. Strong hydrochloric, hydrobromic, and hydriodic acid convert it into the corresponding halogen-compounds; strong nitric and sulphuric acid decompose it; hydrogen sulphide does not act upon it. **Stannic diphenyliodide** is very unstable, and is immediately converted by the excess of hydriodic acid into stannic iodide and benzene: $\text{Sn}(\text{C}^6\text{H}_5)_2\text{I}_2 + 2\text{HI} = \text{SnI}_4 + 2\text{C}^6\text{H}_6$. The **chlorobromide**, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{ClBr}$, after standing for some time, suddenly solidifies to a crystalline mass of stony hardness, consisting of pinacoids with apparently rhombic end-faces; it resembles the chloride, and melts at 39° ; its odour, like that of the chloride, is pungently sweetish; in contact with water it crumbles to a white powder.

Stannic Diphenylchloriodide, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{ClI}$, is very easily decomposed by water, but very stable in the dry state. From its brownish solution in ether it separates in yellow monoclinic crystals, which become perfectly white on exposure to the air; they melt at 69° . This compound is most conveniently prepared by passing dry hydrogen iodide over the crystallised dichloride; the yield, however, is indifferent at the best; a thickish oil is obtained as secondary product. The **chlorobromide** may be prepared in a similar manner.

Stannic Diphenyldibromide, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{Br}_2$, is obtained by treating the oxide with hydrobromic acid at a gentle heat, first as a colourless oil which solidifies when touched with a crystal of the bromochloride; it melts at about 38° . The action of hydriodic acid on stannic diphenyloxide gives rise to benzene and stannic iodide.

Stannic Diphenyl-diethoxide, $\text{Sn}(\text{C}^6\text{H}_5)_2(\text{OC}^2\text{H}_5)_2$, is obtained by the action of sodium-amalgam on the dichloride dissolved in ether-alcohol, and separates from the solution in cubic crystals which melt at 124° , and are decomposed by water, with formation of stannic diphenyloxide.

Stannic Triphenylchloride, $\text{Sn}(\text{C}^6\text{H}_5)_3\text{Cl}$, obtained, as already mentioned, by the action of sodium-amalgam on an ethereal solution of the dichloride, forms large white crystals which, after repeated crystallisation, melt at 100° . Its preparation succeeds only when the sodium-amalgam used contains a certain quantity of moisture. It is also produced when ammonia gas is passed over the fused dichloride. From the stone-hard product alcohol extracts the triphenylchloride and sal ammoniac. A secondary product is also formed, consisting of a sparingly soluble white tin-compound from which water extracts the *hydroxychloride*, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{ClOH}$; the compound in question is perhaps an amidochloride, $\text{Sn}(\text{C}^6\text{H}_5)_2\text{ClNH}_2$.

Stannic Triphenyl oxide also forms salts with oxygen-acids, and when treated with potash yields the hydroxide $\text{Sn}(\text{C}^6\text{H}_5)_2\text{OH} + 1\frac{1}{2}\text{H}_2\text{O}$, which melts at 117° – 118° , and gives off 1 mol. water at 120° .

TITANIUM. At. w. = 50. This element appears to exist in small proportion in the atmosphere of the sun, its presence being indicated by certain dark bands in the ultra-violet portion of the spectrum (Cornu, *Compt. rend.* lxxxvi. 101, 983). It has been found by Schuhmacher (*Jahrb. f. Min.* 1878, 817) in a vesuvian occurring at Rammelsberg in Silesia, in which it appears to replace isomorphously an equivalent quantity of silicon (see VESUVIAN). On the occurrence of titanium as oxide and as ferrosiferous titanate, see pp. 1979, 1980.

Preparation.—S. Kern (*Chem. News*, xxxiii. 57) prepares metallic titanium by passing the vapour of the tetrachloride through a heated bulb-tube containing lumps of sodium, separating the resulting mixture of sodium chloride and titanium with cold water, washing the residual titanium with ether, and drying it over sulphuric acid. Thus prepared, it does not act upon water at any temperature below 500° . Wehrlin a. Giraud (*Compt. rend.* lxxxv. 288) fuse potassium-titanium fluoride with an equal weight of iron-filings, the iron then combining with the liberated titanium, which may be easily isolated by treating the product with hydrochloric acid.

Detection.—In testing an iron ore containing phosphoric acid for titanium, E. H. Bogardus (*Sill. Am. J.* [3], viii. 334) noticed the following reactions: 1. The presence of phosphoric acid appears to prevent the precipitation of titanic acid from its acid solution on boiling. 2. Titanic acid colours turmeric paper brown or orange like boric acid. 3. In presence of phosphoric acid and iron, titanic acid is precipitated from an acid solution by hydrogen sulphide.

Estimation.—W. Bettel (*Chem. News*, xxviii. 93) estimates titanium in minerals by fusing the finely pulverised substance with acid potassium sulphate in a platinum crucible at a heat slowly raised to redness, till the mass passes into the state of tranquil fusion; digests the mass, after cooling, with a moderate quantity of water; filters from separated silica; dilutes with water; adds sulphurous acid till all the iron is reduced; and boils the solution for six hours, renewing the water as it evaporates, after which the separated titanic oxide is collected on a filter, dried, ignited, and weighed.

A. Knop (*Zeitschr. Kryst.* 1, 58) points out that the ordinary methods of estimating titanium do not give exact results, and that the presence of titanium in siliceous minerals and rocks is often overlooked; he finds, however, that correct results may be obtained by the following method. The ammonia precipitate, consisting of ferric oxide, alumina, and titanic oxide, is filtered, washed, ignited, and weighed, then fused with acid potassium sulphate; the melt is dissolved; the solution mixed with tartaric acid, and made alkaline with ammonia; and the iron precipitated by ammonium sulphide. The filtrate is next evaporated to dryness; the residue ignited and mixed with strong sulphuric acid, which completely removes any blackening produced by the tartaric acid, and not previously removed by the ignition; then treated with excess of caustic soda-solution, which dissolves the alumina, leaving sodium titanate to be again fused with potassium sulphate. On dissolving the melt in water and boiling the solution, titanic oxide remains behind. By this method Knop has demonstrated the presence of considerable quantities of titanium in the melanites of the Kaiserstuhl range, and of Frascati near Rome, and in pyroxene from the former locality.

For the estimation of titanium when associated with zirconium, as in astrophyllite, arfvedsonite, and zircon, the following colorimetric method is employed by G. A. König (*Zeitschr. Kryst.* i. 423). The mixture of titanic oxide and zirconia obtained by the ordinary method of analysis having been weighed, a blowpipe-bead weighing 0.65 mg., prepared from 0.12 mg. phosphorus-salt, is coloured with 2 mg. of the mixture, and its tint is compared with those of a series of 10 or 20 test-beads likewise coloured by 2 mg. of oxide containing from 0 to 100 per cent. Al_2O_3 and 100 to 0 per cent. TiO_2 . This method admits of the estimation of 5 or even 2.5 per cent. TiO_2 in the bead.

Chlorides. The Tetrachloride, TiCl_4 , or Titanic Chloride, may be prepared by passing the vapour of carbon tetrachloride over small lumps of titanic oxide placed in a tube heated to bright redness, the titanic chloride thus obtained amounting to about 50 per cent. of the carbon tetrachloride used. The same result may be more economically obtained by using, instead of the carbon tetrachloride, a mixture of carbon monoxide and chlorine in equal volumes (C. W. Watts a. C. A. Bell, *Chem. Soc. J.* 1878, xxxiii. 443).

Titanic chloride is decomposed by sulphuric hydroxychloride, $\text{SO}_2(\text{OH})\text{Cl}$, with

formation of a yellow amorphous deliquescent powder having the composition $\text{ClSO}^2\cdot\text{OTiCl}^3$ (Clausnizer, *Ber.* xi. 2011).

Compounds of Titanic Chloride with Ethers (Demarçay, *Bull. Soc. Chim.* [2], xx. 127; *Compt. rend.* lxx. 1414). Titanic chloride unites directly with the ethers of organic acids, also with *ethyl mercaptan* and *ethyl sulphide*, forming compounds which, according to Demarçay, are constituted according to the formulæ on the right-hand sides of the following equations. With *ethyl acetate* the three following compounds are formed :

Demarçay rests his view on the observation that the compound $\text{TiCl}^3(\text{OC}^2\text{H}^5)$ unites directly with acid chlorides, and with titanic chloride, forming the compounds above mentioned : thus with ethyl acetate it forms the compound

intermediate between the last two in the preceding series.

With *ethyl benzoate* three compounds are also formed, which are more stable and crystallise better than the acetyl-compounds, but are decomposed by water, with formation of benzoic acid and ethyl benzoate. The formulæ are the same as those above given, substituting $\text{C}^7\text{H}^5\text{O}$ for $\text{C}^2\text{H}^5\text{O}$. There is also a compound, $\text{TiCl}^2(\text{OC}^7\text{H}^5\text{O})^2, \text{C}^7\text{H}^5\text{OCl}$, formed by combination of $\text{TiCl}^3\cdot\text{OC}^2\text{H}^5$ and ethyl benzoate.

Perfectly analogous compounds are also formed with the ethylic ethers of butyric, valeric, caproic, and angelic acids, also with amyl acetate and valerate and with methyl benzoate. The ethers of bibasic acids likewise yield analogous but much less stable compounds ; *ethyl oxalate*, for example, yields the two compounds

and *ethyl succinate* the three compounds

With *ethyl hydrosulphide* and *sulphide* four compounds are formed, viz. :

The first two have a blackish-red colour, and do not crystallise well ; the third and fourth crystallise well, the third having a scarlet and the fourth a fine dark red colour. Lastly, the following intermediate compounds have been obtained :

The following bodies have been prepared by P. P. Bedson (*Chem. Soc. J.* 1876, xxix. 309). A compound of titanic chloride with *ethyl oxide*, $\text{TiCl}^4, (\text{C}^2\text{H}^5)^2\text{O}$, is formed by mixing equal parts of the component bodies in a cooled vessel. It is a yellow crystalline body, which melts between 42° and 45° , boils at 118° – 120° , and is resolved by water into hydrogen chloride and titanic oxide. By mixing the constituents in different proportions the compound $2\text{TiCl}^4, 3(\text{C}^2\text{H}^5)^2\text{O}$ is obtained. *Titanic Ethyltrichlorhydrin*, $\text{TiCl}^4(\text{OC}^2\text{H}^5)$, is obtained from the residues left in the preparation of the last-mentioned compound, by the application of a strong heat, or in larger quantity by heating the mixture of ether and titanic chloride in an oil-bath. When pure it forms a crystalline mass, melts at 76° – 78° , and boils at 186° – 188° .

The *Hydrochloride of Titanic Triethylchlorhydrin*, $\text{TiCl}(\text{OC}^2\text{H}^5)^3, \text{HCl}$, is obtained by the action of titanic chloride (1 mol.) on absolute alcohol (4 mol.), the mixture being heated in a water-bath at 80° – 100° , the excess of alcohol, after the action is over, being removed by distillation, and the remaining white crystalline mass recrystallised from alcohol. It forms white crystals, which melt between 105° and 110° , and are decomposed by water. On dissolving it in alcohol and adding a very dilute alcoholic solution of sodium ethylate, sodium chloride separates out, and the liquid contains ethylic titanate, $\text{Ti}(\text{OC}^2\text{H}^5)^4$, which crystallises easily in deliquescent needles, and is converted by addition of water to its ethereal solution, into titanic hydroxide, $\text{Ti}(\text{OH})^4$, which is precipitated (Demarçay, *Compt. rend.* lxxx. 51).

Trichloride, Ti^3Cl^6 , and *Dichloride* or *Titanous Chloride*, TiCl^2 (Friedel a. Guérin, *Compt. rend.* lxxxi. 889).—The trichloride (also, though erroneously, called

sesquichloride) is formed by heating the tetrachloride with reduced silver in a sealed tube, but cannot be separated from the silver chloride formed at the same time, either by solvents or by distillation. On distilling the mixture, the tetrachloride passes over, and metallic silver remains behind. The trichloride is not volatile as stated by Ebelmen. When it is heated in a stream of hydrogen to the temperature of boiling sulphur, at which the tetrachloride is not attacked by hydrogen, the tetrachloride passes over, and a black substance remains, consisting of the dichloride. It is probably this latter compound which in the experiment above described effected the reduction of the silver chloride to metallic silver.

A *hydrated trichloride*, $\text{Ti}^3\text{Cl}^6 + 8\text{H}^2\text{O}$, is formed when the violet solution obtained by the action of hydrochloric acid on titanium is evaporated to the crystallising point. It oxidises with extraordinary facility, with continuous separation of finely divided titanic oxide (Glatzel, *Ber.* ix. 1829).

Titanium dichloride is very difficult to obtain pure, as it is very apt to be contaminated either with a small quantity of oxychloride or of unaltered trichloride. To obtain a pure product it is indispensable to proceed as follows. The trichloride having been prepared by the action of hydrogen on the tetrachloride, the hydrogen is displaced by a stream of carbon dioxide, the trichloride is then introduced into a tubulated retort previously filled with carbon dioxide, and this gas is again displaced by hydrogen. The retort is then placed on a sand-bath, and the bath is heated to dull redness, while a continuous stream of hydrogen is passed through the retort. When the whole of the tetrachloride has been distilled over, the residue is left to cool, the hydrogen is displaced by carbon dioxide, and the residual dichloride is transferred to tubes filled with the same gas. The dichloride in cooling absorbs hydrogen, and unless this gas is expelled the compound will take fire on exposure to the air (Friedel a. Guérin).

Titanium dichloride thus prepared is a black light substance, which greedily absorbs moisture, being thereby converted into a kind of mud. When thrown into water it hisses like red-hot iron, and if touched with a drop of water takes fire. It quickly decomposes water with evolution of hydrogen, and forms a yellow liquid like that which results from the deliquescence of the trichloride in moist air. It is insoluble in ether, carbon sulphide, and chloroform. Absolute alcohol is also decomposed by it, with evolution of hydrogen, and formation of a yellowish liquid which becomes blue-black on addition of ammonia. Bromine combines with the dichloride, giving rise to incandescence, and forming a liquid, probably TiCl^2Br^2 , which boils at 176° . The dichloride volatilises at a red heat in a stream of hydrogen without previous fusion. Heated in the air on platinum-foil, it burns like tinder, giving off vapours of the tetrachloride and leaving titanic oxide. The trichloride likewise absorbs bromine, forming a liquid, probably $\text{Ti}^2\text{Cl}^2\text{Br}$, which boils at 154° (Friedel a. Guérin).

Oxychloride, $\text{Ti}^2\text{O}^2\text{Cl}^2$. This compound, analogous to Ti^2Cl^6 , is formed as a secondary product in brown-red scales in the preparation of the dichloride by the method above described, especially if the precautions as to the exclusion of moisture are not very strictly observed; it may be obtained in larger quantity by exposing titanic oxide at a red heat to the action of a mixture of hydrogen and the tetrachloride. It forms red-brown rectangular laminae, apparently orthorhombic, which are not directly attacked by water or by very dilute nitric acid. On exposure to the air it gradually turns white, from formation of titanic oxide. The crystals are attacked by ammonia, turning first black and then white, without alteration of form; at the same time hydrogen is evolved (Friedel a. Guérin, *Compt. rend.* lxxxii. 509).

Phosphochlorides. The phosphochloride, $\text{TiCl}^4\text{PCl}^3$, which Züttchen obtained by the action of PCl^3 on titanic oxide, and the phosphoroxychloride, $\text{TiCl}^4\text{POCl}^3$, which Weber obtained by treating titanic oxide with phosphorus oxychloride (vi. 1097), may also be produced by the following reactions. The phosphochloride is directly formed by heating molecular proportions of titanic chloride and phosphorus pentachloride in sealed tubes at 150° ; the phosphoroxychloride in like manner by heating 2 mol. PCl^3 with 1 mol. TiO^2 . The latter is an easily crystallisable body, which melts at 110° and boils at 140° . Both these compounds exhibit a remarkable behaviour with alcohols. On throwing them by small portions into ethyl or methyl alcohol, reactions take place, represented by the following equations:

After removal of the alcohol, there remains a gummy mass which has a metallic taste, and is decomposed by water into hydrochloric acid, and a compound,

$\text{TiO}(\text{OC}^2\text{H}^3)_2, \text{PO}^4\text{H}^3$, insoluble in water and in ether, but soluble in alcohol. On heating this compound, ethyl chloride is first given off, then ether, and there remains a compound of titanic oxide with phosphoric acid, $\text{TiO}^2, \text{PO}^4\text{H}^3$ (Wehrlin a. Giraud, *Compt. rend.* lxxxv. 288).

Nitrides. Two of these compounds are known, viz., Ti^3N^1 and Ti^2N^2 . The first, analogous in constitution to TiCl^4 and TiO^2 , was discovered by Wöhler a. Deville, who obtained it by heating potassium-titanium fluoride, or the corresponding sodium-compound, in nitrogen-gas (v. 841). It crystallises in copper-coloured crusts, which when examined by the microscope exhibit triangular summits, apparently belonging to a rhombohedron. When ignited in hydrogen, or even in ammonia-gas, it is easily converted into Ti^2N^2 .

This latter compound, $\text{N} \equiv \text{Ti} - \text{Ti} \equiv \text{N}$, analogous to Ti^2Cl^6 , is produced by strongly igniting the sesquioxide or dioxide of titanium for several hours in a current of perfectly dry ammonia-gas. The product is an amorphous brass-yellow powder, having a density of 5.28 at 18° , and hard enough to scratch topaz. When suspended in water it is transparent with a blue colour, but appears yellow by reflected light. It is converted into titanic oxide by ignition in the air, and is attacked by melting potash, with evolution of ammonia. The same compound is obtained, mixed with charcoal, when titanic oxide is heated to bright redness in cyanogen-gas. It is also frequently produced as a brass-yellow film in the preparation of titanium trichloride, when due precaution is not taken to exclude nitrogen from the apparatus (Friedel a. Guérin (*Compt. rend.* lxxxii. 972).

On *Titanium Ferrocyanides*, see p. 613.

Oxides. *Sesquioxide*, Ti^3O^3 .—This oxide is one of the secondary products obtained in the preparation of the dichloride by heating the trichloride in hydrogen gas (p. 1973) when the air is not completely excluded. A portion of the tube and the boat containing the trichloride then become coated with small, shining, copper-coloured crystals having a violet reflex, and appearing under the microscope as hexagonal laminae, exactly similar in form to iron-glance from Elba, Fe^2O^3 , and to ilmenite, FeTiO^3 . The isomorphism between ferric oxide and titanium-compounds here exhibited is likewise seen in other compounds, as Ti^3Cl^6 and Fe^3Cl^6 , and $\text{Ti}^2(\text{SO}^4)^3$ and $\text{Fe}^2(\text{SO}^4)^3$.

Salts analogous to this oxide are formed when metallic titanium is dissolved in hydrochloric or sulphuric acid; with hydrofluoric acid, on the other hand, TiF^4 is produced (v. 840), but in no case is a salt analogous to the dichloride obtained by the action of an acid on metallic titanium. The *sulphate*, $\text{Ti}^2(\text{SO}^4)^3, 8\text{H}^2\text{O}$, crystallises readily from the violet solution obtained by treating titanium with sulphuric acid and concentrated by evaporation, in laminated groups of small crystals. By oxidation with nitric acid it is converted into titanic sulphate, $\text{Ti}(\text{SO}^4)^2, 3\text{H}^2\text{O}$, which is a perfectly transparent, somewhat yellowish, resinous mass, very hygroscopic and deliquescent. With potassium sulphate it forms the double salt, $\text{Ti}(\text{SO}^4)^2, \text{K}^2\text{SO}^4, 3\text{H}^2\text{O}$, which Warren obtained (v. 616) by fusing titanic oxide with acid potassium sulphate (Glatzel, *Ber.* ix. 1829).

Dioxide or Titanic Oxide, TiO^2 .—This oxide occurs native in the forms of Anatase, Brookite, and Rutile.

The crystalline forms of anatase from the Lercheltny Alp in the Binnenthal are described by C. Klein (*Jahrb. f. Min.* 1875, 337). Four types are distinguishable, according to the predominance of P, $\frac{1}{2}\text{P}$, ∞P or $\frac{3}{2}\text{P}$. The second and third types are those which have been described as *Wieserin*. The mineral occurs in clefts of a micaceous gneiss, accompanied by calcite (less frequently by arragonite), brown hematite, adularia, rock-crystal, mica, chlorite, iron-glance, rutile, and sometimes sphene. The specific gravities of the four types are as follows:

Type	1 (P)	2 ($\frac{3}{2}\text{P}$)	3 (∞P)	4 ($\frac{1}{2}\text{P}$)
Sp. gr.	3.87	3.97	3.83	3.869

In type 2, two kinds of enclosure were observed and distinguished as magnetic iron oxide and rutile (?), to which perhaps the higher specific gravity is due. G. vom Rath (*Jahrb. f. Min.* 1876, 64) describes anatase as a coating on adularia, rutile, and iron-glance, from Monte Carradi in the Tavetsch. A development unusual in anatase is determined by the predominance of $\frac{3}{2}\text{P}$. Anatase and Brookite from the gneiss of the Pfitschin Joch, Tyrol, are described by A. Brezina (*ibid.* 1873, 645).

Anatase and Brookite have been found by Klette (*Zeitschr. geol. Ges.* xxvii. 442), together with quartz and magnesia mica, in a druse of orthoclase from Wolfshau, near Schmiedeberg, in Silesia.

The crystals of Brookite are referred by A. Schrauf (*Jahrb. f. Min.* 1873, 403) to three types, viz., those from Tremadoc, North Wales, those from Ulster County,

New York, and those of English, Russian, and Swiss origin. They are all referable to a monoclinic system with the following elements:

	<i>a</i>	<i>b</i>	<i>c</i>	Axial angle
Type I.	0.844149	: 1	: 0.93887	90° 21'
„ II.	0.846931	: 1	: 0.93795	90° 39.3
„ III.	0.841419	: 1	: 0.943441	90° 6.5'

Schrauf regards brookite as isomorphous with Wolfram, a relation which is best exhibited by the formula TiTiO_4 .

A ferruginous variety of brookite occurs in clefts of the andesite of the Arany Berg in Transylvania. A. Koch (*Jahrb. f. Min.* 1878, 652), from the crystalline form and from an analysis made with a very small quantity of material, inferred that it was a rhombic modification of titaniferous iron, and called it *pseudobrookite*; but Groth (*Zeitschr. Kryst.* iii. 306), correcting Koch's crystallographic determinations, shows that by a proper selection of the axes, the crystallographic elements of the mineral come so near to those of brookite, that it may be regarded as probably a ferruginous variety of the latter. Analysis gave:

TiO_2	$\text{Fe}^*\text{O}^{(*)}$	$\text{CaO}^{(*)}, \text{MgO}^{(*)}$	X ^(*)	Sp. gr
52.74	42.29	4.28	0.69 = 100	4.98

(¹) With a little alumina: partly as FeO . (²) Determined by difference. (³) Loss by ignition.

Rutile. G. vom Rath (*Zeitschr. f. Kryst.* i. 13; *Jahrb. f. Min.* 1877, 297) describes rutile in forms of iron-glance. The small crystals from the Lerchettini Alp in the Binnenthal exhibit the combination $P \cdot P\infty \cdot \infty P \cdot \infty P\infty$, together with a few other octagonal prisms, so placed that their principal axes are parallel to the three diagonals of the base OR of the iron-glance, and the face $\infty P\infty$ is parallel to the base itself. That this peculiar formation is not a mere coating, but a true pseudomorph of rutile after iron-glance, is shown by the interior of the groups, which consists of fine-grained rutile. In the rutile from Hot Springs, near Magnet Cove, Arkansas, outcroppings occur, intergrown parallel to the faces of $P\infty$, which meet in a polar edge of $45^\circ 2'$, the twin-formation eight times repeated nearly forming a closed circle. V. Hansel (*Jahrb. f. Min.* 1878, 528) describes crystals of rutile from Madriach, exhibiting the combination $P \cdot P\infty \cdot \infty P \cdot \infty P\infty$. G. Seligman (*Jahrb. f. Min.* 1877, 828) describes regular intergrowths of rutile with magnetic iron ore, crystallised in tabularly distorted octohedrons, the vertical combination-edges of the rutile lying parallel to the edges of the magnetic iron ore, and the face $\infty P\infty$ of the former to the predominating face of the latter. On the crystalline forms of *Ilmenorutile* from the eastern side of Lake Ilmen, see P. v. Jeremejew (*Zeitschr. Kryst.* ii. 504; *Jahresb. f. Chem.* 1877, 1277).

Titanates. *Ferroso-ferric Titanate (Titaniferous Iron)*.—A specimen of this mineral, rich in magnesium, from the diamond-bearing sand of Du Toit's Pan, South Africa (mistaken by the miners for carbon), has been analysed by E. Cohen (*Jahrb. f. Min.* 1877, 695) with the following result:

	TiO_2	Fe^*O^3	FeO	MgO	Insol. residue	Sp. gr.
Found	52.69	6.91	26.50	11.85	2.07 = 100.02	} 4.436 at 14° .
Corrected	53.79	7.05	27.06	12.10	— = 100	

Calcic Silicotitanate (Titanite, Sphene).—The following analysis by Schmöger of a titanite from the syenite granite, which forms a vein in the eclogite of Waldheim in Saxony, is published by H. Credner (*Zeitschr. geol. Ges.* xxvii. 202):

TiO_2	SiO_2	Al_2O_3	Fe^*O^3	YO	CaO
37.45	31.37	4.79	3.13	0.88	22.38 = 100

By the presence of alumina this mineral is related to the titanite, occurring in syenite near Dresden, described by Groth (*Jahresb. f. Chem.* 1866, 943), and named *Grothite* by Dana (*Mineralogy*, 5th ed., p. 386).

Light-brown to flesh-coloured titanite (*greenovite*, v. 398) occurs near Zermatt, in crystals of the combination $P\infty \cdot P\infty \cdot 2P2 \cdot 4P4 \cdot \frac{1}{2}R2$, together with perowskite on pennine. Manganese, the usual colouring principle of greenovite, was detected only in traces in a bright-coloured crystal, ferrous oxide somewhat more abundantly. Sp. gr. 3.547 (C. Hintze, *Zeitschr. Kryst.* ii. 310). Titanite crystals from the limestone of Ersby in Finland are described by F. J. Wüik (*ibid.* 495), some of rhombohedral habit ($\infty P \cdot 0P$), others tabular from predominance of $\infty P\infty$, the former directly imbedded in the limestone, the latter surrounded by scapolite.

TOBACCO. The following observations on the composition and culture of tobacco have been made by S. W. Johnson (*Annual Report of the Connecticut Board of Agriculture*, 1873, 384).

Tobacco leaf, as sold by the farmer, contains about 30 per cent. of water. The following table shows the ash-constituents (not including sand or CO²) and nitrogen of dry tobacco-leaf from Connecticut and Massachusetts, also the mean ash-constituents of Kentucky tobacco:

	Silica	Chlorine	Sulphuric acid	Phosphoric acid	Lime	Magnesia	Potash	Soda	Sum of ash ingredients	Nitrogen
New England tobacco:—										
Highest percentages .	·30	2·55	1·69	·80	8·23	2·21	7·45	1·81	19·40	5·11
Lowest percentages .	·05	·08	·52	·47	3·17	·94	3·90	·08	12·32	3·20
Mean (12 samples) .	·14	1·55	1·09	·59	5·71	1·36	5·79	·33	16·56	4·24
Kentucky tobacco:—										
Mean (30 samples) .	·35	·48	·54	·64	4·53	1·20	4·82	·27	12·83	—

The percentage of nitrogen is greater than in any other cultivated crop; part of it exists as nitrates.

The composition of tobacco is very variable; like all green crops, its constituents are much influenced by the nature of the soluble matters in the soil. According to Schlösing and Nessler, tobacco burns best when it contains considerable quantities of potassium malate; this condition the manufacturer is able to imitate by treating the leaves with a solution of potassium acetate or of some other organic potassium salt. The presence of chlorides is injurious to combustion, but the evil is obviated if a more than usual proportion of potassium malate is present. Sulphates rather favour and nitrates are prejudicial to proper combustion. Tobacco dried without fermentation is yellow, the depth of colour varying according to the extent of the fermentation.

A good crop of tobacco, yielding 1,260 lbs. of dry leaf and 1,100 lbs. of dry stalk, removes from the soil in lbs. per acre:—

	Sulphuric acid	Phosphoric acid	Lime	Magnesia	Potash	Soda	Sum of ash ingredients	Nitrogen
Leaves . . .	14	7½	73	17	71	5	206	49
Stalks . . .	3	15	15	2	47	10	95½	33
Total . . .	17	22½	88	19	118	15	301½	82

As the stalks are returned to the land, tobacco is not a very exhausting crop, but since the period of growth is very short (three months in the middle of summer) it requires to be abundantly manured. Farmyard manure, guano, fish manure, and gypsum, with potassium salts (avoiding the chloride) under special circumstances, are said to yield good results. As the soil is for the greater part of the year unoccupied by the crop, a serious loss of nitrogen may take place by the washing out of nitrates. To avoid this it has been recommended that rye should be sown as soon as the tobacco is off, and ploughed in as a green crop when cultivation for tobacco commences.

Five sorts of tobacco analysed by E. S. Breidenbaugh (*Amer. Chem.* iii. 306) yielded the following results:

	1	2	3	4	5
SiO ² . . .	0·13	0·13	0·08	0·12	0·13
Cl . . .	0·55	0·05	1·70	0·88	1·05
SO ³ . . .	0·77	0·42	1·14	0·95	0·53
P ² O ⁵ . . .	0·30	0·34	0·40	0·34	0·42
CaO . . .	4·12	1·34	2·46	5·34	4·78
MgO . . .	0·83	0·43	0·80	0·81	1·51
K ² O . . .	2·48	3·12	4·36	2·95	3·41
Na ² O . . .	1·15	0·12	0·23	0·24	0·14
Insoluble residue .	2·23	3·12	1·36	1·18	1·86
H ² O . . .	38·00	59·51	33·76	36·90	27·23
N . . .	1·28	0·39	1·17	0·98	0·74
Organic Matter .	48·16	31·03	52·54	49·31	58·20
	100	100	100	100	100

In several varieties of tobacco consumed in Sweden, and analysed in the laboratory of Asarun, the amount of ash was found to vary from 9 to 17 per cent., and that of the constituents soluble in warm water, from 50 to 64 per cent. (*Dingl. pol. J.* cccxxv. 615).

The ash of Havannah cigars has been analysed by A. Percy Smith (*Chem. News*, xxviii. 261, 324) with the following result:

Potassium Sulphate	7·401
„ Carbonate	9·012
Sodium Sulphate	5·764
„ Chloride	3·272
„ Carbonate	1·039
Calcium Sulphate	4·180
„ Carbonate	45·400
Ferric Oxide and Phosphoric acid	0·460
Calcium and Magnesium Phosphates	9·210
Silica	9·641
Charcoal	3·162
Aluminium, Lithium Carbonate, and loss	1·459
	100·000

According to E. R. Durrwell (*Bull. Soc. Chim.* [2], xxiv. 450), the whiteness of the ash of good tobacco is due to the presence of large quantities of potassium and sodium salts, which swell up as the tobacco burns, and tear the fibres, thereby inducing complete combustion.

Proportion of Nicotine in Tobacco.—L. Ricciardi (*Ber.* xi. 1385) has determined the amount of nicotine in 20 sorts of tobacco raised in the Romagna and in Modena under various conditions of growth and with different manures. The smallest proportion (1·62 per cent.) was found in a Havannah variety; the largest (5·99 per cent.) in a Virginian variety.

Smoke of Tobacco.—G. Krause (*Dingl. pol. J.* ccxiii. 495) has examined tobacco-smoke for the oxides of Carbon. He found in the smoke of several kinds of cigars, obtained by suction either with an aspirator or by the mouth, 9·4 to 16 vol. per cent. CO², and 8·7 to 13·8 per cent. CO. The smoke of a loosely stopped pipe contained 14·7 per cent. CO², and 5·2 per cent. CO; that of a closely stopped pipe contained 9·2 per cent. CO², and 9·2 per cent. CO. H. Schwarz (*ibid.* ccxxvi. 306) found in the smoke of a Virginian cigar, 12 to 12·8 per cent. CO², and 4·0 to 4·76 CO.

On the alleged presence of nicotine in tobacco-smoke, see NICOTINE (p. 1391).

TOLALLYL SULPHIDE, C¹⁴H¹⁰S (v. 850; vi. 1099). This compound, produced by the dry distillation of benzyl monosulphide or bisulphide, was said by Mürcker and by Dorn to melt at 143°–145°, by Fleischer at 166°; Forst, however, finds that after repeated crystallisation from alcohol it melts at 172°–173°. Very small quantities of stilbene lower the melting point considerably. Tolallyl sulphide is less soluble in hot water than stilbene, but dissolves somewhat more readily in ligroin, still more in ether and in chloroform, and crystallises from these solvents in loose, white, highly lustrous laminæ, resembling hydrobenzoin. It sublimes without decomposition, and boils at 350°–360° (thermometer-bulb in the vapour). It does not appear to unite with picric acid. When boiled with chromic acid mixture it blackens, and yields carbonic and benzoic acids. The compound C¹⁴H¹²S, which

Barbier obtained by heating benzyl sulphide, was probably nothing but impure totallil sulphide (Forst, *Liebig's Annalen*, clxxviii. 370).

TOLANE, $C^{14}H^{10}$. This hydrocarbon, which Limpricht a. Schwanert obtained by heating toluylene bromide with alcoholic potash (vi. 1099), is also produced by the action of alcoholic potash on hydrobenzoïn chloride. As thus obtained, it forms characteristic large transparent highly lustrous crystals melting at 60° . It is produced also, in like manner, though somewhat impure, from the chloride of isohydrobenzoïn.

Toluene-vapour passed through a red-hot tube yields chiefly high-boiling products and much charcoal; no phenanthrene (Gräbe, *Liebig's Annalen*, clxxiv. 198). Toluene, heated to dull redness (540° – 550°) in a closed and vacuous tube, yields a small quantity of benzene, together with highly carbonised products (Barbier, *Ann. Chim. Phys.* [5], vii. 615). Heated with hydriodic acid and red phosphorus at 170° – 180° , it yields stilbene, and on further action dibenzyl (Barbier, *Compt. rend.* lxxviii. 1772).

TOLIDINE, $C^{14}H^{12}N^2$. See TOLYL-DIAZINS.

TOLYLENE CHLORIDE syn. with **DICHLOROXYLENE**. See XYLENE-COMPOUNDS.

TOLU BALSAM. According to Baillon (*Pharm. J. Trans.* [3], iv. 385) Tolu balsam and Peru balsam are derived from the same tree, *Tolujifera balsamum*, Linn., and the differences between the two products are due merely to differences in the mode of obtaining them.

TOLUALDEHYDINES. The name *Aldehydine* is given by Ladenburg (*Ber.* xi. 590, 1656) to a class of compounds formed by the union of 1 mol. of an ortho-diamine with 2 mol. aldehyde, the combination being attended with elimination of 1 mol. water. Meta- and para-diamines do not form stable compounds with aldehydes. See TOLUENES (DIAMIDO-).

TOLUENE, $C^7H^8 = C^6H^5(CH^3)$. This hydrocarbon is formed, together with benzene and some of its higher homologues, by passing the vapours of petroleum and lignite tar through a red-hot tube filled with lumps of charcoal (Letny, *Ber.* xi. 1210); also by heating petroleum with aluminium chloride, in presence of oxide of zinc, iron, or lead, and air (Friedel a. Crafts, *Jahresb. f. Chem.* 1878, 1166).

Reactions. 1. With *Oxygen*.—Toluene mixed with aluminium chloride absorbs oxygen, and on decomposing the mixture with water, an oily liquid is separated, from which ether extracts a cresol boiling at 200° (Friedel a. Crafts, *Compt. rend.* lxxvii. 884).

2. With *Bromine*.—Toluene, subjected to exhaustive bromination with bromine containing iodine, yields perbromobenzene and perbromomethane (p. 1067).

3. With *Hydriodic acid*.—Berthelot found that toluene heated in a sealed tube to 270° – 280° is converted into the saturated hydrocarbon heptane, C^7H^{16} (vi. 741). According to Wreden, on the other hand (*Ber.* viii. 769), the product thus obtained is not heptane, but an unsaturated hydrocarbon, C^7H^{14} . In subsequent communications, both Berthelot (*Bull. Soc. Chim.* [2], xxvi. 146) and Wreden (*Ber.* x. 712, 2241; *Liebig's Annalen*, clxxvii. 153) adhere to their former statements, Wreden designating his hydrocarbon, C^7H^{14} , as hexhydrotoluene, and describing it as a colourless mobile liquid having a sp. gr. of 0.772 at 0° , and 0.758 at 20° , a vapour-density of 3.36 (calc. 3.38), and boiling between 94° and 100° . It is not attacked by a mixture of nitric and sulphuric acids at ordinary temperatures, but on heating it is oxidised to carbon dioxide and water.

4. By the action of *iodine chloride*, toluene is converted into *p*-iodotoluene, an oily liquid boiling at 206° .

5. Toluene mixed with *molybdenum pentachloride*, and subjected to the action of *chlorine gas* at the heat of the water-bath, is converted in the first instance into parachlorotoluene (b. p. 158° – 161°), mixed with only very small quantities of the *o*- and *m*-modifications, and by continued action of the chlorine into di- and trichlorotoluenes (Aronheim a. Dietrich, *Ber.* viii. 1401).

5. *Chromyl chloride*, CrO^2Cl^2 , converts toluene into benzaldehyde and benzyl chloride (Etard, *Compt. rend.* lxxxiv. 127).

7. With *antimony trichloride* at high temperatures toluene yields nothing but tarry products.

8. By *sulphuric hydroxychloride*, $SO^2(OH)Cl$, toluene is converted mainly into paratoluenesulphonic acid, together with small quantities of paratoluenesulphochloride and sulphotoluide. When toluene and sulphuric hydroxychloride are mixed

together with phosphoric anhydride, the chief product obtained is paratoluenesulphochloride, together with a small quantity of sulphotoluide (Beckurts a. Otto, *Ber.* xi. 2062).

9. *Action of Heat on a Mixture of Toluene and Benzene.*—When the mixed vapours of these bodies are passed through a red-hot tube, the following hydrocarbons are formed: Benzene, naphthalene, diphenyl, paratolylphenyl, orthoparatolyl, γ -methylene-diphenylene, δ -methylene-diphenylene, phenanthrene, anthracene, para-diphenylbenzene, a hydrocarbon having the formula $C^{22}H^{28}$, a liquid hydrocarbon boiling at 293° – 316° , and melting at 13° , two other liquid hydrocarbons or mixtures of hydrocarbons boiling at 359° – 383° and 404° – 427° respectively, and a solid black bitumene.

The more important changes occurring during this reaction may be represented as follows:

The γ - and δ -methylene-diphenylenes above mentioned are isomeric, not identical, with the methylene-diphenylenes (diphenylene-methanes),* which are obtained by passing diphenylmethane through a red-hot tube, and by reducing diphenylene ketone with zinc-dust or with hydriodic acid and red phosphorus (p. 670); also with Berthelot's coal-tar fluorene (p. 671). The distinguishing characters of the four modifications of methylene-diphenylene are exhibited in the table on p. 1985.

10. *Action of Zinc on a Mixture of Toluene and Benzyl chloride.*—Benzyl-toluenes (Weber a. Zincke, *Ber.* vii. 1153). The products obtained by heating a mixture of toluene and benzyl chloride with zinc-dust consist chiefly of mono- and di-benzyltoluene, $C^{14}H^{14}$ and $C^{22}H^{26}$, together with smaller quantities of anthracene and various volatile hydrocarbons, most probably formed by decomposition of the benzyl chloride.

Monobenzyl-toluene, or *Benzyltolyl*, $C^6H^5.CH^2.C^6H^4.CH^3$, passes over as a colourless oil boiling at 277° (vii. 283). When subjected to incomplete oxidation with chromic acid mixture, it yields a solid and a liquid phenyl-tolyl ketone, $C^6H^5.CO.C^6H^4.CH^3$, the former convertible by further oxidation into parabenzoylbenzoic acid, $C^6H^5.CO.C^6H^4.COOH$, in which $CO.C^6H^5 : COOH = 1 : 4$, the latter into a mixture of meta- and ortho-benzoylbenzoic acids. The crude benzyltoluene is therefore a mixture of three isomeric compounds, in which the radicles $CH^2.C^6H^5$ (benzyl) and CH^3 stand to one another in the relative positions 1 : 4, 1 : 3, and 1 : 2.

The three benzyl-toluenes have not been directly separated one from the other, but the *para*-modification is obtained by distilling solid tolyl-phenyl-ketone with zinc dust. It boils at 279° – 280° (corr. 285° – 286°), remains fluid in a mixture of ice and salt, and is oxidised by chromic acid mixture to parabenzoylbenzoic acid. When passed in the state of vapour through a tube filled with pumice and heated to low redness, it remains unaltered, whereas the mixture of the three benzyl-toluenes yields thereby a large quantity of anthracene (Behr a. van Dorp, *Ber.* vii. 18). The same hydrocarbon is abundantly formed when crude benzyltoluene is heated with lead oxide, its production in both cases being probably due to the ortho-benzyltoluene contained in the mixture (Behr a. van Dorp, *ibid.* vi. 753). According to Barbier (*Jahresb. f. Chem.* 1873, 359), benzyltoluene is decomposed by the action of heat alone into anthracene, toluene, and free hydrogen:

The anthracene thus produced forms brown laminae with Fritzsche's reagent, whence it appears to contain phenanthrene (*q. v.*)

* The compounds here called *methylene-diphenylenes* have hitherto been known as diphenylene-methanes (p. 670); but this name belongs more properly to the compound $C^6H^4=CC^6H^4$, which has not yet been obtained.

Methylene-diphenylenes.

	α -Methylene-diphenylene from diphenylmethane and diphenylene ketone (Graebe, Fittig, and Schmitz)	β -Methylene-diphenylene or coal-tar fluorene (Berthelot; Barbier)	γ -Methylene-diphenylene From benzene and toluene (Carnelley)	δ -Methylene-diphenylene
Melting point	115°-114° (Graebe), 112°-113° (Fittig a. Schmitz).	113°	118° (uncorr.)	208° (uncorr.), 208° (corr.)
Boiling point	300°-305° (Graebe); 294°-295° (Fittig a. Schmitz).	About 305° (corr.)	298° (uncorr.)	About 230°.
Crystalline form	Colourless laminae with faint blue fluorescence.	Sublimes in plates with strong violet fluorescence.	Colourless pearly plates or small needle-shaped prisms, with very faint blue fluorescence.	Small colourless pearly plates.
Solubility	Easily in hot alcohol. Less soluble in cold alcohol, very easily in carbon bisulphide, ether, and benzene.	Very soluble in ether, benzene, carbon bisulphide, and hot alcohol, but only sparingly soluble in cold alcohol.	Moderately soluble in hot alcohol or hot glacial acetic acid, but only sparingly soluble in cold alcohol or cold glacial acetic acid; easily in ether.	Sparingly soluble in cold, but more easily in hot alcohol.
Picrate	Yellow-red or red needles, m. p. = 80°-82°, very easily soluble in alcohol, but decomposed at same time (Graebe). Red-brown prisms, m. p. = 79°-80° (Fittig a. Schmitz).	Red needles, m. p. 80°-82°.	Blood-red needles, m. p. = 79°-81°.	—
Dibromo-compound	Colourless tabular monoclinic prisms, different in form from those of Barbier; m. p. = 162°-167° (Fittig a. Schmitz). Needles, m. p. 153°-154° (Graebe). Very sparingly soluble in alcohol, very easily in ether, benzene, carbon bisulphide, and chloroform.	Monoclinic crystals, m. p. = 166°-167°. Nearly insoluble in ether and alcohol, but readily soluble in carbon bisulphide and chloroform. They change on repeated crystallisation from carbon bisulphide into the same form as those of Fittig a. Schmitz.	Minute octohedrons or needles, the latter changing into the former. M. p. = 162°. Very sparingly soluble in alcohol or ether, whether hot or cold.	—
Dinitro-compound	Colourless needles, m. p. 199°-201°, very slightly soluble in hot alcohol.	Reddish yellow needles, m. p. = above 260° with decomposition, very slightly soluble in ordinary solvents.	—	—
Oxidation-products	Is oxidised with difficulty, and gives only diphenylene ketone.	Is slowly oxidised, giving diphenylene ketone and a quinone, $C_{12}H_4O_2$, m. p. = 181°-182°.	Gives only a quinone and no ketone. The quinone, $C_{12}H_4O_2$, crystallises in golden-yellow needles, m. p. = 280°-281°. Scarcely soluble in cold, and only sparingly soluble in hot alcohol.	Gives only a quinone and no ketone. The quinone, $C_{12}H_4O_2$, is a pure white powder, subliming in needles (m. p. 288°). Insoluble in water, but moderately soluble in glacial acetic acid.

The *dinitrobenzyl-toluene* (m. p. 137°) which Zincke a. Milne obtained by treating crude benzyl-toluene with strong nitric acid (vii. 183), appears from experiments by Plascuda a. Zincke (*Deut. Chem. Ges. Ber.* vii. 982) to be derived from parabenzyl-toluene. Another dinitrobenzyl-toluene is formed at the same time, probably derived from ortho-benzyl-toluene; it crystallises in small concentrically-grouped needles, and melts at 100°.

Dibenzyl-toluenes, $C^{21}H^{20} = CH^2.C^6H^3(CH^2.C^6H^3)^2$.—The crude product remaining after the monobenzyl-toluene has been distilled off is a thick brownish oil, which begins to boil at 320°, and may be completely distilled between 450° and 500°, leaving only a small quantity of tarry residue.

The portion distilling between 320° and 380° may be separated by a series of fractional distillations into anthracene and a liquid product consisting chiefly of monobenzyl-toluene.

The portion distilling between 380° and 420° yields by further fractionation a large quantity of an oily, slightly aromatic, fluorescent liquid, having the composition of dibenzyl-toluene. This hydrocarbon boils at 392°–396° under ordinary pressure, at about 280°–285° under a pressure of 30–40 mm., and has a specific gravity of 1.049. It dissolves easily in alcohol, ether, chloroform, and benzene, does not combine with picric acid, and is converted by nitric acid into resinous nitro-products not admitting of purification. When passed in the state of vapour through a red-hot tube, it splits up into hydrogen, toluene, anthracene, and an isomeride of the latter. By oxidation it yields two isomeric dibenzoylbenzoic acids, $C^{21}H^{14}O^4$ (p. 309), and a third infusible acid having the composition $C^{15}H^{10}O^3$, or probably $C^6H^5-CO-CO-C^6H^5(COOH)^2$. This acid may be formed from one of the dibenzoylbenzoic acids by abstraction of C^6H^3 , or it may be derived from a distinct modification of the hydrocarbon $C^{21}H^{20}$. From this it may be inferred that the dibenzyl-toluene obtained as above is a mixture of two, if not of three, isomeric hydrocarbons.

The oxidation of dibenzyl-toluene likewise yields a considerable quantity of ketones, and by further decomposition, carbonic, acetic, and benzoic acids. The attempt to separate these ketones was not successful, but yielded a viscid honey-yellow mass having the composition $C^{21}H^{16}O^2$, easily soluble in alcohol and ether, distilling unaltered at 300°–305° under a pressure of 30–40 mm., but decomposing when repeatedly distilled under ordinary pressure, and yielding thereby—together with small quantities of water, toluene, benzaldehyde and anthraquinone—a large quantity of anthracene, and an isomeric hydrocarbon differing from phenanthrene, and identical with the one already mentioned, as resulting from the decomposition of benzyl-toluene by heat (see ANTHRACENE, p. 95).

The portion of the crude product of the action of benzyl chloride on toluene in presence of zinc which boils above 420°, yields by further fractionation anthracene and toluene, the formation of which, as well as of the anthracene occurring in the lower-boiling portions, is attributed by Weber a. Zincke to the splitting-up of hydrocarbons having the composition nC^7H^8 , which may be supposed to be formed from nC^7H^7Cl by elimination of $nHCl$. More highly benzylated tolueues are doubtless also present.

11. A mixture of toluene and *benzoyl chloride*, $C^6H^5.CO.Cl$, is decomposed by zinc with evolution of hydrogen chlorides, but the greater part of the benzoyl chloride is decomposed in the same manner as it would be if heated alone (Zincke, *Ber.* vii. 137).

12. *Action of Phosphorus Pentoxide on a mixture of Toluene and Fluorenic Alcohol.* When P^2O^5 (12 g.) is heated for four or five hours in a sealed tube at 140°–150° with a saturated solution of fluorenic alcohol (10 g.) in toluene, the product washed with water, the excess of toluene expelled by a gentle heat, the residual liquid distilled, and the solidified distillate recrystallised, from boiling glacial acetic acid, diphenylene-tolyl-methane, $(C^6H^5)^2=CH.C^6H^4.CH^3$, is obtained in long, slender, silky, lustrous needles melting at 128°, slightly soluble in alcohol and ether, freely in benzene and in hot water; it does not combine with picric acid (Hemilian, *Ber.* xi. 202).

Substitution-derivatives of Toluene.

The substitution of chlorine, bromine, nitril, &c. for an equivalent quantity of hydrogen in toluene may take place either in the C^6H^3 -group or in the CH^3 -group (v. 852). The derivatives of the former class have hitherto been designated as chloro-, bromo-, nitro-toluenes, &c., those of the latter as chlorides, bromides, &c. of benzyl, benzylene, or benzenyl, e.g. $C^6H^5.CH^2Cl$, benzyl chloride; $C^6H^5.CHCli^2$, benzylene dichloride; $C^6H^5.CCl^3$, benzenyl trichloride. Another mode of distinction has been proposed by Beilstein a. Kuhlberg, consisting in placing before the name of the compound the number of the hydrogen-atoms displaced by chlorine, &c., either in the

C^6H^5 -group, or in the CH^3 -group, or in both. Thus the three known dichlorotoluenes may be named as follows:

In speaking of those of the first class, however, in which the substitution takes place wholly in the C^6H^5 -group, the numerical prefix may in most cases be dispensed with, the compounds in question being designated simply as chloro-, bromo-toluenes, &c.

The three chlorotoluenes may also be designated systematically as follows:

BROMOTOLUENES.

(1-0) **Monobromotoluenes**, $\text{C}^6\text{H}^4\text{Br}.\text{CH}^3$. Körner (*Gazz. chim. ital.* 1874) prepares *orthobromotoluene* from orthotoluidine (b. p. 199.5° – 196.6°) by converting the nitrite of this base into the diazoperbromide, and decomposing the latter with alcohol. The product, freed from the greater part of the alcohol by slow distillation, is washed with potash-solution, distilled with steam, dried, and fractionated. It boils at 182° , and smells like orthodibromobenzene. By oxidation with dilute nitric acid (instead of chromic acid) it is easily converted into *o*-bromobenzoic acid (Zincke, *Ber.* vii. 143). *Metabromotoluene* was prepared from *p*-nitrotoluene, by successive conversion into *p*-toluidide, acetotoluide, bromacetotoluide, bromotoluidine, [$\text{CH}^3 : \text{Br} : \text{NH}^2 = 1 : 3 : 4$], the nitrate of this base, the diazoperbromide, and finally into [1 : 3] bromotoluidine. This compound, after drying with phosphoric anhydride, boils at 184° – 184.1° [bar. 754.1 mm.] Another preparation boiled at 184.3° [bar. 758.74]. Its odour is undistinguishable from that of metadibromobenzene. By oxidation it is converted into metabromobenzoic acid, melting at 154° . *Parabromotoluene* is formed, together with the other two modifications and benzyl bromide, by direct bromination of toluene; also from *p*-toluidine by substitution of bromine for NH^2 . After drying with phosphoric anhydride, it melts at 282° , resolidifies at 25.4° , and boils at 184.6° (bar. 760.74); smells very much like *p*-dibromobenzene (Körner).

(2-0) **Dibromotoluenes**, $\text{C}^6\text{H}^3\text{Br}^2.\text{CH}^3$. The six possible dibromotoluenes are obtained either by direct bromination of the monobromotoluenes, or by converting the monobromotoluidines into diazoperbromides, and decomposing these compounds by boiling with alcohol. Their formation by this latter process throws considerable light on the influence of the amido-group, NH^2 , in determining the position taken up by bromine (or other halogen) when it enters into a compound already containing the amido-group; and with this view they have lately been especially studied by Neville a. Winther (*Chem. Soc. J.* 1880, xxxvii. 429–453). With regard to this influence, Körner, in his classical research, ‘On the Isomerism of the Aromatic Compounds containing six atoms of Carbon’ (*Gazz. chim. ital.* 1874, 305; see also p. 161 of this volume), laid down the rule that when a halogen-element, or the nitro-group NO^2 , is introduced into aniline, it takes up the para-position with respect to the NH^2 -group; and Neville a. Winther, in the paper just referred to, have shown that this rule is of more general application, and that when bromine, or other halogen-element, or the nitro-group, is directly introduced into toluidine, as well as into aniline, it takes up the para-position with regard to the amido-group—or if this position is already occupied by any other groups or radicles, that the halogen then takes up one of the two ortho-positions, but that it cannot under any circumstances be made to take up a position meta to the amido-group. Wroblewsky, who prepared five out of the six dibromotoluenes from the corresponding monobromotoluidines by the diazoperbromide reaction (vii. 1165), obtained results which were in some cases inconsistent with Körner’s rule, but the experiments of Neville a. Winther tend, as above said, to show that the rule holds good in every case. The following are the results of these experiments:

(1 and 2). *Ortho-meta-dibromotoluenes*, $\text{CH}^3 : \text{Br} : \text{Br} = 1 : 2 : 3$ and $1 : 2 : 5$. The latter of these modifications is obtained from orthobromo-metatoluidine, and from metabromo-orthotoluidine by the diazo-reaction as follows: Acetorthotoluide, treated with 1 mol. bromine, gives a monobromacetoluide, and this by decomposition with potash gives a monobromotoluidine, which, after separation from small quantities of dibromotoluidine formed at the same time, by solution in dilute hydrochloric acid, precipitation with sodium carbonate, and distillation with steam, melts at 55° – 56°

(Wroblewsky gives 58°). The diazo-perbromide of this monobromotoluidine decomposed by warming it with glacial acetic acid yields the dibromotoluene. The acetyl derivative of meta-toluidine, subjected to the same series of reactions, yields a dibromotoluene which was regarded by Wroblewsky as different from that obtained from orthotoluidine. Neville a. Winther, on the other hand, find that the two products thus obtained are identical; they are both fluid at ordinary temperatures, and do not solidify in a mixture of ice and salt; their nitro-derivatives, obtained by treating them with fuming nitric acid, melt at nearly the same temperature (87.6°–88.6°), and the corresponding amido-compounds at 84°–85.1°.

This dibromotoluene being obtained either from *m*-brom-*o*-toluidine or from *o*-brom-*m*-toluidine, must be an ortho-meta-derivative, viz. either 1 : 2 : 5 or 1 : 2 : 3; and hence also it may be inferred that when bromine is introduced into orthotoluidine, it takes the meta-position relatively to CH³, and that when introduced into meta-toluidine it takes the ortho-position. The mode of formation does not afford the means of deciding by which of the two formulæ the constitution of the dibromotoluene is represented, in other words whether the two bromine-atoms are ortho- or para- to each other; but an *o*-*m*-dibromotoluene different from it may be obtained by the following process:—

By adding an aqueous solution of bromine (rather more than 1 mol.) to *m*-nitro-*o*-toluidine suspended in water, a bromonitro-ortho-toluidine, C⁶H³(NH²)Br(NO²), is obtained, which, when purified by recrystallisation from alcohol, melts at 180.3°–181.3° (corr.) To determine the constitution of this bromonitrotoluidine, Neville a. Winther further prepared the isomeric compound (m. p. 139°) which Wroblewsky obtained by nitrating *m*-brom-*o*-acetoluide, and taking out the acetyl-group; they also prepared bromonitroparatoluidine in two ways, viz., (α) by first nitrating and then brominating, and (β) by first brominating and then nitrating. The four products thus obtained were treated with nitrous gas and alcohol to remove the amido-group, and the resulting bromonitrotoluene was reduced with tin and hydrochloric acid. The bromotoluidine thus produced was also converted into an aceto-compound by boiling with glacial acetic acid for seven or eight hours.

The results are given in the following table:—

	From <i>o</i> -toluidine by first nitrating and then brominating	From <i>o</i> -toluidine by first brom- inating and then nitrating	From <i>p</i> -toluidine by first nitrating and then brominating	From <i>p</i> -toluidine by first brom- inating and then nitrating
Nitrobromotoluidine .	m. p. 180.3°–181.3°	m. p. 143.0°	m. p. 64°–65°	m. p. unpurified, 63°
Nitrobromotoluene .	81.4°–81.8°	81.4°–81.8°	81.4°–81.8°	81°–81.5°
Bromotoluidine .	35.6°–36°	34.5°–37°	36.6°	35°–35.2°
Aceto-compound of the bromotoluidine.	167°–168°	167°–168°	167°–168°	168°

Hence it appears that the bromonitrotoluenes obtained by the four methods above described are identical. The bromotoluidines obtained from them differ slightly in melting point, but not sufficiently to indicate any difference in constitution between the several products. Now it has been shown above that bromine when introduced into orthotoluidine takes up the *meta*-position relatively to the methyl-group, and it is known that the NO²-group also takes up the *m*-position relatively to CH³ in both *o*- and *p*-toluidine. Hence the bromonitrotoluene obtained as above must have the symmetrical constitution 1 : 3 : 5, and it may also be seen that bromine when introduced into paratoluidine takes up the meta-position with regard to CH³.

It follows therefore that of the first two bromonitrotoluidines, one must have the constitution CH³ : NH² : Br : NO² = 1 : 2 : 3 : 5, and the other CH³ : NH² : NO² : Br = 1 : 2 : 3 : 5. Further, on decomposing the diazoperbromide of *m*-bromo-*m*-nitro-*o*-toluidine by heating it with glacial acetic acid, a dibromonitrotoluene was obtained melting at 105.4°; and on reducing this with iron and acetic acid, and distilling the separated base with steam, a dibromotoluidine was formed which melted at 86.4°, and when heated with nitrous gas and alcohol to remove the amido-group, yielded a dibromotoluene which after distillation with steam melted at 27.4°–27.8°, and was

converted by strong nitric acid into a nitro-compound melting at 51° – 62° . The same dibromotoluene was obtained from the above-mentioned aceto-*m*-bromo-*m*-toluide melting at 167° – 168° . This compound, treated with a molecular proportion of bromine in aqueous solution, heat being applied towards the end to complete the absorption, yielded a dibromacetoluide melting at 204° – 205° . On heating this last body with a mixture of hydrogen sulphate and water in equal volumes, then diluting the liquid with water, and cooling, the sulphate of a dibromotoluidine crystallised out, and this salt decomposed with sodium carbonate, yielded a dibromotoluidine melting, after recrystallisation from alcohol, at 88° – 85° . Lastly, on decomposing this base with nitrous gas and alcohol, and distilling with steam, a dibromotoluene was obtained which melted at 27.4° – 28° , and yielded a nitro-compound melting at 56.5° – 57.5° , so that it may be regarded as identical with the dibromotoluene last described.

To decide the question as to which of the two dibromotoluenes obtained as above has the composition 1 : 2 : 5, and which is 1 : 2 : 3, they were converted into dibromobenzoic acids by heating them with dilute nitric acid (1 vol. acid of sp. gr. 1.36 to three of water) for about three days. In this way the fluid dibromotoluene prepared from ortho- and from meta-toluidine was converted into a dibromobenzoic acid melting at 149° – 153° , and yielding on distillation with lime paradibromobenzene melting at 85° – 86° (m. p. of pure *p*-dibromobenzene 89°).

Hence this dibromotoluene has its two bromine-atoms in the para-position with regard to each other, and is therefore the 1 : 2 : 5 modification, $C^6H^3Br.H.H.Br.H$, and consequently the other *o*-*m*-modification melting at 27.4° – 27.8° , prepared from *m*-nitro-*o*-toluidine, has the constitution 1 : 2 : 3 or $C^6H^3Br.Br.Br.H$.

(3). *Symmetrical* or *m-m-Dibromotoluene*, $CH^3 : Br : Br = 1 : 3 : 5$. Wroblewsky obtained this modification only from dibromorthotoluidine; Neville and Winter have obtained it also from dibromoparatoluidine. Orthotoluidine in alcoholic, or in acid aqueous solution treated with a slight excess of bromine, yields (after precipitation with water in the former case, and after distillation with steam) a white crystalline dibromotoluidine melting at 43° – 45° , while paratoluidine similarly treated yields a dibromo-derivative melting at 73° . When these dibromotoluidines were treated with an alcoholic solution of nitrous acid, the first gave after distillation with steam a dibromotoluene melting at 39° ; the second a product which generally melted a little higher, but was easily separated by recrystallisation into two substances, one of which melted at 39° , and was to all appearance identical with the dibromotoluene just described, while the other, obtained only in very small quantity, appeared to be a by-product of the action of the nitrous gas, perhaps an amidazo-compound. The dibromotoluene melting at 39° gave on treatment with fuming nitric acid, a nitro-compound which at first melted at 120° – 125° , but separated on repeated crystallisation into two dibromodinitrotoluenes, one melting at 157.6° – 158.3° , the other at 105° ; and the same dibromotoluene when oxidised with a mixture of chromic and acetic acids was converted into symmetrical dibromobenzoic acid, $[CO^2H : Br : Br = 1 : 3 : 5]$, melting between 207° and 210° (p. 261): hence this dibromotoluene must also be symmetrically constituted, that is, must be represented by the formula $C^6H^3H.Br.H.Br.H$.

(4). *Meta-para-dibromotoluene* [1 : 3 : 4] is prepared by the diazo-perbromide reaction from monobromoparatoluidine. It is liquid at ordinary temperatures, as observed by Wroblewsky, gives a crystalline nitro-derivative melting at 86.6° – 87.5° , and convertible by reduction with iron and acetic acid into an amido-derivative melting at 96.8° – 98° . By oxidation with chromic and acetic acid, this dibromotoluene is converted into a dibromobenzoic acid melting at 232° – 233° , agreeing therefore very nearly with the [1 : 3 : 4] dibromobenzoic acid described by Burghardt, which melted at 227° – 230° (p. 361): hence the constitution of the dibromotoluene is established.

(5 and 6). *Ortho-para-* and *Ortho-ortho-dibromotoluenes*, 1 : 2 : 4 and 1 : 2 : 6.—When the aceto-compound of metatoluidine is treated with 2 mol. bromine, the first molecule is readily absorbed, forming a monobromaceto-compound, but the second is absorbed much more slowly, giving at last a dibromaceto-compound which, on the removal of the acetyl-group with alcoholic potash, gives a mixture of two dibromotoluidines, together with a small quantity of tribromotoluidine. The di- and tribromo-compounds may be separated from monobromotoluidine formed at the same time by distillation from dilute acid, which retains the latter, and then extracted with hot strong hydrochloric acid, the liquid on cooling depositing crystals consisting of a mixture of di- and tribromotoluidine. The portion which had remained undissolved in the hydrochloric acid was repeatedly distilled with steam, the last portions being rejected, and the distillate thus purified was recrystallised from alcohol, whereby a portion (the largest by far) was obtained, melting at 74.6° – 75.3° . This appeared to consist of a single dibromotoluidine, and the mother-liquors contained another dibromotoluidine melting at a lower temperature, viz. 33° – 35° . Now, according to the

theory already explained respecting the orientation of Br with respect to the NH^2 -group, metatoluidine should yield two different dibromo-derivatives, viz.:

and these, on removal of the amido-group, should yield the two dibromotoluenes 1 : 2 : 6 and 1 : 2 : 4. The dibromotoluene obtained from the first (m. p. 74.6° – 75.3°) is an oil which remains liquid at -20° , and gives on nitration at ordinary temperatures a mixture of nitro-compounds separable by crystallisation from alcohol into a mononitrodibromotoluene which crystallises in white needles melting at 80° – 80.6° , and a mixture of di- and trinitrodibromotoluenes melting at 128° – 129° . The same dibromotoluene, treated with dilute nitric acid, yields a dibromobenzoic acid melting at 167° – 169° . The dibromotoluene obtained from the dibromotoluidine melting at 33° – 35° is also an oil which does not solidify at -20° , and gives on nitration a mixture separable by recrystallisation from alcohol into a compound melting at 159° – 161° , and only moderately soluble in alcohol, from which it crystallises in long slender needles; also another in small quantity, melting below 80° . This dibromotoluene, heated with nitric acid, yielded a dibromobenzoic acid melting at 150° – 167° .

The behaviour of these two dibromotoluenes with fuming nitric acid shows that they are different from any of the four above described, and therefore that their constitutions must be 1 : 2 : 4 and 1 : 2 : 6 respectively. To decide which of the two must be represented by the former and which by the latter, they were prepared in other ways.

To obtain the 1 : 2 : 4 modification, ordinary dinitrotoluene (m. p. 70°), which is known to have this constitution, was converted by reduction with alcoholic ammonium sulphide into orthonitroproparatoluidine (m. p. 77° – 78°); this by the diazoperbromide reaction into *o*-nitro-*p*-bromotoluene (large monoclinic tables melting at 44.4° – 45.2°), which on reduction gave *p*-brom-*o*-toluidine, $\text{C}^6\text{H}^3\text{.NH}^2\text{.H.Br.H}$, and this base was converted by the diazoperbromide reaction into 1 : 2 : 4 dibromotoluene, which was thus obtained is an oil not solidifying at -20° , convertible by fuming nitric acid into a mononitro-derivative melting at 80.5° – 81.3° , and by oxidation with dilute nitric acid into a dibromobenzoic acid melting at 168° – 170° . These results show that the dibromotoluene obtained from the dibromometatoluidine which melts at 78° – 84° (*supra*) has also the constitution 1 : 2 : 4. Hence it follows that the dibromotoluene prepared from the dibromotoluidine melting at 33° – 35° must have the constitution 1 : 2 : 6; and this conclusion has been confirmed by a special mode of preparing this last modification for which reference must be made to Neville a. Winther's paper (p. 444).

(1–1). *Dibromotoluene*, or *Bromomethyl-bromobenzene*, $\text{C}^6\text{H}^4\text{.Br.CH}^2\text{Br}$, syn. with Bromobenzyl Bromide (see p. 314).

(3–0). **Tribromotoluenes**, $\text{C}^6\text{H}^2\text{Br}^3\text{.CH}^3$ (Neville a. Winther, *Chem. Soc. J.* xxxvii. 446). (1). $\text{C}^6\text{H}^3\text{Br}^3\text{.Br.Br.H.Br.H}$, prepared from the diazoperbromide of dibromorthotoluidine, crystallises in long flat colourless needles melting at 52° – 53° . By dissolution in nitric acid of sp. gr. 1.52, and precipitation with water, it is converted into a nitro-derivative which, after crystallisation from alcohol, melts at 95° – 170° .

(2). $\text{C}^6\text{H}^3\text{H.Br.Br.Br.H}$, prepared from the diazoperbromide of dibromoparatoluidine, melts at 88° – 89° .

(3). $\text{C}^6\text{H}^3\text{H.Br.Br.H.Br}$ is prepared from the diazoperbromide of the dibromometatoluidine melting at 74° – 75.5° , which has already been shown to have the constitution $\text{C}^6\text{H}^3\text{H.NH}^2\text{.Br.H.Br}$ (*supra*). It crystallises from alcohol in long colourless shining needles melting at 111.2° – 112.8° .

(4). $\text{C}^6\text{H}^3\text{Br}^3\text{.Br.Br.H.Br.H}$ was prepared by converting *m*-bromo-*m*-nitro-*p*-toluidine into the diazoperbromide; this into *m*-bromo-*m*-nitro-*p*-bromotoluene,

(colourless laminæ melting at 62° – 63.6°); reducing this latter with iron and acetic acid, whereby a dibromotoluidine was obtained, which crystallised from alcohol in long colourless needles or flat prisms melting at 58° – 59° ; converting this amido-compound into the corresponding aceto-derivative (m. p. 162° – 163°) by boiling it for twenty-four hours with the strongest glacial acetic acid; suspending this aceto-compound in water, and treating it with bromine, whereby a tribromacetoluide was obtained, crystallising from alcohol in white needles melting at 171° – 173° ; decomposing this compound with alcoholic potash; and treating the resulting tribromotoluidine (m. p. 96° – 96.8°) with nitrous acid and alcohol. In this manner a tribromotoluene was finally obtained, melting at 44.4° – 44.7° . By treating it with nitric acid of sp. gr.

1.52 and precipitating with water, a nitro-compound was formed, which, after frequent recrystallisation, melted at about 106° – 107° . This result sufficiently distinguishes the tribromotoluene under consideration from the first-described modification (m. p. 52° – 53°), which gives a nitro-compound melting at 95° – 170° .

(5). $C^6H^3Br.H.Br.H.Br.H$. This modification was obtained by Wroblewsky from bromo-nitro-orthotoluidine melting at 143° —which has already been shown to have the constitution $C^6H^3NH^2.NO^2.H.Br.H$ (p. 1988)—by converting it, through the diazoperbromide reaction, into a dibromonitrotoluene melting at 69.5° – 70.2° ; and proceeding, as in the last case, by the successive employment of tin and hydrochloric acid, glacial acetic acid, bromine, and boiling alcoholic potash, whereby ultimately a tribromotoluidine is obtained which melts at 93° – 94° , and, when treated with nitrous gas and alcohol, yields a tribromotoluene crystallising in flat needles which melt at 58° – 59° . Now the mode of formation of this tribromotoluene shows that it must be represented by one of the two formulæ:

But the former of these belongs to the modification (m. p. 111.2°) obtained from dibromometatoluidine perbromide: hence the modification under consideration must be represented by the latter formula. This tribromotoluene is converted by nitric acid of sp. gr. 1.52 into a nitro-compound melting, after recrystallisation, at 91° – 91.4° .

(6). $C^6H^3.Br.H.Br.H.Br.$ This modification was prepared in like manner from the tribromometatoluidine which melts at 100° – 101.6° . Now this tribromotoluidine can be obtained by bromination of dibromometatoluidine, $C^6H^3.Br.H.Br.NH^2.H$ (p. 1990), and must therefore be represented either by the formula $C^6H^3.Br.Br.Br.NH^2.H$ or by $C^6H^3.Br.H.Br.NH^2.Br$. It cannot, however, be represented by the first of these formulæ, since, when decomposed by alcohol and nitrous gas, it gives a tribromotoluene which melts at 66° , whereas it has been already shown (p. 1990) that the tribromotoluene derived from this base melts at 44.4° . The dibromotoluidine in question must therefore be represented by the second of the above formulæ, and the tribromotoluene derived from it by the formula $C^6H^3.Br.H.Br.H.Br.$

(4–0). **Tetrabromotoluenes**, $C^6HBr^4.CH^3$. Of these there are three possible modifications:

(1). $C^6CH^3.Br.Br.Br.H.Br$ is prepared from tetrabromometatoluidine (which is obtained by the action of bromine-water on a solution of *m*-bromo-*m*-toluidine, m. p. 35° – 37° , in hydrochloric acid, and crystallises in white needles melting at 223° – 224°) by boiling with alcohol and nitrous gas; also from tribromometatoluidine perbromide. The product obtained by the first process melts at 105° – 108° , that by the second at 106.8° – 108° . By nitration with nitric acid of sp. gr. 1.52, it yields a nitro-compound melting at 215° – 216° .

(2). $C^6CH^3.Br.Br.H.Br.Br$ is obtained by the diazoperbromide reaction from tribromometatoluidine, $C^6CH^3.Br.Br.H.NH^2.Br$ (m. p. 93° – 94°) described above. It melts at 116° – 117° , and yields a nitro-compound melting, after recrystallisation from alcohol, at 213° .

(3). $C^6CH^3.H.Br.Br.Br.Br$ is obtained from tribromometatoluidine,

(m. p. 96° – 96.8°), described on p. 1990. It melts at 111° – 111.5° , and gives a nitro-compound melting at 212° .

(5–0). **Pentabromotoluene**, $C^6HBr^5.CH^3$, is obtained from the diazoperbromide of tetrabromotoluidine (m. p. 223° – 224°), and purified by crystallisation from acetic acid or alcohol, neither of which dissolves it freely; it crystallises in white needles melting at 283° – 285° (Neville a. Winther). It is also produced by adding toluene to an excess of bromine mixed with aluminium bromide in a cooled vessel (Gustavson, *Ber.* x. 971).

The table on p. 1992 exhibits a comparative view of the constitution and distinguishing properties of the several bromotoluenes.

Chlorotoluenes. (1–0). *Monochlorotoluenes*, $C^6H^4Cl.CH^3$.—The *para*-modification, already described (v. 853), may be prepared from solid nitrotoluene by reducing that compound with tin and hydrochloric acid, drenching the hydrochloride of the resulting amidotoluene with fuming hydrochloric acid, passing nitrous gas into the pasty mass till it assumes a yellow-brown colour and the crystals are completely dissolved, and boiling the liquid in a vessel provided with a condensing tube. Nitrogen is then given off, and the acid and aqueous vapours which distil over are accompanied by an oil containing the monochlorotoluene, together with cresol, nitrocresol, and nitrotoluene. To obtain the chlorotoluene pure, the entire product is

treated with tin and hydrochloric acid, then distilled with water, shaken with soda-ley, and again distilled with water. The chlorotoluene thus obtained boils at 150.5° , and solidifies on cooling to about 0° to a colourless laminar mass which melts at 6.5° (Hübner a. Majert, *Ber.* vi. 794).

Parachlorotoluene is also formed by passing chlorine into a mixture of anhydrous toluene and molybdenum pentachloride heated on the water-bath. The action goes on regularly, and soon after 1 equiv. of chlorine has been taken up, the product is found to consist almost wholly of parachlorotoluene boiling at 158° – 161° , and having a density of 1.0735 at 27.2° (? 17.2°). *Orthochlorotoluene* (b. p. 156°) obtained by Griess's reaction from chlorinated orthotoluidine has been already described (vi. 281). *Metachlorotoluene*, prepared in like manner from metachloroparatoluidine, $\text{C}^{\circ}\text{H}^{\circ}\text{CH}^{\circ}\text{H}^{\circ}\text{Cl}^{\circ}\text{NH}^{\circ}\text{H}^{\circ}$, is a liquid which boils at 156° , and is converted by oxidation into metachlorobenzoic acid (Wroblewsky, *Liebig's Annalen*, clxviii. 199).

(0–1) *Chlorotoluene*, *Chloromethylbenzene*, or *Benzyl Chloride*, $\text{C}^{\circ}\text{H}^{\circ}\text{CH}^{\circ}\text{Cl}^{\circ}$.—The preparation of this compound by the action of chlorine on heated toluene, and by that of hydrochloric acid on benzyl alcohol, has already been described; also several of its reactions (see v. 854; vii. 179; viii. 314). On the products obtained by heating it with finely divided zinc and hydrocarbons of the benzene series, see vii. 183; viii. 315.

The action of benzyl chloride on nitrite of silver or potassium does not yield any aromatic nitro-compound, the product consisting of high-boiling non-nitrogenous bodies amongst which are found anthracene, benzoic acid, and benzaldehyde (H. Brunner, *Ber.* ix. 1744).

(2–0) *Dichlorotoluene*, $\text{C}^{\circ}\text{H}^{\circ}\text{Cl}^{\circ}\text{CH}^{\circ}$, is formed by the continued action of chlorine on toluene mixed with molybdc chloride. When purified by continued fractionation, it has a density of 1.2596 at 18.4° , and 1.2518 at 16° ; boils at 196° – 198° . The product thus obtained is, however, a mixture of two isomeric bodies, inasmuch as when oxidised by chromic acid mixture it yields two dichlorobenzoic acids (Aronheim a. Dietrich, *Ber.* viii. 1401).

(0–2) *Dichlorotoluene*, *Dichloromethylbenzene*, or *Benzylene Dichloride*, $\text{C}^{\circ}\text{H}^{\circ}\text{CHCl}^{\circ}$ (see p. 320).

Trichlorotoluenes, $\text{C}^{\circ}\text{H}^{\circ}\text{Cl}^{\circ}$. See vi. 281–2. Aronheim a. Dietrich (*Ber.* viii. 1401), by the action of chlorine on a mixture of toluene and molybdc chloride, have obtained, besides the solid (3–0) trichlorotoluene melting at about 75° (vi. 282), a liquid modification boiling at 237° . According to R. Schultz (*Liebig's Annalen*, clxxxvii. 274), this liquid trichlorotoluene is not a pure substance, but probably a mixture of tri- with di- and tetrachlorotoluenes, as, when treated with nitric acid, it yields a nitro-compound identical with that which is obtained from the solid modification, and on treating it with fuming sulphuric acid, the greater part of the solid modification separates out.

(0–1) **Cyanotoluene**, or **Benzyl Cyanide**, $\text{C}^{\circ}\text{H}^{\circ}\text{CH}^{\circ}(\text{CN})$. This compound, treated with zinc and hydrochloric acid, is converted into a midobenzylmethane,* $\text{CH}^{\circ}(\text{C}^{\circ}\text{H}^{\circ})\text{NH}^{\circ}$, a base metamerie with phenylethylamine or ethylaniline:

This base forms small laminæ having a characteristic odour. It volatilises with steam, dissolves sparingly in water, easily in ether, and absorbs carbonic acid from the air. Its hydrochloride forms lancet-shaped crystals (Bernthsen, *Ber.* viii. 691).

When benzyl cyanide dissolved in ammoniacal alcohol is treated with *hydrogen sulphide*, two compounds are produced, one of which crystallises in needles an inch long, which turn brown at 160° , and melt at 197° – 198° , while the other forms prisms melting at 97° , and resolved at a higher temperature into benzyl cyanide and hydrogen sulphide. This latter compound dissolves sparingly in water, freely in alcohol and ether. Its aqueous solution added to metallic salts quickly throws down metallic sulphides, and when treated with potash is resolved into potassium sulphide and benzyl cyanide. Benzyl cyanide heated with water at 250° is converted into α -toluamide or phenylacetamide, $\text{C}^{\circ}\text{H}^{\circ}\text{CH}^{\circ}\text{CO}^{\circ}\text{NH}^{\circ}$, melting at 154.5° (Bernthsen, *loc. cit.*) This amide is also formed by treating benzyl cyanide with ammonium acetate, according to the equation:

(Bernthsen, *Ber.* ix. 429); and, according to Weddige, by heating benzyl cyanide with an alcoholic solution of potassium hydrosulphide (p. 314).

* In Bernthsen's paper this base is called phenylethylamine; but this name belongs properly to Hofmann's ethylaniline, $\text{C}^{\circ}\text{H}^{\circ}\text{NH}^{\circ}(\text{C}^{\circ}\text{H}^{\circ})$, which is an imido-base or secondary amine, whereas amido-benzyl-methane is an amido-base or primary amine.

Iodotoluene, $C^6H^4.CH^3$. The ortho-modification is very easily prepared from orthotoluidine by the action of nitrous gas and alcohol. It is liquid at ordinary temperatures, boils at 206.5° (at 211° if the entire mercury-column is in the vapour), and is oxidised by nitric acid to orthiodobenzoic acid, melting at 156° – 157° . By treatment with ethyl chlorocarbonate and sodium-amalgam (Wurtz's method, *Compt. rend.* lxxiii. 1298), it is converted into ethylic orthotoluate:

Nitrotoluenes. (1–0) *Mononitrotoluenes*, $C^6H^4(NO^2).CH^3$.—E. J. Mills (*Phil. Mag.* [4], 1. 17) prepares the para-modification by dropping toluene into red fuming nitric acid of sp. gr. 1.48, and distilling the product with water. The mixture of liquid and solid nitrotoluene which then passes over after the unaltered toluene is cooled for half an hour to -17° , and the liquid portion pipetted off. The solid *p*-nitrotoluene thus produced could not be obtained of quite constant melting point, either by sublimation, or by repeated crystallisation from alcohol, or by treatment with fuming sulphuric acid, or by partial solution in dilute alcohol. When twice crystallised from naphtha and then from alcohol, it melted at 51.31° (Mills). By oxidation with *chromic oxychloride*, it is converted into methylnitroquinone (Etard, *Compt. rend.* lxxvii. 989).

Orthonitrotoluene given to dogs exerts a poisonous action, which, however, if the dose is small, soon passes off; by repetition the animals get accustomed to it. Part of the nitro-toluene appears in the urine as orthonitrobenzoic acid (nitrohippuric acid is not formed); but the chief product of the transformation is a compound, $C^{14}H^{10}N^3O^{10} + 2\frac{1}{2}H_2O$, which crystallises in colourless silky needles; dissolves very easily in water, sparingly in cold alcohol, more readily in hot alcohol, but is insoluble in ether. It melts at 148° – 149° ; has an acid reaction; shows strong laboratory power; reduces an alkaline cupric solution, also bismuth-solution and silver-solution; does not ferment with yeast. It is a compound of urea with *uronitrotoluenic acid*, $C^{13}H^{13}NO^8$ (Jaffé, *Russ. Zeitschr. Pharm.* 1878, 513).

(2–0) *Dinitrotoluene*, $C^6H^3(NO^2)^2.CH^3$.—The unsymmetrical modification of this compound, $CH^3 : NO^2 : NO^2 = 1 : 2 : 4$, is obtained by further nitration either of ortho- or of para-nitrotoluene, and is converted by reduction into metadiaphenylenediamine (Baeyer, *Ber.* vii. 1638). Mills (*Phil. Mag.* [4], 1. 17), by treating toluene with a mixture of nitric and sulphuric acids, obtained a dinitrotoluene which after two crystallisations from light petroleum and from alcohol, melted at 69.23° . Liquid mononitrotoluene treated at ordinary temperatures with fuming nitric acid yielded a dinitrotoluene, which after purification melted at 69.17° , but after it had been kept for nineteen months the melting point rose to 69.6° . Solid nitrotoluene treated in small quantities with red fuming nitric acid yielded a dinitro-compound melting at 69.17° ; when larger quantities were used, the product melted at 69.57° . Dinitrotoluene treated with *sodium-amalgam* yields a black uncrystallisable mass (Michler, *Liebig's Annalen*, clxxv. 150).

(3–0) *Trinitrotoluene*, $C^6H^2(NO^2)^3.CH^3$, is obtained by nitrating toluene with fuming nitric acid and treating the product with a mixture of nitric and fuming sulphuric acid. After recrystallisation from light petroleum and alcohol, it melted at 78.85° . It is not altered by boiling for thirty-six hours with red fuming nitric acid. Liquid nitrotoluene heated with nitric and fuming sulphuric acids yielded a trinitrotoluene which melted at 78.88° . The trinitrotoluene obtained in like manner from solid nitrotoluene did not exhibit a constant melting point till it had been submitted to a repetition of the treatment. It then melted at 80.54° .

Nitrobromotoluenes, $C^6H^3(NO^2)Br.CH^3$. Parabromotoluene yields by nitration two solid mononitro-derivatives, one melting at 45° , the other at 34° . The former yields by reduction a bromotoluidine, $C^6H^4(NH^2)Br.CH^3$, convertible by the action of sodium-amalgam and water into orthotoluidine: hence it is an ortho-para-compound, $CH^3 : NO^2 : Br = 1 : 2 : 4$.* Consequently the modification melting at 34° must be the meta-para-compound $1 : 3 : 4$, and this conclusion is confirmed by its formation from metanitroparatoluidine, $CH^3 : NO^2 : NH^2 = 1 : 3 : 4$, by converting this base into the diazoperbromide and decomposing the latter with alcohol. It crystallises from alcohol in slender yellow needles (Wroblewsky a. Kurbatow, *Zeitschr. f. Chem.* 1870, 165; Beilstein a. Kuhlberg, *Liebig's Annalen*, clviii. 335; Wroblewsky, *Ber.* viii. 573).

An *orthonitro-metabromotoluene*, $1 : 2 : 3$ or $1 : 2 : 5$, is formed on agitating meta-bromotoluene for a considerable time with moderately strong nitric acid, and separates

* Compare vii. 1167, where this nitrobromotoluene is described as the *m-p*-modification.

on addition of water as a pale yellow oil solidifying at -17° to a crystalline pulp which may be freed from adhering liquid by pressure between paper. When purified by repeated crystallisation from alcohol, it forms hard, brittle, very large, well-defined rhombic crystals, prismatic or flattened according to the strength of the solution from which they have separated. Both the crystallisation and the dissolution of the crystals in alcohol are accompanied by strong decrepitation. By reduction with tin and hydrochloric acid, this nitrobromotoluene is converted into a metabromorthotoluidine.

The liquid portion of the product is not a distinct modification, as supposed by Wroblewsky (*Zeitschr. f. Chem.* 1870, 240), but a mixture of the compound just described with unaltered metabromotoluene or a dinitrobromotoluene (E. A. Grete, *Ber.* viii. 565).

The *symmetrical* or *m-m*-modification, 1 : 3 : 5, prepared by elimination of the amido-group from nitrobromoparatoluidine, $C^6H^3H.Br.NH^2.NO^2.H$, crystallises from alcohol in shining white prisms, melts at 86° , and boils at 269° – 270° (Wroblewsky, *Ber.* viii. 573).

Nitrochlorotoluenes. Two *nitroparachlorotoluenes*, $C^6H^3(NO^2)Cl.CH^3$, one melting at 8° – 9° , the other at 34° – 35° , are obtained by direct nitration of *p*-chlorotoluene (Engelbrecht, *Ber.* vii. 797).

(1–1) *Orthonitrochlorotoluene*, or *Orthonitrobenzyl Chloride*, $C^6H^4(NO^2).CH^2Cl$ [$NO^2 : CH^2Cl = 1 : 2$], is formed by the action of chlorine on orthonitrotoluene at 150° – 200° , as a viscid oil which has an agreeably aromatic odour, exerts a burning action on sensitive parts of the skin, and solidifies after a while to a network of slender needles. With silver nitrate it forms orthonitrobenzyl acetate, $C^6H^4(NO^2).CH^2(OC^2H^3O)$ (Wachendorff, *Ber.* viii. 1101).

A nitrobenzyl chloride is also formed by dropping benzyl chloride into fuming nitric acid cooled to -15° , and may be purified by washing and recrystallisation from alcohol. By digestion with aqueous ammonia at 100° it is easily converted into secondary nitrobenzylamine, $(C^6H^4NO^2.CH^2)^2NH$, and tertiary nitrobenzylamine, $(C^6H^4NO^2.CH^2)^3N$ (p. 317).

(1–2) *Nitrochlorotoluene*, or *Nitrobenzylene Dichloride*, $C^6H^4(NO^2).CHCl^2$, is formed by the action of fuming nitric acid on benzylene dichloride cooled with water, together with large quantities of benzoic acid and benzaldehyde, which may be removed by treating the product with aqueous sodium carbonate and acid sodium sulphite. The nitrobenzylene dichloride which then remains is converted by oxidation into paranitrobenzoic acid (Hübner a. Bente, *Ber.* vi. 803. See p. 320).

Nitrotrichlorotoluene, $C^6H(NO^2)Cl^3.CH^3$, is prepared by dropping nitric acid of sp. gr. 1.52 on gently warmed pulverised trichlorotoluene till the whole is dissolved, and precipitating with water. When purified by crystallisation from alcohol or benzene it forms long white needles melting at 88.5° . 100 pts. alcohol at 20° dissolve 4.9 pts. of it. By tin and hydrochloric acid it is converted into a trichlorotoluidine which melts at 91° (R. Schultz, *Liebig's Annalen*, clxxxvii. 274).

Dinitrochlorotoluene, $C^6(NO^2)^2Cl^3.CH^3$, prepared by treating trichlorotoluene with a mixture of 2 pts. nitric acid (sp. gr. 1.52) and 1 pt. strong sulphuric acid, crystallises from a large quantity of hot alcohol in small yellow needles, easily soluble in benzene, melting at 225° (Schultz).

Dinitro-p-iodotoluene, $C^6H^2(NO^2)^2I.CH^3$, is formed, together with other compounds, by nitration of para-iodotoluene, and separates in colourless crystals melting at 138° (Glassner, *Ber.* viii. 561).

AMIDOTOLUENES, $C^7H^3N = C^7H^2NH^2$.

I. (1–0) **Amidotoluenes, Toluidines, Tolylamines**, $C^6H^4(NH^2).CH^3$.

PARATOLUIDINE. ORDINARY TOLUIDINE.—To separate this base from ortho- or pseudotoluidine, R. Bindshedler (*Ber.* vi. 1361) dissolves 2500 g. oxalic acid in 25 litres of boiling water, then slowly pours into the solution 10 kg. commercial toluidine, heats the liquid once more to the boiling point, leaves it to cool to 60° with continual stirring, and filters quickly from the crystalline precipitate which forms. This precipitate pressed, washed with water, decomposed with caustic soda, and distilled, yields crystalline paratoluidine. The cooled filtrate is mixed, with stirring, with 2 kg. oxalic acid, whereby a further crystalline precipitate is obtained, consisting of the oxalates of ortho- and para-toluidine, which is set aside for a subsequent preparation of the latter. When the filtered liquid no longer gives a precipitate on agitation with a strong solution of oxalic acid, it is distilled with soda-ley, and the

oily distillate is dried and rectified. The product thus obtained consists of technically pure *orthotoluidine*.

A similar process, founded on the sparing solubility of the acid oxalate of *p*-toluidine in ether free from alcohol, may be applied to the volumetric estimation of the two bases when mixed. On adding oxalic acid to the ethereal solution of the bases, the acid oxalate of *p*-toluidine is first formed, while the *o*-toluidine remains free till the *p*-toluidine is completely saturated. Any excess of oxalic acid that may be added is easily estimated by mixing the liquid with titrated toluidine. Any *o*-toluidine oxalate that may be formed at the same time is thus decomposed, with formation of acid oxalate of *p*-toluidine and free *o*-toluidine (Rosenstiehl, *Bull. Soc. Chim.* [2], xvii. 4). Lorenz (*Ber.* vii. 448) observes that the end of the reaction (*i.e.* the complete precipitation of the para-compound in the ethereal solution) is not easy to recognise. He therefore introduces into the ethereal solution a slip of litmus-paper, which, since oxalate of *orthotoluidine* acts upon litmus-paper, turns red on addition of any excess of oxalic acid beyond that which is required to precipitate the whole of the *p*-toluidine. Still greater exactness may be obtained by adding at once an excess of oxalic acid, filtering from the separated *p*-toluidine oxalate, washing with ether, evaporating, dissolving the residue in a small quantity of water, and titrating the excess of oxalic acid with a decinormal solution of soda. The difference between the quantity of oxalic acid thus found and the amount employed gives the quantity of oxalic acid which has combined with the *paratoluidine*.

Reactions of Paratoluidine. 1. *Oxidation.*—*Paratoluidine* treated with *potassium permanganate* is oxidised to azotoluene or ditolyldiazin, $C^4H^4N^2$; together with a red substance of the same composition, which when treated with ammonia and hydrogen sulphide is converted into symmetrical ditolyl-hydrazine or hydrazotoluene, $C^4H^4N^2$ (Barsilowsky, *Ber.* viii. 695). See also Hoogewerff a. van Dorp (*Ber.* x. 1936; xi. 1202).

2. Reaction with *Iodine Chloride*.—This compound, added to a solution of *p*-toluidine in hydrochloric acid, converts it into diiodo-*p*-toluidine (Michael a. Norton, *Ber.* xi. 197).

3. With *Mercuric Chloride*.—When an alcoholic solution of *p*-toluidine is poured upon an alcoholic solution of mercuric chloride so as to form a layer above it, the compound $HgCl_2.N(C^6H^7NH^2)^2.Hg[NH^2(C^6H^7)Cl]^2$ is gradually formed (O. Klein, *Ber.* xi. 743).

4. With *Mono-chloroacetic acid*.—*Paratoluidine* (2 mol.) heated with 1 mol. chloroacetic acid yields tolyl-glycocine, $C^6H^7.NH.CH^2.CO^2H$, and with ethyl chloracetate the corresponding ether. *Chloroacetamide* and *toluidine* heated together in molecular proportion till they fuse yield tolyl-glycollamide, $C^6H^7.NH.CH^2.CONH^2$, and in like manner tolyl-glycollanilide and tolyl-glycolltoluide may be produced (P. F. Meyer, *Ber.* viii. 1158). See GLYCOLLAMIDES (p. 882). When a solution of *toluidine* in absolute alcohol is heated with *chloroacetic* and *thiocyanic acids*, a brisk reaction takes place, and crystals separate, which when purified by recrystallisation from alcohol and boiling with ether, have the composition $C^6H^7N^2SO^2$, and melt at 176° – 182° . Their formation is represented by the equation:

(Nencki, *J. pr. Chem.* [2], xvi. 1).

5. With *Chloral*.—*Toluidine* dissolves with rise of temperature in chloral, producing trichlorethylidene-ditolyamine, $CCl_3.CH[NH(C^6H^4.CH^3)]^2$ (Wallach, vii. 1179).

6. With *Ethylene Oxide*.—The two substances, heated together in molecular proportion at 100° in a closed flask, unite and form oxethylenetoluidine, $C^6H^{13}NO$ (Demole, *Ber.* vii. 635).

7. With *Dinitrochlorobenzene*, *toluidine* forms chloronitrophenyl-*p*-tolylamine, $C^6H^7Cl(NO^2).NH(C^6H^4.CH^3)$.

8. *Paratoluidine* unites with *picramide*, forming the compound $C^6H^7N.C^6(NO^2)^3H^2.NH^2$, which crystallises in shining black needles having a greenish reflex (Mertens, *Ber.* xi. 843).

9. *Paratoluidine* unites with *paraphenolsulphonic acid*, producing great rise of temperature, and the solid mass which forms on cooling, yields when crystallised from hot water, large semi-transparent, colourless, or yellowish prisms, which cleave readily and melt at 202° . 100 pts. water at 17° dissolve 6.18 pts. of the compound (Lecco, *Monit. scientif.* [5], iv. 423).

ORTHOTOLUIDINE or PSEUDOTOLUIDINE, $C^6.CH^3.NH^2.H^4$.—On the separation of this base from the *para*-modification, see p. 1995.

Reactions.—1. By the action of *iodine chloride*, it is converted into monoiodo-*orthotoluidine* (Michael a. Norton). 2. By oxidation with *potassium permanganate*, it yields *o*-tolyl-diazin (Hoogewerff a. van Dorp, *Ber.* xi. 1202).

3. With *potassium ferricyanide*, it yields uncrystallisable products of oxidation (Barsilowsky, *Ber.* xi. 2155). 4. Heated at 200° – 220° with *methyl alcohol* and hydrochloric acid, it is converted into dimethyl-*o*-toluidine boiling at 206° – 207° . With *picramide*, it forms a compound similar to the *p*-toluidine compound (p. 1996). 5. It unites with *mercuric chloride*, forming a compound which melts at 113° – 115° (Klein, *Ber.* xi. 743). 6. A mixture of *o*-toluidine hydrochloride and a strong solution of zinc chloride cooled to a low temperature (-5°) deposits colourless, concentrically grouped, tabular, anhydrous crystals, consisting of the double salt $\text{ZnCl}_2 \cdot 2(\text{C}_6\text{H}_4\text{N}, \text{HCl})$ (Bibanow, *Monit. scientif.* [3], iv. 925).

The salts of orthotoluidine yield by oxidation a basic substance, $\text{C}_6\text{H}_4\text{N}$ (also occurring in crude aniline-black), having a blue-violet colour, slightly soluble in alcohol, easily in chloroform and aniline, and forming green salts. Hydrochloric acid, added to the chloroform solution, throws down the green hydrochloride (Nietzki, *Ber.* xi. 1093).

METATOLUIDINE, $\text{C}_6\text{H}_3\text{H.NH}_2\text{H}_3$.—F. Lorenz (*Ber.* vii. 448) prepares this base by the following process. Paratoluidine is converted by means of glacial acetic acid or acetic anhydride into paracetoluide; this into its metanitro-derivative, by adding it in small portions to nitric acid of sp. gr. 1.475, and precipitating with snow; and the nitroacetoluide by gentle heating with alcoholic potash into metanitroparatoluidine, $\text{C}_6\text{H}_3\text{H.NO}_2\text{NH}_2\text{H}_2$ (p. 1999). This nitro-base is then mixed to a thin paste with nitric acid; nitrous gas is passed into the mixture; the clear light-brown solution is mixed in a well-cooled vessel with the calculated quantity of dilute sulphuric acid; and the resulting precipitate is washed with ether-alcohol. The diazin-compound thus obtained is converted by boiling with absolute alcohol into metanitrotoluene, which may be purified by distillation with steam, and when reduced by tin and hydrochloric acid yields metatoluidine.

Metatoluidine is a colourless oil, which becomes coloured and resinises on exposure to the air. It has a density of 0.998 at 25° , and boils at 197° . The free base does not change the colour of litmus, but its salts have an acid reaction, so that they might be analysed by titration with soda-ley. They quickly acquire a rose tint.

The *hydrochloride* crystallises from water in rosettes of thin laminae; from alcohol in thin pale-red scales; it is very soluble in alcohol and in water; the aqueous solutions are easily supersaturated. The *nitrate* separates by slow crystallisation in large, thick, rhombic tablets, having a pale-red colour, slightly soluble in ether, very soluble in alcohol, less easily in water, with which it readily forms supersaturated solutions. The *sulphate* forms radiate groups of long, brittle, faintly reddish, transparent needles, easily soluble in water, sparingly in alcohol, insoluble in ether.

Oxalates.—The *acid oxalate*, $\text{C}_6\text{H}_4\text{N}, \text{C}_2\text{H}_2\text{O}_4$, forms large nodular groups of slender needles having a silky lustre, sparingly soluble in water, alcohol, and ether. They begin to volatilise at 75° (possibly from loss of base). The *sesquibasic oxalate*, $(\text{C}_6\text{H}_4\text{N})_2(\text{C}_2\text{H}_2\text{O}_4)_3$, is formed on heating the aqueous solution of the acid salt with the free base, and separates from the warm solution in step-like groups of hard rhombic laminae: it is also formed, in the preparation of the acid salt, when the quantity of oxalic acid present is not sufficient for the formation of the latter. It is not decomposed by recrystallisation. The *normal oxalate* is formed on mixing the warm alcoholic solutions of oxalic acid and metatoluidine, the latter being in large excess, and separates in soft rhombic laminae which contain 1 mol. water, and when dried in the air have very much the aspect of cholesterol; it is very unstable (Lorenz).

The following table (drawn up by Lorenz) contains a comparison of the reactions of the three toluidines with the reagents which, according to Rosenstiehl, are characteristic for ortho- and para-toluidine.

1. The base dissolved in $\text{SH}_2\text{O}^4\text{H}_2\text{O}$ is treated with a solution of *chromic acid* in sulphuric acid of the same concentration. The mixture is coloured:

Orthotoluidine	Metatoluidine	Paratoluidine
Blue, changing on dilution to a permanent red-violet.	Yellow - brown, which becomes greenish-yellow on addition of a small quantity of water, and on further dilution colourless.	Yellow.

2. *Nitric acid* is added to a solution of the base in $\text{SH}_2\text{O}^4\text{H}_2\text{O}$.

An orange-colour is produced, and with very concentrated solutions a brown, becoming yellow on dilution.

The mixture becomes at once red, changing quickly to intense blood-red, then to a dirty dark red, and on dilution to orange.

Blue streaks are produced, which soon tinge the whole liquid; after a minute the colour becomes violet, then red, and after some hours brown.

3. To a solution of the base in equal volumes of water and ether, a few drops of a clear solution of *bleaching powder* are added.

The layer of water becomes first yellow and then brown. The ether separated from the water, and when treated with dilute sulphuric acid is permanently coloured a red violet.

The layer of water becomes a thick brownish-yellow: the ether assumes a reddish colour. When separated and shaken with a few drops of dilute sulphuric acid, the under surface of the ether is coloured violet.

No reaction.

Bromotoluidines. E. A. Grete (*Ber.* vii. 796), by treating metabromotoluene with nitric acid, obtains a mixture of nitro-products which by reduction yields a metabromotoluidine liquid at ordinary temperatures and volatilising with steam. Its sulphate crystallises in laminæ or six-sided prisms; the nitrate in six-sided prisms or plates; the oxalate in needles; the hydrochloride in very soluble needles, branched like those of sal-ammoniac.

Metabromorthotoluidine, $C^6H^3BrN^2.H^2O$, which Wroblewsky obtained by brominating orthotoluidine and decomposing the resulting ortho-acetoluide with potash (vii. 1176), is also produced by the action of tin and hydrochloric acid on the corresponding nitrometabromotoluene (m. p. 54° – 55°). It crystallises from alcohol in well-defined rhombohedrons having their upper and lower summits alternately truncated. It volatilises with steam, melts at 57.5° – 58° , dissolves very easily in alcohol, and with moderate facility in water. By sodium-amalgam it is completely decomposed, apparently with formation of toluene and ammonia. By boiling with glacial acetic acid it is converted into *metabromacetoluide*, melting at 156° . The *sulphate*, $(C^6H^3BrN)^2.H^2SO^4$, crystallises from its aqueous solution by slow evaporation in regular quadratic tablets. The *nitrate*, $C^6H^3BrN.HNO^3$, forms six-sided, often flattened needles with pyramidal summits. The *hydrochloride*, $C^6H^3BrN.HCl$, forms long, thin, often flattened needles very soluble in water. The *oxalate*, $(C^6H^3BrN)^2.C^2H^2O^4$, crystallises in tufts of long needles (Grete, *Ber.* viii. 565).

Hübner a. Roos (*Ber.* vi. 799) have obtained, by nitration of parabromotoluene, a mixture of nitrobromotoluidines, yielding by reduction:

(1). *α-Parabromotoluidine*, melting at 32° [apparently identical with the bromotoluidine described by Hübner a. Wallach as melting at 31° , by Beilstein at 30° , by Körner, at 27° , and by Wroblewsky (vi. 1104) at -2°]. The *hydrochloride* of this bromotoluidine forms large, six-sided, rhombic tablets; the *nitrate* transparent, pale-red, rhombic tablets, soluble in 120.9 pts. water at 11.5° ; the *sulphate*, $2C^6H^3BrN.H^2SO^4$, colourless, sparingly soluble laminæ.

(2). *β-Parabromotoluidine*, melting at 75° , or, according to Wroblewsky, at 67° .

(3). An *orthobromotoluidine*, in the form of a liquid which does not solidify at 0° , and forms crystalline salts, the hydrochloride and nitrate crystallising in rhombic tablets, the sulphate in needles.

On *Symmetrical Bromotoluidine*, $CH^3 : NH^2 : Br = 1 : 3 : 5$, melting at 34.5° – 37° , see p. 1988.

Dibromotoluidines, $C^6H^2Br^2(NH^2).CH^3$. — On the modification $C^6H^3 : Br : NH^2 : Br = 1 : 2 : 3 : 6$ and $1 : 2 : 4 : 5$, see p. 1990. A dibromotoluidine is formed, together with sulphuric acid, on heating paramidotoluenemeta-sulphonic acid with 2 mol. bromine:

(H. v. Pechmann, *Liebig's Annalen*, clxxii. 195; *Ber.* vii. 718).

Tri bromotoluidine, $C^6H^2Br^3.CH^3$. — This compound appears to be known in three modifications, the constitution of which has not however been made out. One of these, which crystallises in needles melting at 112° – 113° , is formed by the action of bromine on *o*-toluidine-*m*-sulphonic acid, and on *p*-toluidine-*m*-sulphonic acid. It sublimes easily without decomposition, and does not unite with acids (pp. 2016, 2019). Another modification is obtained, together with sulphuric acid, by the action of water and bromine on amidorthobromotoluenemetasulphonic acid (p. 2019). It crystallises from alcohol in yellow needles and volatilises with steam in nearly white flocks which melt at 82° (Schäfer, *Ber.* vii. 1355). A third modification is obtained by adding bromine-water in excess to a cold saturated solution of metatoluidineorthosulphonic acid, as a flocculent precipitate, which when recrystallised from alcohol, with addition of animal charcoal, forms thin, fragile, faintly reddish needles melting at 95° . By cautious sublimation it may be obtained in snow-white needles melting at 101° . It is insoluble

in soda-ley and hydrochloric acid; but dissolves in strong sulphuric acid, and is precipitated therefrom by water without alteration (Lorenz, *Ber.* vii, 448).

Iodotoluidines (Michael a. Norton, *Ber.* xi. 107).

Monoo-iodo-o-toluidine, $C^6H^3I(NH^2).CH^3$.—Acetorthotoluide, $C^6H^3(NH.C^2H^3O)CH^2$, dissolved in glacial acetic acid, is converted by the action of iodine chloride into iodaceto-toluide, which crystallises from water or alcohol in short thick needles melting at 165.5° , sparingly soluble in cold, more readily in hot water, very easily in alcohol and ethyl acetate, soluble also in strong nitric acid without separation of iodine.

This iodacetoluide is converted by boiling with hydrochloric acid into iod-o-toluidine hydrochloride which crystallises in needles. The free base crystallises from alcohol in long white needles melting at 86° , very sparingly soluble even in hot water, easily soluble in alcohol, ether, and acetic acid; it volatilises readily with vapour of water. Heated with strong sulphuric acid it decomposes, evolving vapours of iodine. The *nitrate* crystallises in colourless needles, somewhat sparingly soluble in water. The platinumchloride does not crystallise well.

The base treated with nitrous acid is converted into a diazin-compound which forms a light-yellow crystalline precipitate easily soluble in alcohol, and convertible by boiling with alcohol into the corresponding iodotoluene, which when oxidised by nitric acid yields *meta*-iodobenzoic acid melting at 184° . The base is therefore a *meta*iodo-orthotoluidine.

Orthotoluidine treated with iodine chloride likewise yields a monoiodorthotoluidine.

Di-iodo-p-toluidine, $C^6H^2I^2(NH^2).CH^3$, formed by the action of iodine chloride on paratoluidine dissolved in hydrochloric acid, crystallises in ramified groups of slender needles, melting at 124.5° , moderately soluble in cold, freely in hot alcohol.

Nitrotoluidines. *Metanitroparatoluidine*, $C^6H^3.H.NO^2.NH^2.H^2$.

Lorenz (*Liebig's Annalen*, clxxii. 177) prepares this compound by converting paracetoluide into its metanitro-derivative (m. p. 92°), and treating the latter at a gentle heat with alcoholic potash. It crystallises from alcohol in thick red prisms, melting at 109° ; after recrystallisation from water at 114° . According to Panebianco (*Gazz. chim. ital.* 1879, 358), the crystals are monoclinic, having the axial ratio $a : b : c = 1.35781 : 1 : 1.75472$. Angle $ac = 54^\circ 51'$. According to Friederici (*Ber.* xi. 1970), this nitrotoluidine crystallises from dilute alcoholic solution in brick-red shining laminae, from concentrated alcoholic solution in slender needles or long thick prisms, and volatilises with water-vapour in red flocks made up of needle-shaped crystals. Moderately strong hydrochloric acid dissolves it readily when heated, and the solution on cooling deposits the *hydrochloride*, $C^6H^3(NO^2)N.HCl$, in well-defined light-yellow prisms, which are instantly decomposed by water. The *nitrate*, $C^6H^3(NO^2)N.HNO^3$, forms light yellow, highly lustrous, six-sided plates or slender needles likewise decomposed by water.

Methyl-toluidines. *Mono- and Di-methyl-p-toluidine* are formed when vapour of methyl chloride is passed into *p*-toluidine boiling in a reflux apparatus through which a current of steam is passed, 3.5 pts. of the toluidine attacked being converted into the mono-methyl-derivative to 1 pt. converted into the dimethyl-derivative. The ethereal extract of the crude product freed from unattacked toluidine by sulphuric acid, leaves on evaporation an oil which becomes very hot in contact with acetic anhydride, and after repeated distillation yields *acetomonomethylparatoluidine*, $C^6H^7.N(CH^3)(C^2H^3O)$, which forms colourless crystals, melts at 83° , boils at 283° , dissolves easily in alcohol and ether, sparingly in water. By successive saponification with hydrochloric acid and soda-ley, it yields *monomethylparatoluidine* as a colourless aromatic oil boiling at 208° . *Nitroso-methyl-p-toluidine*, $(C^6H^7)N(CH^3)(NO)$, obtained by the action of potassium nitrite on methyl toluidine dissolved in hydrochloric acid, is insoluble in water, easily soluble in alcohol and ether, and melts at 54° .

Dinitromethylparatoluidine, $C^6H^7.NH[CH(NO^2)^2]$, produced by the action of fuming nitric acid on a solution of the acetyl-compound in glacial acetic acid, crystallises from dilute alcohol in light-red needles melting at 129° , and dissolving, without decomposition, in glacial acetic and hot hydrochloric acid (A. L. Thomsen, *Ber.* x. 1582).

Dimethyl-p-toluidine, $C^6H^{13}N = (C^6H^7)(CH^3)^2N = C^6H^4[N(CH^3)^2].CH^3$.—On the formation of this base by intramolecular interchange from trimethyl-phenylammonium iodide, and its subsequent conversion into methyl-xylyl and cumidine, see A. W. Hofmann (vii. 57). It is also formed by distillation of trimethyl-*p*-tolylammonium hydroxide, passing over as a colourless aromatic oil which boils at 208° .

Dimethyl-orthotoluidine, prepared in like manner, boils at 183°. *Trimethyl-orthotolyl-ammonium Iodide* crystallises in large needles which acquire a purple colour on exposure to the air (A. L. Thomsen, *loc. cit.*)

Bromodimethyl-metatoluidine is formed by the action of bromine on dimethyl-metatoluidine dissolved in two or three times its volume of hydrochloric acid. The light yellow liquid thereby produced is poured off from an oil which separates, into cooled soda-ley, and the crystals which form are freed by pressure from adhering liquid, and recrystallised from alcohol. The compound is thus obtained in white shining laminae, unctuous to the touch, insoluble in water, easily soluble in the other ordinary solvents; it melts at 98°, and boils at 276° (Wurster a. Riedel, *Ber.* xii. 1796).

Nitroso- and Nitro-derivatives of Dimethyl-m-toluidine (Wurster a. Riedel, *loc. cit.*).—*Nitroso-dimethyl-m-toluidine Hydrochloride*, $C^6H^2(NO)N.HCl$, is deposited on adding a saturated solution of sodium nitrite to a solution of dimethyl-metatoluidine in dilute hydrochloric acid. It is sparingly soluble in cold, but dissolves in hot water in presence of hydrochloric acid, and crystallises on cooling in yellow needles. The free base obtained by decomposing the hydrochloride with sodium carbonate crystallises from ether in green plates or needles melting at 92°; from a chloroform solution mixed with ligroin in moss-green needles; from benzene in dark-green efflorescent crystals containing benzene; from water in laminae. It forms steel-blue double salts with amines (aniline, toluidine), is converted by potash-ley into a red-brown azoxy-compound, and is resolved by soda-ley into dimethylamine and a nitrosocresol, $C^6H^3(NO)(OH).CH^3$, which crystallises in white needles, melting at 145°–150°, soluble in alcohol, benzene, chloroform, and glacial acetic acid, slightly soluble in boiling water and in ether; yielding an acetyl-derivative which forms prismatic crystals soluble in alcohol and melting at 92°; and converted by the action of nitric acid on its solution in glacial acetic acid into trinitrocresol.

Nitrosodimethyl-m-toluidine, treated with tin and hydrochloric acid, is converted into a dimethyl-tolylene-diamine, $N^2H^2(CH^3)^2(C^6H^5)$, which, when oxidised by sulphuric acid and manganese dioxide, yields a crystalline compound (m. p. 67°) identical with the toluquinone $C^6H^2O^2$ (*q.v.*) prepared from paratoluidine. Dimethyl-tolylene-diamine is therefore a derivative of paratoluidine, and since it is obtained by reduction of nitrosodimethyl-m-toluidine, it follows that the nitroso-group in the latter compound must occupy the para-position with regard to the amido-group. Hence the constitution of nitrosodimethyl-m-toluidine must be represented by the formula $C^6CH^3.NO.H.H.N(CH^3)^2.H$ (Riedel, *Ber.* xiii. 126).

Nitrodimethylmetatoluidine is formed when potassium permanganate is added to an aqueous solution of nitrosodimethylmetatoluidine hydrochloride, and may be extracted from the liquid with ether. It crystallises in long yellow needles melting at 84°. The corresponding *dinitro*-derivative is obtained in yellow needle-shaped crystals melting at 107°, by adding nitric acid to a solution of dimethylmetatoluidine in glacial acetic acid. If the nitration is carried on with dilute nitric acid, or if the mixture of sulphuric and nitric acids is kept perfectly cold, three nitro-derivatives are obtained, viz., the mono-nitro-derivative melting at 84°, and two dinitro-derivatives melting at 107° and 168° respectively. The latter is less soluble in alcohol than the dinitro-compound which melts at 107° (Wurster a. Riedel).

On *Colouring Matters* derived from Methyl- and Dimethyl-toluidine, see Monnet, Reverdina. Nölting (*Ber.* xi. 2278; *Chem. Soc. J.* xxxvi. 310).

(0-1) **Amidotoluene**, or **Benzylamine**, $C^6H^5.CH^2(NH^2)$. This base, originally obtained by the action of ammonia on benzyl chloride (v. 867), and afterwards by decomposing benzyl isocyanate or isocyanurate with potash (vii. 181), may also be prepared by the action of alcoholic potash on benzyl-acetamide (from acetamide and benzyl chloride). The *hydrochloride* separates from alcoholic solution in large plates. The *platinochloride* crystallises in orange-coloured plates, the *sulphate* in transparent crystals freely soluble in water (C. Rudolph, *Ber.* xii. 1297).

Tri-p-bromobenzylamine, $(C^6H^4Br)^3N = (CH^2Br.C^6H^4)^3N$, is formed by the action of alcoholic ammonia at ordinary temperatures on parabromobenzyl bromide, and separates immediately as a crystalline pulp, together with a substance scarcely soluble in alcohol. The triamine is insoluble in water, but dissolves in alcohol, ether, benzene, and carbon sulphide, and crystallises from alcohol in prisms melting at 78°–79°.

The substance nearly insoluble in alcohol is the corresponding *hydrobromide*, $(C^6H^4Br)^3N.HBr$. It crystallises in white scales melting at 270°, insoluble in water, easily soluble in ether (Jackson a. Lowery, *Ber.* x. 1209).

Mono-, Di-, and Tri-orthobromobenzylamines are formed by heating

α -bromobenzyl bromide at 100° for two hours with alcoholic ammonia. The tertiary base, $(\text{C}^6\text{H}^4\text{Br.CH}_2)^3\text{N}$, separates from the product in crystals, which, after recrystallisation from ether, melt at 121.5° ; its *platinochloride*, $[(\text{C}^6\text{H}^4\text{Br.CH}_2)^3\text{NH}]^3\text{PtCl}_6$, is insoluble in water and in ether, and very sparingly soluble in alcohol. The primary base, $\text{C}^6\text{H}^4\text{Br.CH}_2\text{NH}_2$, is obtained from the liquid filtered from the crystals of the tertiary base by evaporating to dryness, treating the residue with carbonic acid, exhausting with water (the secondary base then remaining undissolved), mixing the extract with caustic soda, and washing the oil thereby precipitated. It is a colourless oil yielding a *carbonate* in white crystals melting at 95° , and a *hydrochloride*, in needles melting at 208° , both soluble in water and in alcohol. The *platinochloride*, $(\text{C}^6\text{H}^4\text{Br.CH}_2\text{NH}_2)^2\text{PtCl}_6$, forms orange-yellow needles insoluble in ether, slightly soluble in water and in alcohol. The secondary base, $(\text{C}^6\text{H}^4\text{Br.CH}_2)^2\text{NH}$, solidifies in a freezing mixture to rhombic needles melting at 36° , having a pleasant odour, insoluble in water. The *hydrochloride* melts at 166° ; the *platinochloride*, $[(\text{C}^6\text{H}^4\text{Br.CH}_2)^2\text{NH}]^2\text{PtCl}_6$, is a dark yellow precipitate insoluble in ether, moderately soluble in alcohol and in water.

Chlorobenzylamines.—*p*-Monochlorobenzylamine, $\text{C}^6\text{H}^4\text{Cl.NH}_2$, is liquid. Di-*p*-chlorobenzylamine, $(\text{C}^6\text{H}^4\text{Cl})^2\text{NH}$, melts at 89° ; tri-*p*-chlorobenzylamine, $(\text{C}^6\text{H}^4\text{Cl})^3\text{N}$, at 196° (Jackson a. Field, *Ber.* xi. 904).

Iodobenzylamines.—Di- and Tri-*p*-iodobenzylamine, $(\text{C}^6\text{H}^4\text{I.CH}_2)^2\text{NH}$, and $(\text{C}^6\text{H}^4\text{I.CH}_2)^3\text{N}$, are produced simultaneously by boiling *p*-iodobenzyl bromide (p. 2007) with alcoholic ammonia. The *tri-derivative*, which is the less soluble part of the product, may be purified by recrystallisation from ether. It forms white needles, melting at 114° – 115° , insoluble in water and in cold alcohol, slightly soluble in hot alcohol, also in ether, benzene, and carbon sulphide. The *platinochloride*, $[(\text{C}^6\text{H}^4\text{I.CH}_2)^3\text{NH}]^3\text{PtCl}_6$, crystallises in yellow needles nearly insoluble in water and in alcohol. Di-*p*-iodobenzylamine forms white needles having an aromatic odour and melting at 76° . It is insoluble in water, but dissolves readily in hot alcohol, ether, benzene, and carbon sulphide. The *platinochloride*, $[(\text{C}^6\text{H}^4\text{I.CH}_2)^2\text{NH}]^2\text{PtCl}_6$, forms light yellow crystals nearly insoluble in water and in alcohol (Mabery a. Jackson, *Ber.* xi. 55).

Ethylbenzylamines. Diethylbenzylamine, $\text{NH}(\text{C}^2\text{H}_5)^2$, formed by heating diethylamine with benzyl chloride in molecular proportions, boils at 211° – 212° (V. Meyer, *Ber.* x. 309).

Triethylbenzylammonium Iodide, $\text{N}(\text{C}^2\text{H}_5)^3(\text{C}^6\text{H}_5)\text{I}$.—According to Ladenburg a. Strüver (*Ber.* x. 43), and Ladenburg (*ibid.* 561, 1152, 1634), on the one hand, and V. Meyer (*ibid.* 309, 964, 978, 1291) on the other, this compound admits of two modifications, $\text{N}(\text{C}^2\text{H}_5)^3\text{C}^6\text{H}_5\text{I}$ and $\text{N}(\text{C}^2\text{H}_5)^2\text{C}^6\text{H}_5\text{C}^6\text{H}_5\text{I}$, the former, designated as above, being obtained by the union of triethylamine and benzyl iodide, the latter, called benzyl-triethylammonium iodide, from benzyl-diethylamine and ethyl iodide by heating with water; also, together with the hydriodides of benzyldiethylamine and benzytriethylamine, by heating benzylamine at 130° with ethyl iodide. Both these iodides crystallise in large white crystals; both yield the same periodide, $\text{N}(\text{C}^2\text{H}_5)^3\text{C}^6\text{H}_5\text{I}^3$, which is formed either by direct combination or by boiling the solutions of the monoiodides with hydriodic acid, and crystallises in metallic lustrous prisms melting at 87° ; moreover, the corresponding picrates resemble each other very closely, consisting of yellow prisms melting below 100° . The *platinochlorides*, however, are, according to Ladenburg a. Strüver, not identical, that of triethylbenzylammonium chloride crystallising in tufts of prisms, or in well-defined, apparently monoclinic crystals, whereas that of benzytriethylammonium chloride forms tabular crystals, apparently rhombic, which, by keeping or recrystallisation, are converted into the former *platinochloride*. According to Ladenburg, also, the iodide of triethylbenzylammonium changes into that of benzytriethylammonium when its solutions are concentrated. Altogether, however, the difference between the two iodides does not appear to be satisfactorily made out.

Phenylbenzylamine, or *Benzylaniline*, $\text{NH}(\text{C}^6\text{H}_5)(\text{CH}_2.\text{C}^6\text{H}_5)$. This base, metameric with Hofmann's tolylaniline (iv. 454), is formed: (1). Together with aniline hydrochloride, by heating benzyl chloride (b. p. 176°) with aniline at 160° for twenty-four hours:

(M. Fleischer, *Liebig's Annalen*, cxxxviii. 225).

(2). By the action of nascent hydrogen (zinc-dust and HCl, or sodium-amalgam and water) on benzoethianilide (p. 1924):

(Bernthsen a. Trompeter, *Ber.* xi. 1756).

Benzylaniline solidifies at low temperatures to a crystalline mass, and crystallises from hot alcohol in four-sided prisms, insoluble in water, easily soluble in alcohol and ether. It melts at 32°, remains liquid at 12°, and boils at 310° (Fleischer); melts at 33° (B. and T.) [Tolylaniline, $\text{NH}(\text{C}^6\text{H}_5)(\text{C}^6\text{H}_4\cdot\text{CH}_3)$, melts at 87° and boils at 334.5° (corr.)]. The *hydrochloride*, $\text{C}^{13}\text{H}^{13}\text{N}\cdot\text{HCl}$, forms white well-defined crystals easily soluble in water and alcohol, sparingly in ether, and turning green on exposure to the air or on drying (Fleischer); white laminae melting at 197° (B. and T.). The *platinichloride* forms concentric groups of yellow-red laminae (B. and T.). The *cadmichloride*, $\text{C}^{13}\text{H}^{13}\text{N}\cdot\text{CdCl}_2$, dissolves readily in hot alcohol, and crystallises in tufts of white needles which are decomposed by drying or by the action of water (Fleischer).

In contact with *mercuric chloride*, benzyaniline forms a green mass which dissolves with blue colour in alcohol, assumes a darker colour on prolonged heating, and then dissolves in alcohol with crimson colour. Benzyaniline heated with *benzoyl chloride* forms a yellowish oil, which gradually solidifies in contact with water and alkali, and crystallises from alcohol in well-defined six-sided monoclinic prisms, consisting of phenylbenzylbenzamide, $\text{N}(\text{C}^6\text{H}_5)(\text{C}^6\text{H}_7)(\text{C}^6\text{H}_4\text{O})$. This compound is insoluble in ether, melts at 104°, and dissolves in strong nitric acid, forming a yellow nitro-compound (Fleischer).

Benzylidiphenylamine, $\text{N}(\text{C}^6\text{H}_7)(\text{C}^6\text{H}_5)_2$, formed by the action of nascent hydrogen on benzodiphenylthiamide, crystallises in long white needles melting at 86.5°–87°. It is nearly insoluble in water, slightly soluble in cold alcohol, easily in hot alcohol and in ether; does not exhibit basic properties (Berntsen a. Trompeter).

Derivatives of Toluidine containing Acid Radicles.

Acetoluides, $\text{C}^6\text{H}_4(\text{NH}\cdot\text{C}^6\text{H}_3\text{O})\cdot\text{CH}_3$. *Para*-acetoluide is dimorphous. By spontaneous evaporation of its alcoholic solution it is obtained in monoclinic crystals having the axial ratio $a : b : c = 1.21654 : 1 : 0.78885$, and the axial angle $106^\circ 7' 20''$. Observed forms $\infty \text{P} \infty$, 0P , ∞P , $-\text{P}$, P , ∞P , $2\text{P} \infty$. Cleavage perfect parallel to 0P , less distinct parallel to $\infty \text{P} \infty$. Twin-plane parallel to 0P . In a cleavage plate parallel to 0P , the angle of the optic axes in oil was for red light $106^\circ 10' (\rho < \nu)$. Dispersion very weak. On cooling from a warm alcoholic solution, on the other hand, or from a supersaturated solution, the compound is deposited in orthorhombic crystals, partly transparent needles without distinct summits, partly flat needles with distinct summits, and in the latter case mostly turbid. Axes $a : b : c = 0.65147 : 1 : 0.32885$. Observed forms $\infty \text{P} \infty$, $\infty \text{P} \infty$, 0P , ∞P , P , ∞P , $2\text{P} 2$. The transparent needles exhibit only the faces $\infty \text{P} \infty$, $\infty \text{P} \infty$ and ∞P . Cleavage not recognisable. The plane of the optic axes is $\infty \text{P} \infty$; the acute bisectrix is normal to $\infty \text{P} \infty$. $\rho < \nu$. Angle $2\text{H}_a = 84^\circ$ for red. This case of dimorphism is the third which has been observed in the paraseries (Parebianco, *Gazz. chim. ital.* 1878, 426).

By oxidation with potassium permanganate in hot aqueous solution, *p*-acetoluide yields an acetamidobenzoic acid, $\text{C}^6\text{H}_4(\text{NH}\cdot\text{C}^6\text{H}_3\text{O})(\text{CO}_2\text{H})$, which melts with partial decomposition at about 250°, and is converted by hydrochloric acid into the hydrochloride of paramidobenzoic acid (A. W. Hofmann, *Ber.* ix. 1299).

On the reaction of *p*-acetoluide with *phosphorus pentachloride*, see *Ethenyl-tolylamidines* (p. 746).

o-Acetoluide dissolved in glacial acetic acid is converted by iodine chloride into mono-iod-*o*-acetoluide; *p*-Acetoluide, on the other hand, is not attacked by iodine chloride (see IODOTOLUIDINES, p. 1999).

Metabromorthacetoluide, $\text{C}^6\text{H}_3\text{NH}(\text{C}^6\text{H}_3\text{O})\cdot\text{Br}\cdot\text{H}^+$, formed by boiling metabrom-orthotoluidine (p. 1998) with glacial acetic acid for six hours, separates from aqueous solution in white capillary coral-like forms, which under the microscope appear to be made up of slender needles; it melts at 156° (Grete, *Ber.* viii. 565).

Benzotoluides, or Tolybenzamides, $\text{C}^{14}\text{H}^{13}\text{NO} = \text{CH}_3\cdot\text{C}^6\text{H}_4\cdot\text{NH}\cdot\text{CO}\cdot\text{C}^6\text{H}_5$. The *para*-modification, obtained by treating *p*-toluidine with benzoyl chloride (v. 872), melts, according to Kelbe (*Ber.* viii. 875), at 155°, and is easily resolved by boiling with alkalis into toluidine and benzoic acid. By nitration it yields a mono- and a dinitro-compound, which may be separated by crystallisation from an alcoholic alkaline solution, the mononitro-compound crystallising out first. This latter compound forms yellow needles melting at 143°. It is insoluble in water, and is resolved by hydrochloric acid at 200° into benzoic acid and *metanitrotoluidine*, which crystallises from alcohol in red needles melting at 110°. By the action of hydrogen it is converted into *anhydroadiamidobenzotoluide*, a volatile, very stable basic compound which crystallises in colourless needles, melts at 232°–233°, is insoluble in water, but dissolves in alcohol and in aqueous potash. Its *hydrochloride* is easily decomposable, and only

sparingly soluble in cold water. The *sulphate* crystallises in red needles (Kelbe). C. A. Bell (*Ber.* vii. 1504) describes a nitrobenzotoluide obtained by the action of benzoyl chloride on nitrotoluidine (m. p. 77·5°). It crystallises in light yellow prisms melting at 172°, and is reduced by tin and hydrochloric acid to a benzoyltolylene-diamine which crystallises in colourless needles melting at 142°.

Dinitrobenzotoluidine forms colourless needles, easily soluble in alcohol and glacial acetic acid, melting at 186°. By heating with hydrochloric acid or with alcoholic potash at 150°, it is converted into a dinitrotoluidine, which dissolves in hot water, melts at 186°, and is converted by hydrogen into a base, $C^6H^3(NH^2)^2NH_2.O^6C^6H^3$, which crystallises in grey opaque needles, soluble in alcohol and ether, and melting at 182°–183°. Its sulphate contains 1 mol. water of crystallisation. Dinitrobenzotoluide is converted by hydrogen sulphide into an amidonitrobenzotoluide, which crystallises in red needles melting at 137°–139° (Kelbe, *loc. cit.*)

Benzotoluidide, $C^6H^3.CS.NH(C^6H^7)$. See THIAMIDES (p. 1953).

Diamidotoluenes, or **Tolylenediamines,** $C^6H^6(NH^2)^2 = C^6H^3(NH^2)^2.CH^3$ (v. 872; vii. 1180).

PARA-ORTHOTOLYLENEDIAMINE, $CH^3 : NH^2 : NH^2 = 1 : 2 : 4$ (m. p. 99°), also called *Metatolylenediamine*. This modification is converted by boiling with excess of glacial acetic acid into a *diacetotolylenediamine* melting at 224°, which, when treated with cold fuming nitric acid, yields *nitrodiacetotolylenediamine* melting at 253°, soluble in 300 pts. of boiling acetone, insoluble in alcohol and ether. This nitro-aceto-compound dissolves with decomposition in hot hydrochloric acid, and the solution on cooling deposits red crystals which, as well as the solution, are decomposed by ammonia, yielding a *nitrotolylenediamine*, which dissolves in hot water, and crystallises in yellow-red needles melting at 154°; dissolves also in hot dilute acids, forming easily decomposable crystallisable salts, and in hot alcohol. This nitrotolylenediamine, treated with nitrogen dioxide or nitrous gas, yields a red, very stable amorphous body having the composition $C^6H^3(NO^2)(NH^2)N^2.C^6H^3(NO^2)(NH^2)(NH)$. If the reaction takes place in an acid solution, there is also formed a colourless bye-product—probably a nitroethylresol, which gives off nitrogen when boiled with alcohol. It crystallises in shining prisms; is insoluble in water, but dissolves easily in alcohol; volatilises with steam; melts at 72°–73°, and boils at about 285° (Ladenburg, *Ber.* viii. 1209).

When *p-o*-tolylenediamine dissolved in alcohol is treated with *carbon bisulphide*, large quantities of hydrogen sulphide are given off, and on leaving the solution to digest for two days at the ordinary temperature, then evaporating it to a syrup, and exhausting with benzene, a yellow residue is left, soluble in alcohol, and on adding water to the alcoholic solution, a yellow crystalline precipitate is obtained, consisting of tolylene thiocarbamide, $N^2(C^6H^6)(CS)H^2$ (R. Lussy, *Ber.* viii. 291).

(*p-o*)-Tolylenediamine, treated with ethylchlorocarbonate, yields tolylene-urethane, $C^{12}H^{10}N^2O^4$, which crystallises from alcohol in dazzling white silky needles melting at 137°:

When a concentrated aqueous solution of (*p-o*)-tolylenediamine sulphate is mixed with a warm solution of an equivalent quantity of *potassium thiocyanate*, the solution then evaporated, the residue exhausted with alcohol, and the filtrate purified with animal charcoal and left to crystallise, a crystalline mass is obtained, which dissolves readily in water, and gives the thiocyanate reaction with ferric chloride. Hence the immediate product of the reaction is *tolylenediamine thiocyanate*, $(CN.S)^2C^6H^6$, but this salt soon changes, even without heating, into tolylenethiocarbamide, $(CS=N)^2C^6H^6$ (Lussy, *Ber.* vii. 1263).

With *furfural* in presence of an acid, this tolylenediamine forms a metallically lustrous salt containing the elements of the two bodies *minus* the elements of water (H. Schiff, *Ber.* xi. 830). (*p-o*)-Tolylenediamine reacts with salts of *paraditolaldiazin* (azotoluene), so as to produce diamidoditolaldiazin, or the chrysoidine of the toluene series, $C^{14}H^{10}N^4 = C^6H^7.N=N.C^6H^3(NH^2)^2$, which crystallises in stellate groups of orange-yellow needles melting at 183°, easily soluble in alcohol and ether, nearly insoluble in water. Its salts crystallise more readily than those of chrysoidine. The *platinochloride* has a crimson colour (see CHRYSOIDINE, p. 470).

PARA-META-TOLYLENEDIAMINE, $C^6.CH^3.H.NH^2.NH^2.H^2$ (also called *Ortho-tolylenediamine*), is obtained by reduction of *m*-nitro-*p*-toluidine (vi. 1180), also

together with acetic acid, by reduction of *m*-nitro-*p*-trichloracetoluide with tin and hydrochloric acid (Friederici. *Ber.* xi. 1970):

This base melts at 89°. When treated in very dilute aqueous solution containing sulphuric acid, with a dilute solution of *potassium nitrite*, it is converted into a amid-

azototylene or amidotylene-diazin, $\text{C}^6\text{H}^3\text{N}^2 = \text{NH}^2.\text{C}^6\text{H}^3 \begin{smallmatrix} \text{N} \\ \parallel \\ \text{N} \end{smallmatrix}$, which crystallises from toluene in large prisms containing 118 per cent. toluene of crystallisation, melts at 83°, and distils almost without decomposition at 323° (Ladenburg, *Ber.* ix. 219).

Reaction of (p-m)-Tolylenediamine with Aldehydes.—The combination of 1 mol. (*p-m*)-tolylenediamine and 2 mol. of an aldehyde, with elimination of 1 mol. water, gives rise to a class of bodies called tolualdehydines, which have been prepared and examined by Ladenburg (*Ber.* xi. 590, 1656).

Tolubenzaldehydine, $\text{C}^{11}\text{H}^{18}\text{N}^2$, is prepared by heating the diamine with benzaldehyde at 140°, and may also be obtained by heating the hydrochloride of the diamine with benzaldehyde, first at 100° and then at 130°, till hydrochloric acid ceases to be evolved. The crude product is dissolved in hot dilute hydrochloric acid, and the crystals which separate on cooling are decomposed by ammonia. The free base is soluble in alcohol, acetone and acids, and is deposited from an alcoholic solution, in transparent, monoclinic prisms which melt at 195·5°. In small quantities it sublimes without decomposition. The *hydrochloride*, $\text{C}^{11}\text{H}^{18}\text{N}^2.\text{HCl}.\text{H}^2\text{O}$, is but slightly soluble in strong hydrochloric acid, and separates out in long, needle-shaped crystals from a solution in the hot dilute acid.

Tolubenzaldehydine Ethiodide.—Two kinds of crystals are produced by the union of ethyl iodide with the aldehydine, viz., thick prisms or tables, and long needles, both of which are soluble in water and in alcohol; they have the same composition, $(\text{C}^{11}\text{H}^{18}\text{N}^2.\text{C}^2\text{H}_5\text{I}.\frac{1}{2}\text{H}^2\text{O})$, and melt at 180°–181°. An alcoholic solution of iodine converts this compound into $\text{C}^{12}\text{H}^{23}\text{N}^2\text{I}_2$, which crystallises in brown plates melting at 123°. By the action of silver oxide on tolubenzaldehydine ethiodide an oily liquid is formed, the hydrochloric acid solution of which gives with platinum chloride a yellow crystalline precipitate of *tolubenzaldehydine ethylplatinochloride*, $(\text{C}^{12}\text{H}^{23}\text{N}^2\text{Cl})_2.\text{PtCl}_4$. *Tolubenzaldehydine Methiodide*, $\text{C}^{11}\text{H}^{18}\text{N}^2.\text{C}^2\text{H}_3\text{I}$, forms white needle-shaped crystals which melt with decomposition at 209°.

Tolubenzaldehydine oxidised with potassium permanganate yields an acid which melts at 253·5°–254·5°, and probably consists of *dibenzylideneamidobenzoic acid*,

Tolufurfuraldehydine, $\text{C}^{17}\text{H}^{14}\text{N}^2\text{O}^2$, obtained by heating (*p-m*)-tolylenediamine with furfural on the water-bath—or better by the action of furfural on the hydrochloride of (*p-m*)-tolylenediamine—crystallises in white silky prisms melting at 128·5°, easily soluble in ether, alcohol, benzene, and toluene, sparingly in ligroin. The *nitrate* crystallises in needles; the *platinochloride* forms yellow crystals easily soluble in alcohol; the *sulphate* crystallises from alcohol in prisms.

Tolufurfuraldehydine methiodide, $\text{C}^{17}\text{H}^{14}\text{N}^2\text{O}^2.\text{CH}_3\text{I}$, obtained by treating the aldehydine with excess of methyl iodide, crystallises in brilliant laminae having a bitter taste, very sparingly soluble in cold water, slightly more soluble in alcohol, and melting at 195·5°. The corresponding *chloride* forms colourless shining laminae easily soluble in water, and very poisonous; the *platinochloride* is a yellow powder. On adding an alcoholic solution of iodine to an alcoholic solution of tolufurfuraldehydine methiodide, a tri-iodide, $\text{C}^{18}\text{H}^{17}\text{N}^2\text{O}^2\text{I}_3$, is formed as a yellow-brown crystalline precipitate, and crystallises from hot alcohol in light-brown needles melting at 126°–128°. The alcoholic filtrate mixed with excess of iodine-solution deposits the *pentiodide*, $\text{C}^{18}\text{H}^{17}\text{N}^2\text{O}^2\text{I}_5$, in steel-blue oblique prisms melting at 100°.

Tolu-anisaldehydine, $\text{C}^{12}\text{H}^{22}\text{N}^2\text{O}^2$, is prepared by adding anisaldehyde to a dilute aqueous solution of (*p-m*)-tolylenediamine hydrochloride, with addition of a little alcohol, and may be separated from the hydrochloride by ammonia and purified by crystallisation from alcohol. It forms stellate groups of needles, very soluble in alcohol and chloroform, sparingly in light petroleum, melting at 152°–156°.

(*p-m*)-Tolylenediamine and *Salicylaldehyde*, heated together at 110°, yield, not an aldehydine, but condensation-products, formed by combination of 1 mol. of the diamine and 3 mol. salicylaldehyde, with elimination of 3 mol. water, or of 2 mol. diamine and 3 mol. aldehyde, with elimination of 3 mol. water. The former com-

pound, $C^{28}H^{22}N^4O^3$, crystallises from alcohol in stellate groups of needles which melt at 106° – 110° , and are converted by long boiling with hydrochloric acid into an amorphous body which dissolves in potash-ley, forming a blue fluorescent liquid from which it is precipitated by carbonic acid. The second body, $C^{38}H^{32}N^4O^3$, called *azurine*, is obtained by heating the diamine with twice its weight of the aldehyde at 135° , and treating the product with hot dilute hydrochloric acid. The acid solution is filtered; the white amorphous precipitate thrown down on adding strong hydrochloric acid to the filtrate is dissolved in alcoholic potash and shaken up with ether; the ethereal solution is evaporated to dryness; and the residue is dissolved in water, precipitated by carbon dioxide, and recrystallised from amyl alcohol. Azurine is characterised by the blue fluorescence of its solutions, and forms colourless tabular crystals soluble in amyl alcohol and acetone, melting at 250.5° .

Methenyl-tolylenediamine, $C^8H^8N^2 = C^7H^8 \begin{smallmatrix} \text{NH} \\ \text{N} \end{smallmatrix} \text{CH}$, formed by prolonged heating of *p-m*-tolylene-diamine with formic acid, passes over on distillation at a very high temperature, and solidifies to a crystalline mass melting at 101° ; it has not, however, been obtained quite pure. Its *hydrochloride* is very soluble. The *platinochloride*, $(C^8H^8N^2.HCl)^2PtCl_4$, crystallises from water in yellow prisms (Ladenburg, *Ber.* x. 1123).

Ethenyl-tolylenediamine, $C^9H^{10}N^2 = C^7H^8 \begin{smallmatrix} \text{N} \\ \text{NH} \end{smallmatrix} \text{C.CH}^3$, is formed on mixing ethylic acetoacetate and *p-m*-tolylene-diamine in molecular proportions. The temperature of the mixture sinks whilst the diamine dissolves, but afterwards rises, water then separating out, and the mixture solidifying to a crystalline mass (m. p. 82°), which has the composition $C^{14}H^{18}N^2O$, and when heated to 116° splits up into ethyl acetate and ethenyltolylene-diamine melting at 198° – 199° . The reaction takes place by two stages as follows:

(Ladenburg a. Rugheimer, *Ber.* xii. 951).

Benzenyl-p-m-tolylenediamine, $C^{11}H^{12}N^2 = CH^3.C^6H^3 \begin{smallmatrix} \text{N} \\ \text{NH} \end{smallmatrix} \text{C.C}^6H^5$.—To prepare this compound, a flask containing a mixture of *p-m*-tolylene-diamine and acetophenone in molecular proportions is gradually heated in an oil-bath to 180° , at which temperature it is kept for thirty-six hours, the loss of acetophenone by volatilisation being made up by dropping in small quantities from time to time. The reaction is supposed to take place as follows:

On exhausting the product with hydrochloric acid, a solution is obtained which, on cooling, deposits needle-shaped crystals of the hydrochloride of benzenyl-*p-m*-tolylene-diamine. The free base melts at 240° , and is identical in its properties with the anhydro-base which Kelbe obtained from mononitrobenzotoluide (p. 2002) (Ladenburg a. Rugheimer, *loc. cit.*)

Phthalyltolylene-diamines (R. Biedermann, *Ber.* x. 1160).—*Monophthalyltolylene-diamine*, $C^7H^8 \begin{smallmatrix} \text{NH.CO} \\ \text{NH.CO} \end{smallmatrix} \text{C}^6H^4$, and *Diphthalyltolylene-diamine*, $C^7H^8 = \left(N \begin{smallmatrix} \text{CO} \\ \text{CO} \end{smallmatrix} \text{C}^6H^4 \right)^2$, are formed by heating (*p-o*)-tolylene-diamine with phthalic anhydride, with or without addition of phosphoric anhydride, strong sulphuric acid, sodium acetate, or strong alcohol; also by the action of phthalyl chloride on tolylenediamine hydrochloride.

The *monophthalyl-base* crystallises in needles having a golden-yellow colour and silky lustre, and is best purified by repeated crystallisation from nitrobenzene. It melts at 192° , and is only very slightly soluble in hot water, but dissolves readily in hot alcohol and glacial acetic acid. Dilute hydrochloric acid at the boiling heat converts this substance into diphthalyltolylene-diamine and a base, $C^{27}H^{24}N^4O^4$, represented by the constitutional formula $C^7H^8(NH.CO.C^6H^4.CO.NH.C^6H^4.NH^2)^2$. This base is easily soluble in water, and is resolved by repeated evaporation with hydro-

chloric acid into phthalic acid and (*p-o*)-tolylenediamine. Its hydrochloride is easily soluble, crystallises in rhomboidal laminæ, and forms a reddish-yellow platinochloride, $C^{27}H^{24}N^6O^4 \cdot 2HCl, PtCl_4$.

Diphthalyltolylenediamine, $C^{21}H^{14}N^2$, is quite insoluble in water and in alcohol, and separates from solution in glacial acetic acid, in small shining crystals melting at 232° – 233° . It resists the action of hydrochloric acid, but is gradually decomposed by hot soda-ley.

(*m-o*)-Tolylenediamine (m. p. 80°) yields a monophthalyl-derivative melting at $104\frac{1}{2}^\circ$, and a diphthalyl-derivative melting at 272° . Both are colourless.

(1–0) **Hydroxytoluenes**, $C^6H^4(CH^3).OH$. *Tolyl Alcohols*.—Cresols (pp. 582, 1540). From the results of Tiemann a. Schotten's experiments on the conversion of cresols into hydroxytoluic aldehydes (p. 2027), it appears that coal-tar cresol is a mixture of the three isomeric cresols, *ortho*-, *meta*-, and *para*-. The three cresols are also present together in horse-urine in the form of sulphonic acids, and are produced by the dry distillation of vegetable matters: hence it may be inferred that they are produced in the one case as in the other by decomposition of the same plant-constituent (C. Preusse, *Zeitschr. physiol. Chem.* ii. 355). A cresol (modification not stated) is formed by oxidation of toluene in presence of aluminium chloride (Friedel a. Crafts, *Compt. rend.* lxxxvi. 884).

According to Baumann a. Herter (*Ber.* ix. 138), cresol (commercial, or prepared from horse-urine), when given to animals in their food, is converted in the organism into a cresol sulphonic acid, which is eliminated in the urine.

On the reaction of Cresols with *chloroform* and *sodium hydride*, see HYDROXY-TOLUIC ALDEHYDES (p. 2027).

On their reaction with *potassium chlorate* and *hydrochloric acid*, see TOLUQUINONES.

(0–1) **Hydroxytoluene**, or **Benzyl Alcohol**, $C^6H^5.CH^2OH$. When *beron chloride* is passed into this alcohol, hydrogen chloride is evolved, and dibenzoyl, $C^{14}H^{14}$, is formed, together with benzyl chloride (Councler, *Ber.* x. 1655).

Benzyl Acetate treated with *sodium* is converted into the benzylic ether of hydrocinnamic or β -phenylpropionic acid (p. 1068). In like manner *benzyl butyrate*, $CH^3.CH^2.CH^2.COO.CH^2.C^6H^5$, is converted by the action of sodium into the benzylic ether of normal phenylvaleric acid, $C^6H^5(CH^2)^4.COO.CH^2.C^6H^5$, which boils at 250° and yields phenylvaleric acid melting at 78° (Conrad a. Hodgkinson, x. 254).

Ethyllic Benzylacetacetate (pp. 14, 317) is converted by saponification partly into methyl-phenylethyl ketone, $CH^3.CO.(CH^2.CH^2.C^6H^5)$, partly into dibenzylacetic acid, $(C^6H^5.CH^2)^2.CH.COOH$, and acetic acid, perhaps thus:

(L. Ehrlich, *Liebig's Annalen*, clxxxvii. 11).

Parabromobenzyl-compounds (Jackson a. Lowery, *Ber.* x. 1209).—The alcohol, $C^6H^4Br.CH^2OH$, is most easily prepared by boiling parabromobenzyl bromide (p. 314) with water for some days, in a flask with reversed condenser. It is also obtained by heating parabromobenzyl acetate to 150° with aqueous ammonia. It forms long, colourless, elastic, flat needles, having a fine nacreous lustre and unpleasant odour, melting at 69° , and dissolving easily in boiling water, alcohol, ether, benzene, and carbon bisulphide.

The *acetate*, formed by heating the bromide with sodium acetate in alcohol, decomposes when distilled, and has not yet been obtained pure.

The *cyanide*, $C^6H^4Br.CH^2CN$, obtained by boiling the bromide with alcoholic solution of potassium cyanide, is a crystalline body of strong disagreeable odour, melting at 46° , and dissolving easily in alcohol, ether, benzene, glacial acetic acid, and carbon bisulphide, but not in water. Heated at 100° with hydrochloric acid in sealed tubes, it is converted into parabromalphenatoluic acid, $C^6H^4Br.CH^2.COOH$; see TOLUIC ACIDS (p. 2026).

The *thiocyanate*, $C^6H^4Br.CH^2SCN$, formed by boiling the bromide with potassium thiocyanate, crystallises in needles, melting at 25° , and dissolving very easily in alcohol.

Orthobromobenzyl-compounds (Jackson a. Field, *Ber.* xiii. 1218).—The bromide, $C^6H^4Br.CH^2Br$, obtained by the action of bromine on boiling bromotoluene, is purified by distillation in vapour of hydrobromic acid; it crystallises in broad tablets melting at 30° . The alcohol, $C^6H^4Br.CH^2OH$, is produced by the action of

aqueous ammonia at 160° in a sealed tube, or of alcoholic potash on the acetate (formed from the bromide by means of alcoholic sodium acetate); also by boiling the bromide for several days with water. It crystallises from hot water, or better from ligroin, in needles melting at 80°; sublimes readily, and distils with vapour of water. By potassium permanganate it is oxidised to *o*-bromobenzoic acid. The *cyanide* prepared from the bromide with alcoholic potassium cyanide, is, in the crude state, a dark-coloured oil. Heated with hydrochloric acid in a sealed tube at 130°, it is converted into bromophenylacetic acid, $\text{C}^6\text{H}^4\text{Br}.\text{CH}_2\text{COOH}$, melting at 102.5°–103° (see *TOLUIC ACIDS*, p. 2027). The *thiocyanate*, $\text{C}^6\text{H}^4\text{Br}.\text{CH}_2\text{SCN}$, is an oil which does not solidify in a freezing mixture.

p-Chlorobenzyl-compounds.—The *chloride*, $\text{C}^6\text{H}_4\text{Cl}.\text{H}.\text{H}.\text{Cl}.\text{H}_2$, forms long white shining needles melting at 29°, having a pleasant aromatic odour, and acting strongly on the mucous membranes. It is very volatile, sublimes readily, dissolves easily in hot alcohol, also in ether, benzene, carbon sulphide, and glacial acetic acid. The *bromide*, $\text{C}^6\text{H}_4\text{Cl}.\text{CH}_2\text{Br}$, prepared from *p*-chlorotoluene, melts at 48.5°, and boils at 225°–230°. *Di-p*-chlorobenzyl bromide boils at 280°–290°; the corresponding *chloride* at 288°. *Tri-p*-chlorobenzyl chloride boils at 196° (Jackson a. Field, *Ber.* xi. 904). Beilstein a. Kuhlberg (*Liebig's Annalen*, cl. 286), by treating trichlorotoluene with chlorine at the boiling heat, obtained a trichlorobenzyl chloride boiling at 273° (vi. 282).

p-Iodobenzyl-compounds.—The *bromide*, $\text{C}^6\text{H}_4\text{Br}.\text{H}.\text{H}.\text{I}.\text{H}_2$, formed by heating *p*-iodotoluene in bromine-vapour, best between 115° and 150°, crystallises in white flat needles having an aromatic odour, and attacking the mucous membranes; it melts at 78.75°, sublimes in needles, is insoluble in water, but dissolves readily in hot alcohol, ether, benzene, and carbon sulphide. The *alcohol*, $\text{C}^6\text{H}_4\text{Br}.\text{CH}_2\text{OH}.\text{H}.\text{H}.\text{I}.\text{H}_2$, prepared from the bromide by boiling with water, or from the corresponding acetate by means of aqueous ammonia, crystallises from carbon sulphide in white scales having a silky lustre and unpleasant odour; it melts at 71.75°; dissolves readily in alcohol, ether, benzene, and carbon sulphide. The *cyanide*, $\text{C}^6\text{H}_4\text{I}.\text{CH}_2\text{CN}$, prepared from the bromide, crystallises in white nacreous plates melting at 50.5°, insoluble in water, easily soluble in alcohol, ether, carbon sulphide, and benzene. Heated at 100° with fuming hydrochloric acid, it is converted into iodophenylacetic acid, $\text{C}^6\text{H}_4\text{I}.\text{CH}_2\text{COOH}$ (see *α*-TOLUIC ACID). The *thiocyanate*, $\text{C}^6\text{H}_4\text{I}.\text{CH}_2\text{SCN}$, is obtained from the bromide by means of potassium thiocyanate, as an oil which gradually solidifies, but after purification by crystallisation from alcohol, it forms long white shining plates melting at 40°. It has a disagreeable odour, is moderately soluble in hot alcohol, easily in ether, benzene, carbon sulphide, and glacial acetic acid (Mabery a. Jackson, *Ber.* xi. 55).

TOLUENESULPHONIC ACIDS, $\text{C}^6\text{H}^4(\text{CH}_3)\text{SO}^3\text{H}$. The three toluenesulphonic acids (*o*-, *m*-, and *p*-) are formed, together with the corresponding chlorides, by treating toluene (1.12 pt.) cooled to 10° with sulphuric hydroxychloride (2.8 pts.), the reaction taking place according to the following equation:

The best mode of proceeding is to pour the toluene by successive portions into the cooled sulphuric hydroxychloride. The mixed sulphonic chlorides may be separated from the rest of the product by pouring the whole into ice-cold water; and on cooling these mixed chlorides to –20°, the *para*-compound separates in the solid state, while the *ortho*- and *meta*-compounds remain liquid. These chlorides may be converted into the corresponding amides, which may be separated by fractional crystallisation. Tolueneparasulphonic acid is obtained from the corresponding chloride, purified by crystallisation from ether, by boiling it with water; the *ortho*- and *meta*-acids by heating the corresponding amides with hydrochloric acid, the former at 135°–140°, the latter at 150° (Claesson a. Wallin, *Ber.* xii. 1848).

The table on p. 2008 exhibits the properties of several salts of the three acids thus prepared, and of the corresponding amides.

The three toluenesulphonic acids are also produced by the action of sulphurous acid on the corresponding diazo-compounds (F. Müller a. Wiesinger, *Ber.* xii. 1348). The *meta*-acid is further obtained by debromination of the *p*-bromotoluene-*m*-sulphonic acid, $\text{CH}_3 : \text{SO}^3\text{H} : \text{Br} = 1 : 3 : 4$, produced by the action of fuming sulphuric acid at 160°–180° on *p*-bromotoluene; also by dechlorination of the *ortho*-chlorotoluenesulphonic acid described by Hübner a. Majert (p. 2013).

The following salts and derivatives of the *meta*- and *ortho*-sulphonic acids are described by Hübner a. Post (*Liebig's Annalen*, clxix. 1–69), the description of the salts differing in several instances from those given by Claesson a. Wallin.

Para	Meta	Ortho
$C^7H^7SO^3H + H^2O$. Crystallises better than the isomerides. Long thick leaflets, or flat prisms. Deliquescent.	$C^7H^7SO^3H + H^2O$. Thin crystalline scales. Very soluble and deliquescent.	$C^7H^7SO^3H + 2H^2O$. Thin leaflets. Very easily soluble. Deliquescent.
$C^7H^7SO^3K + H^2O$. Long prisms, like nitre. Soluble.	$C^7H^7SO^3K + H^2O$. Needles or thin plates, united to form nodules. Very easily soluble.	$C^7H^7SO^3K + H^2O$. Tables of rhombic or almost quadratic habit. Soluble.
$C^7H^7SO^3Na + 3H^2O$. Rectangular plates; easily soluble.	$C^7H^7SO^3Na + H^2O (?)$ Long leaflets, very soluble.	$C^7H^7SO^3Na + H^2O$. Plates, easily soluble.
$C^7H^7SO^3Ag$. Long plates, easily soluble.	$C^7H^7SO^3Ag$. Long leaflets, very soluble.	$C^7H^7SO^3Ag$. Plates, easily soluble.
$(C^7H^7SO^3)^2Ca + 4H^2O$. Crystallises well in apparently monoclinic prisms. Easily soluble.	$(C^7H^7SO^3)^2Ca + 3H^2O$. Long fine needles; very easily soluble.	$(C^7H^7SO^3)^2Ca$. Separates from its solutions on cooling, in leafy crystals.
$(C^7H^7SO^3)^2Ba + H^2O$. Tufts of slender needles. 1 pt. dissolves in 4·8 pts. water at 12°.	$(C^7H^7SO^3)^2Ba + H^2O$. Crystallises indistinctly. 1 pt. in 4·4 water at 12°.	$(C^7H^7SO^3)^2Ba + H^2O$. Thin laminae. 1 pt. in 26 water at 12°.
$(C^7H^7SO^3)^2Pb$. Long needles, moderately soluble.	$(C^7H^7SO^3)^2Pb + 3H^2O$. Rectangular plates, easily soluble.	$(C^7H^7SO^3)^2Pb + H^2O$. Crystalline scales, sparingly soluble.
$(C^7H^7SO^3)^2Mg + 6H^2O$.	$(C^7H^7SO^3)^2Mg + 8H^2O$.	$(C^7H^7SO^3)^2Mg + 7H^2O$.
$(C^7H^7SO^3)^2Zn + 6H^2O$. Four-sided pointed prisms.	$(C^7H^7SO^3)^2Zn + 7H^2O$. Rectangular leaflets.	$(C^7H^7SO^3)^2Zn + 7H^2O$. Large prisms.
$(C^7H^7SO^3)^2Cd + 6H^2O$. Large rectangular plates.	$(C^7H^7SO^3)^2Cd + 5H^2O$. Small oblique-angled plates.	$(C^7H^7SO^3)^2Cd + 2H^2O$. Small rectangular plates, very soluble.
$(C^7H^7SO^3)^2Mn + 6H^2O$. Large rectangular plates.	$(C^7H^7SO^3)^2Mn + 7H^2O$. Plates, or radiating tufts.	$(C^7H^7SO^3)^2Mn + 2H^2O$. Square plates.
$(C^7H^7SO^3)^2Cu + 6H^2O$. Needles and oblique-angled plates.	$(C^7H^7SO^3)^2Cu + 4H^2O$. Leaflets.	$(C^7H^7SO^3)^2Cu + 4H^2O$. Six-sided leaflets.
$C^7H^7SO^2NH^2$. Crystallises from water and alcohol in leaflets. Sparingly soluble in water; more so in alcohol. 1 pt. amide in 515 pts. of water at 4°, or in 13·5 pts. of alcohol at 5°. M. p. 136°.	$C^7H^7SO^2NH^2$. Crystallises from alcohol and water in long, leafy forms. Sparingly soluble in water; more so in alcohol. 1 pt. amide in 248 pts. water at 9°, or in 5·7 pts. of alcohol at 5°. M. p. 107°–108°.	$C^7H^7SO^2NH^2$. From water and alcohol in quadratic octohedrons and prisms. Insoluble in cold water; sparingly soluble in alcohol. 1 pt. amide in 958 pts. water at 9°, or in 28 pts. of alcohol at 5°. M. p. 153°–154°.

Toluenemetasulphonic acid, $C^6H^3H.SO^2H.H^3$. — The *barium salt*, $[C^6H^4(CH^3)SO^2]^2Ba + 2H^2O$, is very soluble in water and alcohol, and forms a crystalline powder. The *lead salt*, $[C^6H^4(CH^3)SO^2]^2Pb + 2H^2O$, crystallises from a concentrated aqueous solution in thin plates grouped in rosettes, and from absolute alcohol in long needles. The *calcium salt*, $[C^6H^4(CH^3)SO^2]^2Ca$, is very soluble in water. On heating a concentrated alcoholic solution, the salt separates in small glistening plates, which redissolve on cooling. The *sodium salt*, $C^6H^4(CH^3)SO^2Na + \frac{1}{2}H^2O$, is very soluble in water, and crystallises from absolute alcohol in large shining plates. The *potassium salt*, $C^6H^4(CH^3)SO^2K + \frac{1}{2}H^2O$, is a similar compound, crystallising from alcohol in plates resembling naphthalene.

Metatoluenesulphonic chloride, $C^6H^4(CH^3)SO^2Cl$, is a limpid pale-yellow liquid, having a penetrating smell. It does not solidify at -10° , and is not decomposed by water even at 130° . Ammonia converts it into $C^6H^4(CH^3)SO^2.NH^2$, crystallising from water at 40° in large plates, and at 20° in thin needles melting at $90^\circ-91^\circ$.

Metatolyl sulphhydrate, $C^6H^4(CH^3)SH$, is formed by acting with tin and hydrochloric acid on the chloride. It is a heavy refractive liquid, having a powerful smell, and attacking the skin. Boiling dilute nitric acid converts it into the disulphide, $[C^6H^4(CH^3)S^2]$, an oily liquid boiling at about 150° .

Toluenearthosulphonic acid, $C^6H^3SO^2H.H^4$, obtained by the action of water and sodium-amalgam on β -parabromotoluenesulphonic acid, forms very soluble salts. The *lead salt*, $(C^6H^7SO^2)^2Pb + 4H^2O$, crystallises in needles. The *barium salt*, $(C^6H^7SO^2)^2Ba + 4H^2O$, and the *potassium salt*, $C^6H^7SO^2K + H^2O$, form monoclinic plates; the anhydrous *sodium salt* crystallises in needles. The *chloride*, $C^6H^7SO^2Cl$, is an oily liquid. The *amide*, which is freely soluble in water, alcohol, and ether, crystallises in monoclinic plates melting at $152^\circ-153^\circ$.

Orthotolyl Sulphhydrate, $C^6H^3.SH.H^4$, prepared by treating the chloride of the brominated acid just described with tin and hydrochloric acid, and the resulting bromotolyl sulphhydrate with sodium-amalgam and alcohol, crystallises from alcohol in soft glistening plates insoluble in water. Its *lead salt*, $[C^6H^4(CH^3)S]^2Pb$, is a bright brick-red precipitate which readily absorbs oxygen and turns white (Hübner a. Post).

Tolueneparasulphonic acid, $C^6CH^3.H.H.SO^2H.H^3$, is converted by fusion with sodium formate into paratoluic acid, the reaction being similar to that by which terephthalic acid is formed from parasulphobenzoic acid: $C^6H^7.SO^2H + CHNaO^2 = C^6H^7O^2 + SO^2HNa$. The yield is small, but paratoluic acid is the only product (Remsen, *Ber.* viii, 1412).

Toluenedisulphonic Acids, $C^6H^2(SO^2H)^2.CH^3$. The table on p. 2010 exhibits a comparison of the properties of the α - and β -disulphonic acids obtained by Hakansson, and the γ -acid by Senhofer (vii, 1170, 1171).

Gnehm a. Ferrer prepare (*Ber.* x, 542) toluenedisulphonic acid by adding 1 pt. of toluene by small portions to 3 or 4 pts. of sulphuric anhydride melted in a capacious flask by means of hot water; then heat the mixture to $150^\circ-180^\circ$ for two hours, and ultimately for a short time at 200° . The dark syrupy liquid thus formed contains a disulphonic acid which appears to be identical with Hakansson's α -acid. The same acid is formed on passing the vapour of toluene into sulphuric acid heated to 240° .

Bromotoluenesulphonic Acids, $C^6H^3Br(SO^2H).CH^3$ (Hübner a. Post, *Liebig's Annalen*, clxix, 1-69). (1). Parabromotoluene dissolved in fuming sulphuric acid, either at a temperature not exceeding 80° or at $160^\circ-180^\circ$, yields two monosulphonic acids, distinguished as α and β , the constitution of which is as follows:

	CH^3	SO^2H	Br
α -acid	1	3	4
β -acid	1	2	4

The two acids may be separated by recrystallisation of their barium salts, that of the α -acid being much more soluble than the β -salt.

α -Parabromotoluene-sulphonic acid is a very soluble, crystalline laminated mass. The *barium salt*, $[C^6H^3Br(CH^3)SO^2]^2Ba + 7H^2O$, forms colourless, well-defined, long and compact rhombic needles. The *lead salt*, $[C^6H^3Br(CH^3)SO^2]^2Pb + 3H^2O$, is obtained from a concentrated solution in long needles, which, when recrystallised from a dilute solution, are converted into small, light yellow, compact rhombic plates. The *strontium salt*, $[C^6H^3Br(CH^3)SO^2]^2Sr + 7H^2O$, crystallises in hard, four-sided pyramids.

The *α -amide*, $C^6H^3Br(CH^3)SO^2.NH^2$, obtained by treating the impure chloride of the acid with solid ammonium carbonate, and then adding concentrated ammonia, dissolves sparingly in cold water, freely in alcohol, ether, and hot water, and crystallises in long, soft, silky needles, melting at $151^\circ-152^\circ$.

	α -Acid	β -Acid	γ -Acid
Free acid . . .	Viscid; bears a heat of more than 100° without decomposition.		Viscid, mixed with crystals; decomposed at the heat of a water-bath.
Potassium salt .	Firmly coherent crusts; crystals with faces curved like a weaver's shuttle; containing 1 mol. H ² O, which is scarcely given off at 160°, certainly not at 110°.	Nodular groups of microscopic crystals.	Short, well-defined prisms containing 1 mol. H ² O; giving off water and becoming opaque on exposure to the air.
Ammonium salt .	Beautiful limpid six-faced prisms or tablets, containing 1 mol. H ² O.	Small thin tablets.	Easily soluble needle-shaped crystals, often appearing crossed.
Barium salt .	Crystallises with difficulty in small prisms, containing at 17° 1.33 pt. water to 1 pt. salt; at ordinary temperatures 1½ to 2, at 100° 1 mol. water.	Indistinctly crystalline crusts, containing 1 mol. H ² O; the solution at 15° contains 11.66 pts. water to 1 pt. salt.	Easily soluble crystalline pulp; in the air-dried state it contains 3½ H ² O.
Cadmium salt .	Radio-crystalline mass, or long slender needles.	—	Easily soluble gummy mass.
Silver salt . .	Colourless, rather large crystals, with curved faces. The only anhydrous salt. Blackens slightly when exposed to light.	—	Yellow crystalline deposits, gradually blackening when exposed to light; contains 2 mol. H ² O; difficult to obtain in the anhydrous state.

α -Nitro-*p*-bromotoluenesulphonic acid, C⁶H³Br(NO²)(CH³)SO³H, produced by adding the anhydrous barium salt to warm fuming nitric acid, crystallises in small, pale-yellow, deliquescent needles, and forms very soluble salts. Its *barium salt*, [C⁶H³Br(NO²)(CH³)SO³]²Ba + H²O, separates by slow evaporation in thin yellow needles, and from a concentrated solution in crystals resembling sal-ammoniac. The *lead salt*, [C⁶H³Br(NO²)(CH³)SO³]²Pb + 2½ H²O, crystallises in colourless, glistening octohedrons, or sometimes in needles, which also contain water, but are more soluble in alcohol than the octohedrons. The *strontium salt*, [C⁶H³Br(NO²)(CH³)SO³]²Sr + 5 H²O, crystallises in thin, fan-shaped needles. The *sodium salt*, C⁶H³Br(NO²)(CH³)SO³Na, forms long and very thin needles.

α -Parabromosulphobenzoic acid, is prepared by boiling potassium α -parabromotoluenesulphonate with a chromic acid solution. On concentrating the solution, the salt C⁶H³Br(CO²H)SO³K + H²O crystallises out in thin needles. The *barium salt*, C⁶H³Br{ $\begin{smallmatrix} \text{CO}^2 \\ \text{SO}^3 \end{smallmatrix}$ }Ba + ½ H²O, crystallises in thin, glistening plates; the salts C⁶H³Br{ $\begin{smallmatrix} \text{CO}^2 \\ \text{SO}^3 \end{smallmatrix}$ }Ca, and C⁶H³Br{ $\begin{smallmatrix} \text{CO}^2 \\ \text{SO}^3 \end{smallmatrix}$ }Pb + 2 H²O form small needles.

β -Parabromotoluenesulphonic acid is readily soluble in water and alcohol,

sparingly in ether, and forms a crystalline laminated mass. It is not converted into an isomeric modification by heating it to 210° . Its *barium salt*, $[\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3]^2\text{Ba} + \text{H}_2\text{O}$, crystallises, when a dilute solution is slowly evaporated, in hard, compact plates, and from a concentrated solution in very thin and brilliant plates. If it be mixed with one of the isomeric salts, or with the calcium salt, it separates from a concentrated solution as a white powder. The *lead salt*, $[\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3]^2\text{Pb} + 3\text{H}_2\text{O}$, crystallises in silky, stellar needles. The *calcium salt*, $[\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3]^2\text{Ca} + 4\text{H}_2\text{O}$, is very soluble, and forms either thin, long rhombic needles, or compact plates. The *sodium salt*, $\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3\text{Na} + \text{H}_2\text{O}$, crystallises in thin, transparent, four-sided prisms. The *magnesium salt*, $[\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3]^2\text{Mg} + 8\frac{1}{2}\text{H}_2\text{O}$ (?), forms soft, silky tufts, and $[\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3]^2\text{Sr} + \text{H}_2\text{O}$ thin plates. The *copper salt*, $[\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3]^2\text{Cu} + 7\text{H}_2\text{O}$, crystallises in large, pale-blue plates.

The *β -chloride*, $\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^2\text{Cl}$, obtained by the action of phosphorus pentachloride on the acid or its sodium salt, crystallises from chloroform in plates, melting at about 35° , and having a peculiar smell.

The *β -amide*, $\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^2\text{NH}_2$, crystallises from water in long, slender, glistening needles, melting at 166° – 167° .

β -Nitrobromotoluenesulphonic acid, $\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)(\text{CH}^3)\text{SO}^2\text{H}$, formed by adding dry β -parabromotoluenesulphonic acid to warm fuming nitric acid, crystallises from ether in deliquescent scales, having a very bitter taste. Its *barium salt*, $[\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)(\text{CH}^3)\text{SO}^3]^2\text{Ba} + 2\text{H}_2\text{O}$, crystallises in warty needles. The *lead salt*, $[\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)(\text{CH}^3)\text{SO}^3]^2\text{Pb} + 3\text{H}_2\text{O}$, separates from solution in ether-alcohol in thin, colourless needles. The *copper salt*, $[\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)(\text{CH}^3)\text{SO}^3]^2\text{Cu} + 6\text{H}_2\text{O}$, forms microscopic, four-sided green prisms. The *silver salt*, $\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)(\text{CH}^3)\text{SO}^3\text{Ag}$, is a precipitate consisting of glistening scales. The *strontium salt*, $[\text{C}^6\text{H}^2\text{Br}(\text{NO}^2)(\text{CH}^3)\text{SO}^3]^2\text{Sr} + 7\text{H}_2\text{O}$, dissolves freely in water and alcohol, and forms small yellow needles. The *sodium salt* is very soluble, and could not be obtained in distinct crystals.

β -Parabromosulphobenzoic acid, $\text{C}^6\text{H}^3\text{Br}(\text{SO}^3\text{H})\text{CO}^2\text{H}$.—When β -parabromotoluenesulphonic acid is boiled with chromic acid mixture, a large portion is completely destroyed, while another is slowly oxidised to the corresponding benzoic acid, which forms a deliquescent mass, and yields very soluble salts. The barium and calcium salts consist of microscopic plates.

Orthobromotoluene-metasulphonic acid, $\text{CH}^3 : \text{Br} : \text{SO}^3\text{H} = 1 : 2 : 3$ or $1 : 2 : 5$.—Orthobromotoluene, gently heated with fuming sulphuric acid, yields only one sulphonic acid, the barium salt of which, when treated with sodium-amalgam, yields *meta*-toluenesulphonic acid : hence the constitution of the orthobromosulphonic acid must be represented by one of the formulæ above given, but the reactions hitherto studied do not enable us to decide between them. The salts of this acid crystallise well, and do not give off their water of crystallisation till heated above 100° ; only a few of them give it off over sulphuric acid. The *barium salt*, $[\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3]^2\text{Ba} + 2\text{H}_2\text{O}$, forms rhomboidal plates; the *strontium salt* is a very similar body. The *calcium salt* crystallises very slowly from a concentrated solution in compact rhombic six-sided plates containing $2\text{H}_2\text{O}$. The *lead salt* crystallises, with $2\text{H}_2\text{O}$, from very strong solutions in very thin small plates, and from a dilute solution in tufts of needle-shaped crystals. The *sodium salt*, $\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^3\text{Na} + \frac{1}{2}\text{H}_2\text{O}$, forms well-defined brilliant rhomboidal plates. The *potassium salt* crystallises, also with $\frac{1}{2}\text{H}_2\text{O}$, in plates or short thick white needles. The *copper salt* is very soluble, and crystallises in very thin light-coloured plates; the *zinc salt* in small glistening needles; the *magnesium salt* in small scales.

The *chloride*, $\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^2\text{Cl}$, prepared by treating the dry sodium salt with phosphorus pentachloride, forms a crystalline mass, consisting of needle-shaped crystals, and having a pungent smell. It crystallises from ether in large plates, melting at 52° – 53° . It is but slowly acted upon by caustic soda or boiling water, dissolves sparingly in concentrated sulphuric acid, and without change in fuming nitric acid. At 250° it begins to boil, and at 260° it is decomposed into charcoal, sulphur dioxide, and $\text{C}^6\text{H}^3\text{BrCl}(\text{CH}^3)$. When heated with water at 200° for several days, it is reconverted into orthobromotoluene-sulphonic acid, no isomeric modification being formed.

The *amide*, $\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SO}^2\text{NH}_2$, is sparingly soluble in cold water, more freely in boiling water, very readily in alcohol and ether, and crystallises in long glistening needles, melting at 133° – 134° , and boiling, with decomposition, at about 290° .

Orthobromotolyl sulphhydrate, $\text{C}^6\text{H}^3\text{Br}(\text{CH}^3)\text{SH}$, is formed by boiling the chloride with tin and hydrochloric acid. It is a refractive limpid liquid, having a peculiar smell, and boiling with decomposition, but volatilising with steam. The *lead salt* is a bright yellow precipitate. On heating the sulphhydrate with dilute nitric acid, or

acting on the sodium salt with alcoholic iodine, the *disulphide*, $(C^6H^3Br(CH^3)S)^2$, is formed, crystallising from alcohol in small needles, and from a mixture of xylene and alcohol in long needles melting at 56° – 58° .

Orthobromonitrotoluenesulphonic acid is a deliquescent mass, readily soluble in alcohol and ether. The free acid, as well as its salts, has a very bitter taste. The following four salts crystallise from water in microscopic but well-defined crystals:

$C^6H^2Br(NO^2)(CH^3)SO^2Na + H^2O$ crystallises in tufts of long needles, and is less soluble in water than the preceding salts.

Orthobromosulphobenzoic acid, $C^6H^2Br(SO^2H)CO^2H$, was prepared by oxidising the barium salt of the corresponding toluenesulphonic acid with chromic acid solution. Its *potassium salt*, $C^6H^2Br(CO^2H)SO^2K + \frac{1}{2}H^2O$, crystallises from water in thin plates resembling naphthalene. The *barium salt*, $C^6H^2Br\{CO^2\}_{SO^2}Ba + 2H^2O$, separates, on adding alcohol to the concentrated solution, in tufts of glistening and very thin needles. When treated with sodium-amalgam it yields toluene-metasulphonic acid. The *lead salt*, $C^6H^2Br\{CO^2\}_{SO^2}Pb + 2H^2O$, forms small white glistening needles; the *calcium salt* is very soluble, and forms long silky needles.

Orthobromotolueneparasulphonic acid, $CH^3 : Br : SO^2H = 1 : 2 : 4$, is formed by the action of hydrobromic acid on the diazo-compound, $C^7H^6\{SO^2\}_{N=N}$, produced by passing nitrous gas into a mixture of equal volumes of water and alcohol in which orthotoluidine-parasulphonic acid is suspended (p. 2017). Its *potassium salt*, $C^7H^6BrSO^2K$, forms nodular groups of microscopic very soluble needles. The *barium salt*, $(C^7H^6BrSO^2)^2Ba + 2H^2O$, crystallises in irregular microscopic plates, which dissolve sparingly in cold water, and do not give off their water over sulphuric acid. The *lead salt*, $(C^7H^6BrSO^2)^2Pb + 2\frac{1}{2}H^2O$, forms nodular masses without recognisable crystalline form. It dissolves sparingly in cold water, and gives off part of its crystallisation-water over sulphuric acid. The *chloride* melts at 54° ; the *amide* separates from hot water in microscopic prisms which melt at 151° , dissolve sparingly in water, easily in alcohol (Hayduck, *Liebig's Annalen*, clxxii, 206).

Nitro-orthobromotoluene-parasulphonic acid, $C^6CH^3.Br.NO^2.SO^2H.H.H$, or $C^6.CH^3.Br.H.SO^2H.NO^2.H$, is formed by the action of hydrobromic acid on the nitro-diazotoluenesulphonic acid obtained by adding orthotoluidine-parasulphonic acid to cold fuming nitric acid (p. 2017); also by nitration of orthobromotoluene-*p*-sulphonic acid. It remains on evaporation as a compact mass of microscopic needles easily soluble in water and in alcohol. The *barium salt*, $[C^7H^3Br(NO^2)SO^2]^2Ba + 3H^2O$, crystallises in tufts of needles which have a satiny lustre, are sparingly soluble in cold, easily in hot water, and do not give off any water over sulphuric acid. The *chloride* crystallises in microscopic needles; the *amide*, $C^7H^3Br(NO^2)SO^2NH^2$, separates from alcohol in long needles easily soluble in water, sparingly in boiling alcohol. Both these compounds when heated decompose without previous fusion.

The nitro-acid is converted by *ammonium sulphide* into an amidorthobromotoluene parasulphonic acid—obtained, however, only in an impure and amorphous state—which is converted by sodium-amalgam into metatoluidine-parasulphonic acid, $CH^3 : NH^2 : SO^2H = 1 : 3 : 4$ (Hayduck).

Tribromotoluene-parasulphonic acid, $CH^3 : Br : Br : SO^2H : Br = 1 : 2 : 3 : 4 : 5$ or $1 : 2 : 3 : 4 : 6$, is obtained by evaporating diazotoluene-parasulphonic acid with hydrobromic acid, as a yellowish deliquescent mass. Its *barium salt*, $(C^7H^4Br^3SO^2)^2Ba + 1\frac{1}{2}H^2O$, crystallises in white nodules very slightly soluble in water; the *potassium salt*, $C^7H^4Br^3SO^2K$, in dazzling white needles, very soluble in hot, much less soluble in cold water. The *chloride* is an uncrystallisable viscid oil; the *amide*, a reddish non-crystalline powder, nearly insoluble in boiling water (Hayduck, *Liebig's Annalen*, clxxiv, 354).

Metabromotoluenesulphonic acid.—The action of sulphuric acid on metabromotoluene might give rise to four isomeric acids, viz., $CH^3 : Br : SO^2H = 1 : 3 : 2$, $1 : 3 : 4$, $1 : 3 : 6$, and $1 : 3 : 6$; and, according to Wroblewsky (vii, 1172), three of these are actually produced. Grete, on the other hand (*Ber.* vi, 790; viii, 565; *Liebig's Annalen*, clxxvii, 233), finds that this reaction gives rise to only one sulphonic acid, the salts of which exhibit the following characters:—The *barium salt*, $(C^7H^4BrSO^2)^2Ba$, crystallises in laminae resembling naphthalene (Wroblewsky's

β -salt), the first and last crops of crystals being exactly alike. The *strontium salt*, $(C^7H^6BrSO^3)^2Sr + H^2O$, forms nodular groups of short triangular colourless laminae, hygroscopic in the anhydrous state. The *calcium salt*, $(C^7H^6BrSO^3)^2Ca + 2H^2O$, crystallises in large, transparent, shining, six-sided prisms, often flattened to long six-sided plates, which under the microscope are seen to be of rhombic form and very sharply defined. The anhydrous salt is scarcely at all hygroscopic. The *magnesium salt*, $(C^7H^6BrSO^3)^2Mg + 6H^2O$, crystallises in concentrically radiate groups of snow-white shining needles which do not give off their water till heated above 200° . It is very soluble and extremely hygroscopic. The *copper salt*, $(C^7H^6BrSO^3)^2Cu + 4H^2O$, forms pale blue rhombic tablets often grouped in rosettes. Its neutral solution has a fine green colour, and the solid salt, when dehydrated at 220° , acquires a splendid dark green colour changing to light green on cooling. At 250° it turns brown. The *lead salt*, $(C^7H^6BrSO^3)^2Pb + 3H^2O$, has the aspect of potassium chlorate, and appears under the microscope to consist of sharply defined tablets grouped in rosettes. The *potassium salt* is extremely soluble in water, and is precipitated from the solution by alcohol as an oily liquid which solidifies on trituration to a crystalline mass. When fused with potash it yields salicylic acid (Grete).

A *bromotoluenemetasulphonic acid* is formed by the action of alcohol under pressure on the diazo-compound $C^7H^5Br \left\langle \begin{smallmatrix} SO^3 \\ N=N \end{smallmatrix} \right\rangle$ obtained from bromoparatoluidine-metasulphonic acid (p. 2021), and forms, after purification, a colourless crystalline mass. Its *potassium salt*, $C^7H^5BrSO^3K$, crystallises from a moderately dilute solution in fine prisms. The *barium salt*, $2(C^7H^5BrSO^3)^2Ba + 7H^2O$, forms long thick needles slightly soluble in cold water. The *lead salt*, $(C^7H^5BrSO^3)^2Pb + 3H^2O$, crystallises from hot water in groups of long needles, sparingly soluble in cold water. The *chloride* melts at 53° ; the *amide* at 134° (v. Pechmann, *Ber.* vii. 1718).

Chlorotoluenesulphonic Acids, $C^7H^7ClSO^3 = C^6H^5Cl(SO^3H).CH^3$. From the mixture of chlorotoluenes produced by passing chlorine into toluene in presence of iodine, Vogt a. Henniger obtained, by the action of fuming sulphuric acid, two isomeric chlorosulphonic acids (vii. 878, 1172), and more recently Hübner a. Majert (*Ber.* vi. 790) have in like manner obtained three chlorotoluenesulphonic acids, which may be separated by means of their barium salts.

Orthochlorotoluenesulphonic acid.—The *potassium salt* of this acid, $C^7H^6ClSO^3K + \frac{1}{2}H^2O$, crystallises in large colourless quadric tables, truncated at the summits, and having a nacreous lustre; becomes anhydrous at 100° ; is more soluble than either of the three preceding salts. The *sodium salt* resembles the potassium salt in appearance and in its amount of water, but is more soluble. The *ammonium salt*, $C^7H^6ClSO^3NH^4 + H^2O$, forms rosettes of dull colourless needles. The *barium salt*, $(C^7H^6ClSO^3)^2Ba + 2H^2O$, forms small, somewhat elongated lozenge-shaped laminae, often with truncated summits, and usually grouped together by their narrow edges. They have a strong lustre when dried, and become anhydrous at 180° . The *calcium salt*, $(C^7H^6ClSO^3)^2Ca + 2H^2O$, forms radiate groups of long flat crystals, truncated at the ends. The *lead salt*, $(C^7H^6ClSO^3)^2Pb + 2H^2O$, forms rosettes of short compressed needles, truncated at the ends, and having a strong lustre. The *copper salt*, $(C^7H^6ClSO^3)^2Cu + \frac{1}{2}H^2O$, forms well-defined thick blue crystals of the regular system. The *cuprammonium salt* forms small regular crystals of a splendid dark blue colour.

This chlorotoluenesulphonic acid yields by oxidation an orthochlorosulphobenzoic acid, the *acid potassium salt* of which, $C^6H^5Cl(SO^3K)(CO^2H) + H^2O$, crystallises in felted groups of slender asbestos-like needles; the *normal barium salt*, $C^6H^5Cl(SO^3BaCO^2) + 2H^2O$, in indistinct stellate groups of small needles; and the *normal lead salt*, $C^6H^5Cl(SO^3PbCO^2) + 2H^2O$, in indistinct nodules.

By the action of *sodium-amalgam*, the orthochlorotoluenesulphonic acid is converted into toluenemetasulphonic acid (p. 2008). Hence its constitution must be $CH^3 : Cl : SO^3H = 1 : 2 : 3$ or $1 : 2 : 5$.

α -Parachlorotoluenesulphonic acid.—The *barium salt*, $(C^7H^6ClSO^3)^2Ba + \frac{1}{2}H^2O$, forms long pointed needles which on recrystallisation yield groups of small highly lustrous laminae with truncated summits. It dissolves in 7 pts. water at 14.5° . The *sodium salt*, $C^7H^6ClSO^3Na + 5H^2O$, forms long pointed needles, or small highly lustrous elongated quadrilateral crystals with truncated summits.

β -Parachlorotoluenesulphonic acid.—The *potassium salt*, $C^7H^6ClSO^3K + H^2O$, crystallises only from very strong solutions in delicate colourless needles having a silky lustre; it readily forms supersaturated solutions. The *barium salt*, $(C^7H^6ClSO^3)^2Ba + H^2O$, forms thick amber-yellow nodules or transparent crystalline crusts or colourless microscopic laminae. The *calcium salt*, $(6H^2O)$, forms rosettes of small truncated tables or small elongated efflorescent laminae. The *lead salt*, $(8H^2O)$,

forms rosettes of snow-white needles. The *copper salt*, $(7H^2O)$, forms large light blue brittle laminae. The *cuprammonium salt* forms crusts of small thick crystals having a deep indigo-blue lustre and efflorescing in the air.

The barium salts of the ortho- and of the β -parachlorosulphonic acid agree in crystalline form and amount of water with the corresponding salts of the brominated acids.

Iodotoluenesulphonic Acids. Paraiodotoluene, like the corresponding bromo-compound, when treated with sulphuric anhydride, yields two isomeric sulphonic acids.

β -Paraiodotoluenesulphonic acid, $C^6H^4(CH^3)I.SO^2H$, is prepared by very gradually mixing paraiodotoluene with the calculated quantity of sulphuric anhydride, both dissolved in chloroform. It is a colourless, deliquescent, crystalline mass, which does not give up any iodine to caustic soda-solution at 200° . Its *potassium salt*, $C^6H^4I.SO^2K + H^2O$, forms shining, very soluble laminae. The *sodium salt*, $C^6H^4I.SO^2Na + \frac{1}{2}H^2O$, forms dense aggregates of whetstone-like very soluble crystals. The *barium salt*, $(C^6H^4I.SO^2)^2Ba + H^2O$, crystallises in thin laminae: it is the least soluble of the salts of this acid. The *calcium salt*, $(+3H^2O)$, forms very soluble needles having a silky lustre; the *copper salt*, $(+6H^2O)$, light blue easily soluble needles. The *amide*, $C^6H^4I.SO^2NH_2$, forms colourless crystals, which melt at 178° – 179° , dissolve in hot water, and more readily in alcohol.

The barium salt of α -Paraiodotoluenesulphonic acid separates from the last mother-liquors of the β -salt after prolonged sojourn over sulphuric acid, in long, colourless, very soluble needles, which have the composition $(C^6H^4I.SO^2)^2Ba + 4H^2O$, and retain the same amount of water on recrystallisation (H. Glassner, *Ber.* viii. 560).

Nitrotoluenesulphonic Acids. *Paranitrotoluenecorthosulphonic acid*, $C^6H^4.SO^2H.H.NO^2.H^2$, which Beilstein a. Kuhlberg obtained by the action of fuming sulphuric acid on *p*-nitrotoluene (vii. 1173), crystallises from water in transparent, well-defined, rhombic tablets or prisms, which have the composition $C^6H^4(NO^2).SO^2H + 2\frac{1}{2}H^2O$, give off their water at 130° , and melt at $133\cdot5^\circ$. From a solution strongly acidulated with sulphuric acid, it separates anhydrous, and then melts at 180° . It dissolves easily in water, alcohol, ether, and chloroform. 100 pts. of the aqueous solution contain 67·71 pts. of the hydrated acid at 23° , and 71·45 pts. at 28° . The *barium* and *lead salts* have the composition assigned to them by Beilstein a. Kuhlberg; the latter, however, when dried over sulphuric acid or at 120° , gives off only $1\frac{1}{2}H^2O$, the rest ($\frac{1}{2}H^2O$) at 190° . The *potassium* and *ammonium salts* form long, slender, anhydrous needles. The *chloride*, $C^6H^4(NO^2).SO^2Cl$, crystallises from ether in rhombic tablets melting at 43° to $44\cdot5^\circ$, dissolves readily in ether and in chloroform, sparingly in alcohol. The *amide*, $C^6H^4(NO^2).SO^2NH_2$, separates from aqueous solution in long brittle needles melting at 186° , sparingly soluble in alcohol, ether, and cold water, more readily in hot water, still more in ammonia. By reduction with hydrogen sulphide it yields the corresponding amido-acid (Jenssen, *Lieb. Ann.* clxxii. 230).

Hart a. Remsen (*Ber.* x. 1046), by treating paranitrotoluene with fuming sulphuric acid, obtained two isomeric mononitro-acids, separable by means of their calcium salts, the solution first depositing long needles having the composition $[C^6H^4(NO^2).SO^2]^2Ca + 4H^2O$, and afterwards, together with these, large monoclinic prisms containing $6H^2O$, which retained their form on recrystallisation. Which of these two salts is derived from Beilstein a. Kuhlberg's acid is a point not yet determined.

Dinitrotoluenesulphonic Acids, $C^6H^2(NO^2)^2(SO^2H).CH^3$ (H. Schwanert, *Lieb. Ann.* clxxvi. 342; *Ber.* x. 28). When a mixture of toluene and fuming sulphuric acid, which contains *p*- and *o*-toluenesulphonic acids—or a mixture of toluene, fuming sulphuric acid, and strong nitric acid, which contains *o*-nitrotoluene-*p*-sulphonic acid (in excess) and *p*-nitrotoluene-*o*-sulphonic acid—is boiled for some time with strong nitric acid, two dinitrotoluenesulphonic acids are produced. The dinitrotoluenecorthosulphonic acid produced from the *o*-nitrotoluene-*p*-sulphonic acid—and therefore the more abundant of the two—is easily purified by means of the sparing solubility of its barium salt; less easy to purify is the dinitro-acid obtained from paranitrotoluene-ortho-sulphonic acid, the barium salt of which is a pale-yellow, easily soluble, granular mass, having, when dried over sulphuric acid, the composition $[C^6H^4(NO^2).SO^2]^2Ba + 4H^2O$.

Dinitrotoluene-para-sulphonic acid, the only one of the two which has yet been exactly investigated, is prepared as follows: To a cooled mixture of 200 g. toluene with an equal volume of fuming sulphuric acid is added, at first by drops, about 2 kg. nitric acid of sp. gr. 1·5; the mixture is heated in a retort as long as red fumes are given off; and the distillate is then poured back, this treatment being

repeated five or six times, and finally the nitric acid is distilled off as completely as possible. The residual liquid, which solidifies on cooling, is mixed with twice its volume of water, which separates a small quantity of dinitrotoluene; the liquid is filtered, strongly concentrated, and redissolved in water; and one-fourth of the solution, after neutralisation with lead carbonate, is mixed with the remaining three-fourths. The solution filtered from the lead sulphate—which is free from lead—is then mixed with a strong solution of barium chloride, whereupon it deposits, together with a little barium sulphate, crystalline barium dinitrotolueneparasulphonate, which may be purified by recrystallisation from hot water. The average yield of this salt is 330 grams.

The acid separated from this salt by sulphuric acid, crystallises in pale-yellow rhombic prisms, $C^7H^5(NO_2)_2SO_3H + 2H_2O$, which soon change to a sandy powder; when very slowly separated, however, it does not exhibit this latter character; it acquires a sulphur-yellow colour in sunshine, and slowly becomes moist on exposure to the air. Its taste is very sour and bitter. It begins to soften at 110° , gives off its water of crystallisation at 140° , and melts at 165° . It is very soluble in water, alcohol, and ether. Its salts are for the most part but slightly soluble, become yellow to brownish on exposure to the air, and detonate sharply when heated.

The *potassium salt*, $C^7H^5(NO_2)_2SO_3K$, obtained by decomposing the barium salt with potassium carbonate, crystallises from water in long white rhombic prisms; from alcohol in small, shining, strongly refractive plates. It dissolves in 191 pts. water at 14.5° , in 1190 pts. 94 per cent. alcohol at 22° , more freely in the same liquids at their boiling points, but is insoluble in ether. The *ammonium salt*, $C^7H^5(NO_2)_2SO_3NH_4$, obtained by neutralisation, forms white, flexible, rhombic prisms soluble in 24 pts. water at 18° . The *barium salt*, $[C^7H^5(NO_2)_2SO_3]_2Ba + 4H_2O$, crystallises in white silky prisms, which have a very bitter taste, and do not give off their water completely below 160° . The *calcium salt*, $[C^7H^5(NO_2)_2SO_3]_2Ca + 2H_2O$, forms groups of white needles and scales. The *lead salt*, obtained by neutralising the acid with lead carbonate, crystallises from hot aqueous solution in warty groups of yellowish needles containing $[C^7H^5(NO_2)_2SO_3]_2Pb + 2H_2O$; from the concentrated mother-liquor in yellow laminæ with 3 mols. H_2O . The *copper salt*, $[C^7H^5(NO_2)_2SO_3]_2 + 4H_2O$, forms blue-green oblique rhombic prisms which give off their water at 160° .

The *chloride*, $C^7H^5(NO_2)_2SO_2Cl$, is prepared by heating the potassium salt with phosphorous pentachloride in a sealed tube at 150° for several hours, washing the viscid product with hot water, pressing and drying the residue, and exhausting the residue with boiling ether. It crystallises from ether in slender needles or long rhombic prisms, which melt at 123° – 125° , and dissolve also in alcohol.

The *amide*, $C^7H^5(NO_2)_2SO_2NH_2$, prepared by the action of ammonia on the chloride, and purified by recrystallisation from hot ammoniacal water with the aid of animal charcoal, forms white laminar crystals resembling those of benzoic acid; from alcohol it crystallises in rhombic needles. It is slightly soluble in hot water, becomes coloured when dried in the air, and melts at 203° .

Amidotoluenesulphonic Acids, or Toluidinesulphonic Acids, $C^7H^5NSO_3 = C^7H^5(CH_3)(NH_2)(SO_3H)$.

(1). **Orthotoluidine-metasulphonic Acid**, most probably $CH_3 : NH_2 : SO_3H = 1 : 2 : 5$. This acid is obtained: *a.* Together with a small quantity of a more soluble isomeride, by heating orthotoluidine with twice its weight of fuming sulphuric acid at 160° – 180° (Gerver, *Liebig's Annalen*, clxix. 373). *β .* By the action of heat on ethylsulphate of orthotoluidine (Pagel, *Ber. vii.* 1392):

γ . By the action of heat on orthotoluidine sulphate (Neville a. Winther, *Chem. Soc. J.* 1880. xxxvii. 625):

δ . By the action of ammonium sulphide on the orthonitrotoluene-metasulphonic acid produced by the action of boiling alcohol under pressure on *o*-nitrodiazotoluene-*m*-sulphonic acid (Neville a. Winther).

This sulphonic acid crystallises from water in yellowish oblique rhombic prisms or plates, $C^7H^5NSO_3H + 2H_2O$, which lose their water at 120° and crumble to a yellowish-white powder. It is readily soluble in hot water, but does not dissolve in absolute alcohol, ether, benzene, or chloroform. Its *potassium salt*, $C^7H^5NSO_3K + \frac{1}{2}H_2O$, is readily soluble in water and dilute alcohol, and forms silky crystals. The *sodium salt*, $C^7H^5NSO_3Na + H_2O$, forms feathery crystals, and dissolves freely in water, more sparingly in dilute alcohol. The *barium salt*, $(C^7H^5NSO_3)_2Ba + 3H_2O$, is readily soluble in water, sparingly in boiling dilute alcohol, and crystallises in long striated

six-sided prisms. The *lead salt*, $(C^6H^5NSO_3)^2Pb + 1\frac{1}{2}H^2O$, crystallises from dilute alcohol in compact, white, six-sided prisms. The *silver salt*, $C^6H^5NSO_3^+Ag$, is a white precipitate consisting of small plates. When boiled with water it dissolves with partial decomposition, which however may be prevented by adding a few drops of nitric acid, and crystallises on cooling in white plates.

Orthotoluidinesulphonic acid dissolves in sulphuric acid, and on heating this solution strongly, sulphur dioxide is given off. When the acid is distilled with potash, orthotoluidine passes over, and the residue contains sulphuric acid and only a trace of sulphurous acid. On adding bromine in small quantity or in excess to the aqueous solution, *tribromorthotoluidine* (m. p. 112) is precipitated, and the solution contains dibromorthotoluidine-sulphonic acid, hydrobromic acid, and sulphuric acid (Gerver). According to Neville a. Winther, on the other hand, bromine slowly added to the aqueous acid in quantity not exceeding the molecular proportion, forms no precipitate but only a slight reddish opalescence; and if the liquid be then boiled, filtered, and evaporated, a *monobromotoluidinesulphonic acid*, $C^6H^4(NH^2)BrSO_3H$, crystallises out; and on further addition of bromine, a copious flocculent precipitate is formed, which, after purification by two or three distillations in a current of steam, crystallises from ether in long white needles, melting at $43-45^\circ$, and identical in every respect with the dibromorthotoluidine, $C^6CH^3.NH^2.Br.H.Br.H$, already mentioned (p. 1989).

From the constitution of this dibromotoluidine it may be inferred that the sulpho-group in the toluidinesulphonic acid from which it was formed, must occupy one of the meta-positions, 3 or 5 with regard to the CH^3 , and this conclusion is confirmed by the melting points of the sulphochloride and sulphonamide obtained from the toluenesulphonic and bromotoluenesulphonic acids produced from this acid. On passing nitrous gas into a cold solution of the toluidinesulphonic acid, a tolylene-diazine

sulphite, $C^6H^4N^2SO_3 = C^6H^4 \begin{smallmatrix} N=N \\ SO_3 \end{smallmatrix}$, is precipitated as a white slightly explosive powder, which when heated on a water-bath with concentrated hydrobromic acid, is decomposed, with formation of a bromotoluenesulphonic acid; the potassium salt of which, when treated with phosphorus pentachloride, is converted into a sulphochloride, $C^6H^4(NH^2)SO_2Cl$, melting at $55.6^\circ-56.6^\circ$, agreeing therefore nearly with the bromotoluenesulphochloride (m. p. $52^\circ-53^\circ$), described by Hübner a. Müller (*Zeitschr. f. Chem.* 1870, 449) as having the sulpho-group in the meta-position relatively to CH^3 . The chloride heated with ammonia gives an amide melting at $146.2-147.2^\circ$. The toluenesulphonic acid obtained by heating the above-mentioned orthotolylene-diazine sulphite under pressure with alcohol, or by reducing the bromotoluenesulphonic acid with sodium-amalgam, gave, on treating its potassium salt with PCl_5 , a liquid sulphochloride which yielded with ammonia an amide melting at $106.5^\circ-107.5^\circ$ (Neville a. Winther), at 104° (Pagel).

To ascertain whether the sulpho-group is ortho- or para- to the amido-group, meta-bromorthotoluidine-metasulphonic acid,

was heated in a sealed tube with hydrochloric acid and water for several hours with the view of removing the sulpho-group, and leaving a monobromorthotoluidine; but instead of this a mixture was obtained consisting of a dibromorthotoluidine melting at $43^\circ-44^\circ$, and two monobromorthotoluidines, one an oil, the other a solid body melting at $54^\circ-57^\circ$ (ordinary bromotoluidine), whence it appeared that whichever of the two monobromotoluidines was first formed, was partly decomposed into dibromotoluidine and toluidine, and partly converted into an isomeric monobromotoluidine. To discover which of the two monobromotoluidines was formed in the first instance, ordinary monobromorthotoluidine, which is known to have the structure $C^6CH^3.NH^2.H.H.Br.H$, was heated with water or hydrochloric acid at 170° , or above, for many hours, but without undergoing any alteration. This seemed to show that the liquid bromotoluidine, $C^6CH^3.NH^2.Br.H^3$, must be the immediate product of the removal of the sulphur-group from the metabromorthotoluidine-metasulphonic acid. But to obtain further evidence of this, an attempt was made to prepare the bromotoluidine, $C^6CH^3.NH^2.Br.H^3$, by another process. For this purpose metabromometacetoluide, $C^6CH^3.H.Br.H.NH(C^2H^5O).H$, was nitrated with a mixture of 2 vol. nitric acid of sp. gr. 1.52, and 1 vol. of sp. gr. 1.45, and the acetyl-group was removed from the resulting nitro-compound by dissolving it in a freshly-made mixture of 2 vol. sulphuric acid and 1 vol. water. In this manner a base was obtained melting at $87^\circ-88^\circ$, and having the structure of *m*-brom-*o*-nitro-*m*-toluidine, $C^6CH^3.NO^2.Br.H.NH^2.H$, the NO^2 -group taking the para-position with respect to the NH^2 , according to a law previously established (p. 1987). This nitrobromotoluidine treated with a solution of nitrous gas in alcohol was converted into metabromortho

nitrotoluene, $C^6H^5.CH^3.NO^2.Br.H^3$, which distilled with steam as an oil, and gave, on reduction with tin and hydrochloric acid, liquid monobromotoluidine, $C^6H^5.NH^2.Br.H.H.H$. Lastly, on heating this compound with hydrochloric acid in a tube at 160° for twelve hours, and distilling the contents with steam, a substance was obtained which melted at $40^\circ-47^\circ$; and on neutralising the residue in the flask and continuing the distillation, an oil was obtained, together with crystals melting at 53.55° (ordinary monobromorthotoluidine melts at $55^\circ-56^\circ$). Hence it appears that the bromotoluidine which is the immediate product of the decomposition of metabrom-orthotoluidine-metasulphonic acid must have the constitution $C^6H^5.NH^2.Br.H.H.H$: consequently the acid just mentioned must be represented by the formula $C^6H^5.NH^2.Br.H.SO^3H.H$, and the corresponding orthotoluidine-metasulphonic acid by the formula $C^6H^5.NH^2.H.H.SO^3H.H$, or $CH^3 : NH^2 : SO^3H = 1 : 2 : 5$ (Nevile a. Winther).

Orthotoluidine-parasulphonic Acid, $C^6H^5.NH^2.H.SO^3H.H^2$, is obtained, together with paratoluidine-orthosulphonic acid, by the following process: A number of litre-flasks are charged with 200 c.c. toluene and 200 c.c. fuming sulphuric acid, and shaken, at first gently, afterwards more briskly, to make the liquids mix. To the viscid or crystalline mixture of ortho- and paratoluenesulphonic acid thus produced, nitric acid of sp. gr. 1.5 is added by drops, the liquids being strongly shaken after each addition, and then left to cool, and this treatment is repeated till the addition of a further quantity of nitric acid no longer produces any rise of temperature. The mixture of orthonitrotoluene-parasulphonic and paranitrotoluene-orthosulphonic acids is then poured into a sixfold volume of water, and the mixture, strained from any dinitrotoluene that may have separated, is neutralised with calcium hydrate. The acids are separated by means of their barium salts, or better of their lead salts (the salt of the orthonitro-acid in either case separating out first), and then converted into amido-acids by means of ammonium sulphide. If the nitro-acids have been separated by means of their calcium salts, the amido-acids formed from them require a further purification by conversion into barium salts, that of the orthamido-acid crystallising out first, while that of the paramido-acid remains in the mother-liquor (Weckwarth, *Liebig's Annalen*, clxxii. 191; *Ber.* vii. 450).

Orthotoluidine-parasulphonic acid crystallises in needles and prisms (Weckwarth). 100 pts. of water at 11° dissolve 0.974 parts of it; hot water dissolves it much more abundantly (Hayduck, *ibid.* clxxii. 204, and clxxiv. 343; *Ber.* vii. 552 and 1353). Its warm aqueous solution is coloured dark violet by ferric chloride. On adding a few drops of fuming nitric acid to the concentrated aqueous solution and diluting with water, a precipitate is formed, and if the liquid be then boiled it turns yellow (Weckwarth). The barium salt, $[C^6H^5(NH^2)SO^3]_2Ba + 2\frac{1}{2}H^2O$, forms beautiful crystalline plates, which give off their water over sulphuric acid, dissolve easily in boiling, less easily in cold water. The lead salt, $[C^6H^5(NH^2)SO^3]_2Pb$, forms yellowish prisms, much less soluble than the barium salt (Hayduck).

The acid is not altered by heating at 200° with fuming hydrochloric acid; or, with the exception of slight carbonisation, with fuming sulphuric acid, in which respect it differs from the paratoluidinesulphonic acids (p. 2018). When distilled with potash it gives off a large quantity of ammonia and a small quantity of aniline; by fusion with potash at a moderate heat it yields *o*-amidobenzoic (anthranilic) acid. It is not altered by fusion with sodium formate. Distilled with manganese dioxide and sulphuric acid it yields a distillate smelling of quinone, from which however only very small quantities of microscopic tablets can be obtained. By the action of potassium chlorate and hydrochloric acid it is converted into trichlorotoluquinone, $C^6H^3Cl^3O^2$, which crystallises in large, shining, yellowish plates, melting at 232° (p. 2029).

Orthotoluidine-parasulphonic acid is converted by bromine into dibromorthotoluidine-*p*-sulphonic acid, $C^6H^3Br^2(NH^2)SO^3H$, which crystallises from hot water in needles containing 1 mol. H^2O (p. 2021); by nitrous acid and alcohol into a diazin-compound, $C^6H^5 < \begin{smallmatrix} SO^3 \\ N=N \end{smallmatrix} >$, which forms a crystalline powder exploding when struck, and by cold fuming nitric acid into a nitrodiazin-compound, $C^6H^5(NO^2) < \begin{smallmatrix} SO^3 \\ N=N \end{smallmatrix} >$, which separates on dilution with ice-cold water as a bulky white precipitate exploding by heat and by percussion.

Metatoluidine-orthosulphonic Acid, $C^6H^5.H.NH^2.H.H.SO^3H$ (Lorenz, *Liebig's Annalen*, clxxii. 185; *Ber.* vii. 449). This acid is produced, together with a disulphonic acid, by heating 1 pt. metatoluidine with 3 pts. fuming sulphuric acid at $160^\circ-175^\circ$; on diluting the product with water, the monosulphonic acid is precipitated, while the disulphonic acid remains in solution.

Metatoluidine-orthosulphonic acid crystallises in thick rhombic plates, which dissolve sparingly in water, are insoluble in alcohol, and carbonise without previous fusion when heated above 275°. The *barium salt*, $(C^6H^4NSO_3)^2Ba + 9H_2O$, crystallises in thin plates or long prisms easily soluble in water. The *lead salt*, $(C^6H^4NSO_3)^2Pb + 3\frac{1}{2}H_2O$, forms crystalline nodules.

Bromine, added in excess to an aqueous solution of the acid, decomposes it completely into sulphuric acid, hydrogen bromide, and a tribromotoluidine, $C^6H^2Br^3CH_3$, which crystallises from alcohol in reddish needles melting at 95° (p. 1998). On treating the toluidine-sulphonic acid immersed in alcohol of 60 per cent. with nitrous acid, it is converted into a diazo-acid, which when boiled with alcohol yields toluene-orthosulphonic acid. This shows that the amido-acid is a metatoluidine-orthosulphonic acid,

Lorenz represents it by the first of these formulæ; in other words, he regards it as a consecutive modification; but since the experiments of Neville a. Winther have shown that SO^3H , like Br , NO^2 , &c., when directly introduced into an amido-compound, takes by preference the para-position with respect to the NH^2 -group, it is more probable that the acid in question has the unsymmetrical constitution $1 : 2 : 5$.

The metatoluidine-disulphonic acid, formed as above mentioned, decomposes very readily on evaporation into the monosulphonic acid and free sulphuric acid. Treated with baryta-water and carbon dioxide, it yields an *acid barium salt*, $(C^6H^4N.SO^3H.SO^3)^2Ba + 12\frac{1}{2}H_2O$, crystallising in felted groups of slender needles, which give off their water at 160°. The *lead salt*, $C^6H^4N(SO^3)^2Pb + 2H_2O$, forms hard yellowish-white crusts, sparingly soluble in water, insoluble in alcohol.

Paratoluidine-orthosulphonic Acid, $C^6CH^3.SO^3H.H.NH^2.H^2$ (Jenssen, *Liebig's Annalen*, clxxii. 230; *Ber.* vii. 55). This acid, identical with the toluidine-sulphonic acid described by Buff and by Malyscheff (vi. 288; vii. 1179), is formed, together with the *p-m*-modification, by the action of sulphuric acid on paratoluidine, and by reduction of paranitrotoluene-orthosulphonic acid (p. 2014) with hydrogen sulphide. It crystallises in hard colourless rhombohedrons, slightly soluble in hot water, insoluble in alcohol and ether. Its warm aqueous solution is coloured red by ferric chloride. On dissolving it in a few drops of fuming nitric acid, the liquid remains clear on dilution with water, and becomes blood-red on boiling. These characters distinguish it from the *o-p*-acid (Weckwarth, p. 2017). Bromine added to its boiling aqueous solution forms a bromamidodisulphonic acid, $C^6H^4Br(NH^2)SO^3H$ (p. 2020), convertible into a diazin-compound which crystallises in small yellow or brown needles, and may be transformed by the usual methods into the corresponding toluene-, cresol-, bromotoluene-, and chlorotoluene-sulphonic acids. The *toluene-sulphonic acid* thus obtained is identical with the β -acid described by A. Wolkow (vii. 1168); the *brominated acid*, with the parabromotoluenesulphonic acid of Hübner a. Post (p. 2009); and the *chlorinated acid* with the β -parachlorotoluenesulphonic acid described by Hübner a. Majert (p. 2013). The *paracresolsulphonic acid*, on the other hand, $C^6H^4(OH)SO^3H + 5H_2O$, is different from that which Engelhardt a. Latschinoff obtained by the action of sulphuric acid on paracresol (vi. 506).

Paratoluidine-metasulphonic Acid, $C^6CH^3.H.SO^3H.NH^2.H^2$ (H. v. Pechmann, *Lieb. Ann.* clxxiii. 195). This acid, first described by Sell (v. 527), is formed, together with paratoluidine-orthosulphonic and a paratoluidine-disulphonic acid, by heating paratoluidine with fuming sulphuric acid. The relative quantities of these acids obtained vary with the temperature, the metasulphonic acid being produced most abundantly at comparatively low, the ortho- and the di-sulphonic acid at higher temperatures. Direct experiment shows that each of the monosulphonic acids, when heated for twenty minutes at 180°-200° with twice its weight of sulphuric acid, is partly converted (the metasulphonic acid for the greater part) into the isomeric monosulphonic and the disulphonic acids. The separation of the metasulphonic from the orthosulphonic acid is facilitated by the greater solubility of the former in water and especially in alcohol. The separation may also be effected through the medium of the lead salts, the metasulphonate being but sparingly soluble, the orthosulphonate very easily soluble, in water. The disulphonate remains in the mother-liquor of the two monosulphonates.

The paratoluidine-metasulphonic acid thus prepared agrees for the most part in its properties with that described by Sell, Malyscheff, and Buff (vii. 1179). It dissolves at ordinary temperatures in 10 pts. water, is nearly insoluble in alcohol, and quite insoluble in ether. The crystals effloresce over sulphuric acid, and give off their water completely at 130°. The aqueous solution is coloured red by ferric chloride, especially when heated. The acid heated with water at 130° is resolved

into sulphuric acid and toluidine, the latter being also formed on distilling the acid with potassium hydroxide. On fusing it with the latter, till the evolution of hydrogen slackens considerably, the chief product obtained is parahydroxybenzoic acid. It is not altered by fusion with sodium formate. The *barium salt*, $(C^7H^5NSO_3)^2Ba + 3H^2O$, crystallises from strong solutions in colourless six-sided laminae, easily soluble in water, insoluble in alcohol, and giving off their water at 130° . The *lead salt*, $(C^7H^5NSO_3)^2Pb + 2H^2O$, forms long colourless needles, much less soluble than the barium salt.

The corresponding diazin-compound, which is best prepared by treating the amido-acid with nitrous acid and alcohol under water at 30° – 40° , is converted by heating with alcohol under pressure into toluenemetasulphonic acid (p. 2018), by boiling with water into paracresolmetasulphonic acid (p. 2009), and by hydrobromic acid into parabromotoluene-metasulphonic acid (p. 2021).

Paratoluidine-metasulphonic acid, when added to cold fuming nitric acid, is converted into orthonitrodiazotoluene-metasulphonic acid, which, when boiled with alcohol under pressure, yields an *o*-nitrotoluene-*m*-sulphonic acid convertible by ammonium sulphide into *o*-toluidine-*m*-sulphonic acid (p. 2015). The *p*-toluidine-*m*-sulphonic acid, brought into contact with 2 mol. *bromine*, is completely resolved into sulphuric acid and dibromotoluidine:

With a larger quantity of bromine a similar reaction takes place, resulting in the formation of tribromotoluidine. When, however, bromine-vapour (1 mol.) is passed through a cold aqueous solution of the (*p*-*m*) acid, there is formed—together with a precipitate of dibromotoluidine—a bromoparatoluidine-metasulphonic acid (p. 2021), which remains in solution and may be separated therefrom by means of its sparingly soluble barium salt.

Bromamidotoluenesulphonic or Bromotoluidinesulphonic Acids, $C^7H^4Br(NH^2).CH^3$. M. Schäfer (*Liebig's Annalen*, clxxiv. 357; *Ber.* vii. 1355) has prepared the bromamido-acids analogous to Hübner a. Post's nitrobromotoluenesulphonic acids (p. 2010) by reduction with ammonium sulphide; also the corresponding diazin-acids or tolyl-diazinsulphites by treating the amido-acids with nitrous gas and alcohol, and from these by boiling with water, the corresponding cresol-sulphonic acids. A comparative view of the properties of these several derivatives is given in the following table:

	Derivatives of nitro- <i>o</i> -bromotoluene- <i>m</i> -sulphonic acid	Derivatives of nitro- <i>p</i> -bromotoluene- <i>m</i> -sulphonic acid	Derivatives of nitro- <i>p</i> -bromotoluene- <i>o</i> -sulphonic acid
Free amido-acid	Crystallises hot from water in long rhombic laminae, from alcohol in nodules. Dissolves at 21° in 188 pts. water, and in 32 pts. alcohol. Resolved by bromine and water into sulphuric acid and tribromotoluidine, which crystallises from alcohol in yellow needles, and volatilises with steam in nearly white flocks melting at 82° .	Crystallises from water in grey-white needles. Very sparingly soluble in water, more freely in alcohol.	Crystallises from water in small well-defined prisms, sparingly soluble in water (1 pt. in 31), more freely in alcohol; yields with bromine and water a tribromotoluidine which crystallises from alcohol in yellow shining scales melting at 72° .
Barium salt	$[C^7H^4Br(NH^2)SO^3]^2Ba + H^2O$. Microscopic square plates, very soluble in water, sparingly in alcohol.	$[C^7H^4Br(NH^2)SO^3]^2Ba + 4H^2O$. Small, white nodules.	$[C^7H^4Br(NH^2)SO^3]^2Ba + 2H^2O$. White, easily soluble microscopic needles.

	Derivatives of nitro- <i>o</i> -bromotoluene- <i>m</i> -sulphonic acid	Derivatives of nitro- <i>p</i> -bromotoluene- <i>m</i> -sulphonic acid	Derivatives of nitro- <i>p</i> -bromotoluene- <i>o</i> -sulphonic acid
Lead salt	$[\text{C}^7\text{H}^5\text{Br}(\text{NH}^2)\text{SO}^3]^2\text{Pb} + \text{H}^2\text{O}$. Easily soluble, elongated plates, turning yellow in the air.	—	—
Sodium salt	—	—	$\text{C}^7\text{H}^5(\text{NH}^2)\text{SO}^3\text{Na} + 2\text{H}^2\text{O}$. Indistinct, microscopic, very soluble crystals.
Diazin-compound	Brownish, easily decomposable powder, converted by water and by hydrobromic acid into one and the same cresolsulphonic acid.	Short, thick, red needles, exploding by percussion, and easily decomposed by water, alcohol, and hydrobromic acid.	Pale red microscopic (rhombic?) crystals, detonating when struck or when heated to 160° . Easily decomposable. Converted by HBr into dibrom- <i>o</i> -toluenesulphonic acid.
Cresolsulphonic acid	—	—	Brown syrup.
Barium salt	Prepared with water: greyish-white, indistinct, very soluble crystals, containing $4\text{H}^2\text{O}$. Prepared with HBr: Spicular crystals containing $3\text{H}^2\text{O}$.	$[\text{C}^7\text{H}^5\text{Br}(\text{OH})\text{SO}^3]\text{Ba} + \text{H}^2\text{O}$. Easily soluble laminae.	$[\text{C}^7\text{H}^5\text{Br}(\text{OH})\text{SO}^3]^2\text{Ba} + 3\text{H}^2\text{O}$. Easily soluble, long white branched needles.
Lead salt	$[\text{C}^7\text{H}^5\text{Br}(\text{OH})\text{SO}^3]^2\text{Pb} + 2\text{H}^2\text{O}$. Long white four-sided prisms, quickly turning yellow on exposure to the air.	—	—

Bromoparatoluidine-orthosulphonic acid, $\text{C}^7\text{H}^5\text{Br}(\text{NH}^2)\text{SO}^3\text{H}$, obtained by the action of bromine on a boiling aqueous solution of *p*-toluidine-*o*-sulphonic acid (p. 2018), crystallises in white, shining, slender needles, which become dark on exposure to light, and in solution; dissolve but very sparingly in water even at the boiling heat; are insoluble in alcohol and ether, but dissolve with moderate facility in hydrochloric and hydrobromic acid. It does not yield bromotoluidine when fused with potash. Its *potassium salt*, $\text{C}^7\text{H}^5\text{BrNSO}^3\text{K} + \text{H}^2\text{O}$, forms thick, hard, soluble prisms. The *barium salt*, $(\text{C}^7\text{H}^5\text{BrNSO}^3)^2\text{Ba} + 7\text{H}^2\text{O}$, crystallises from water in thick prisms, from alcohol in beautiful needles; gives off almost all its water of crystallisation over sulphuric acid; dissolves easily in water, less easily in alcohol. *Lead salt*, easily soluble laminae. *Silver salt*, white needles, which very easily turn brown, and are but slightly soluble in cold water (Jenssen, *Liebig's Annalen*, clxxii. 230; *Ber. vii. 55*). According to Weckwarth (*Ber. vii. 450*), this brominated acid, treated under alcohol with nitrous gas, is converted into a diazin-compound, $\text{C}^7\text{H}^5\text{Br} \begin{smallmatrix} \text{SO}^3 \\ \text{N}=\text{N} \end{smallmatrix}$, which when heated with alcohol yields a bromotoluenesulphonic acid, apparently identical with Wroblewsky's β -acid (vii. 1172), and therefore consisting of meta-bromotoluene-orthosulphonic acid (p. 2012). Consequently the bromamido-acid

under consideration must be a metabromoparatoluidine-orthosulphonic acid, $C^6H^3SO^3H.Br.NH^2.H^2$ or $C^6H^3SO^3H.H.NH^2.Br.H$. This acid boiled with silver nitrate gives up the whole of its bromine as silver bromide. With fuming nitric acid it forms a red solution, which, when carefully diluted with a small quantity of water, deposits after some time shining yellow laminae of the diazin-nitro-compound, $C^7H^1(NO^2)Br<\overset{SO^3}{N=N}>$, which detonate when heated, and dissolve in water with evolution of nitrogen and formation of a nitrobromocresolsulphonic acid (Weckwarth).

Bromoparatoluidine-metasulphonic acid is formed, together with dibromotoluidine, on passing the vapour of bromine (1 mol.) through the cold aqueous solution of paratoluidine-metasulphonic acid (p. 2018), the dibromotoluidine being precipitated, while the brominated sulphonic acid remains in solution, and may be separated therefrom by means of its sparingly soluble barium salt. The free acid, $3C^7H^3Br(NH^2)SO^3H + 2H^2O$, crystallises from water or alcohol, in which it is readily soluble, in yellow needles, which give off their water of crystallisation at 130° , and decompose without previous fusion at a temperature above 200° . It is insoluble in ether. It is not altered by boiling with aqueous potash, but when distilled with potassium hydroxide it yields bromotoluidine as a colourless oil, which unites with acids forming crystallised salts.

Potassium Bromoparatoluidine-metasulphonate, $C^7H^3BrNSO^3K$, forms thick colourless prisms, moderately soluble in cold, more soluble in hot water. The *barium salt*, $(C^7H^3BrNSO^3)^2Ba + 2H^2O$, forms hard, shining, colourless plates, which do not effloresce over sulphuric acid; it dissolves sparingly in cold, more freely in hot water, but is insoluble in alcohol. The *lead salt*, $(C^7H^3BrNSO^3)^2Pb$, forms colourless shining needles, very slightly soluble in cold, more freely in hot water. The *silver salt*, $C^7H^3BrNSO^3Ag$, is precipitated by silver nitrate from the solution of the ammonium salt in thin short needles, and crystallises from hot water in long colourless needles. It is nearly insoluble in cold water, and turns grey when exposed to light.

The brominated amido-acid is converted by nitrous acid into a brown-red pulverulent diazin-compound, $C^7H^3Br<\overset{SO^3}{N=N}>$, which, when heated with alcohol under pressure, yields a bromotoluenemetasulphonic acid (p. 2013), (v. Pechmann, *Ber.* vii. 452).

Dibromorthotoluidine-para-sulphonic acid, $C^7H^4Br^2(NH^2)SO^3H + H^2O$, produced by the action of bromine on orthotoluidine-para-sulphonic acid (p. 2017), crystallises from hot water in long capillary needles; from hot alcohol in stellate groups of needles. Both these solvents dissolve it with difficulty in the cold, readily at boiling heat. At a higher temperature the acid gives off its crystallisation-water and crumbles to a hygroscopic powder, and at a still stronger heat (150°) it decomposes without previous fusion. The *barium salt*, $[C^7H^4Br^2(NH^2)SO^3]^2Ba + 9H^2O$, forms spherical groups of needles easily soluble in water, and becoming anhydrous over sulphuric acid. Cold fuming nitric acid converts it into a nitrodiazin-compound, which forms a white precipitate consisting of microscopic needles (Hayduck, *Ber.* vii. 1353).

Diamidotolueneparasulphonic or Tolylenediamineparasulphonic Acids, $C^7H^{10}N^2SO^3 = C^6H^2(NH^2)^2SO^3H.CH^3$ (H. Schwanert, *Liebigs Annalen*, clxxxvi. 360) is formed by the action of ammonium sulphide on the corresponding dinitro-acid (p. 2014), and crystallises from hot water, in presence of animal charcoal, in white, striated, shining, translucent, oblique rhombic prisms, which turn grey when exposed to light, do not melt even at 280° , dissolve in 1470 pts. water at 14° , more freely in hot water, but are insoluble in alcohol. The aqueous solution quickly turns yellowish-brown. The solutions of its salts also quickly become dark-coloured when evaporated; they crystallise with difficulty or not at all, and are not precipitated by alcohol. The *barium salt*, $(C^7H^9N^2SO^3)^2Ba + 4H^2O$, is obtained, on evaporating its solution prepared with barium carbonate, as a blue-grey amorphous residue, which, after repeated solution and treatment with animal charcoal, becomes lighter in colour, but not quite white; it dissolves readily in water and in alcohol. A *lead salt* has been obtained, crystalline, but not of constant composition. The *potassium salt* is obtained by evaporation of its solution only as a brown uncrystallisable syrup.

With *acids*, on the other hand, the diamido-acid easily forms crystallisable compounds, which, however, must be recrystallised from acidulated water, since they are decomposed by pure water. The *hydrochloride*, $C^7H^{10}N^2SO^3.HCl + 2H^2O$, forms white to silver-grey, shining, short oblique rhombic prisms, soluble in water, slightly also in alcohol. The *hydrobromide* is analogous in composition, and exhibits similar characters. The *nitrate*, $C^7H^{10}N^2SO^3.NO^3H + H^2O$, forms a light felted faintly reddish mass, com-

posed of small oblique rhombic needles, soluble in water, slightly also in alcohol. The sulphate, $(C^6H^4N^2SO_3)^2SO^4H^2 + H^2O$, crystallises in white shining rhombic laminae.

Monobromodiamidotoluene-para-sulphonic acid, $C^6HBr(NH^2)^2(SO^3H).CH^3$, is formed by drenching the diamido-acid with 20 pts. hot water, and adding bromine by drops (1 mol. bromine to 2 mol. of the acid), and crystallises from the resulting green-blue solution on cooling in small greyish-green shining tablets, or short thick rhombic prisms, with unequal pyramidal end-faces, sparingly soluble in water. The *potassium salt*, $C^6H^4BrN^2SO^3K + 2\frac{1}{2}H^2O$, is obtained by evaporating its brownish-yellow solution, taking care that no solid salt separates out on the edges, in geodes of pale-yellow tablets, very easily soluble in water, nearly insoluble in alcohol. When heated to 100° , it gives off its water, but does not change colour; but when quickly heated to 105° , or dehydrated at 120° , it turns blue, without loss of weight, and then dissolves in water with splendid blue colour. The yellowish salt cannot be recovered from the blue solution, which, when evaporated, leaves a blue amorphous salt (hence the precaution above mentioned). The *barium salt* is a greyish-white crystalline substance, containing a varying amount of barium, very soluble in water, and turning blue under the same circumstances as the potassium salt; the free acid likewise exhibits a similar behaviour.

When 1 mol. *bromine* is added by drops to 1 mol. of the diamido-acid under 20 pts. hot water, a greyish-green crystalline powder separates, which may be regarded as a mixture of the mono- and dibrominated acids, and when heated at 120° with hydrobromic acid and amorphous phosphorus, is reconverted into the diamidotoluene-sulphonic acid. Larger quantities of bromine produce more complete decomposition.

The diamido-acid treated with *nitrous acid* and alcohol is converted into a brown-red amorphous diazin-compound which has not been exactly investigated.

Hydroxytoluenesulphonic or Cresolsulphonic Acids, $C^6H^3(CH^3)OH.SO^3H$, are formed by heating the corresponding tolyl-diazin sulphites, $C^6H^3<\underset{N=N}{SO^3}>$ (so-called diazotoluenesulphonic acids) with water (vii. 932, 934), and by heating cresols with sulphuric acid (vi. 506; vii. 932, 934; viii. 583).

Orthocresol-para-sulphonic acid, $C^6CH^3OH.H.SO^3H.H^2$, which Engelhardt a. Latschinoff obtained by heating *o*-cresol with sulphuric acid (vi. 507), may also be prepared by boiling the diazin-derivative of *o*-toluidine-*p*-sulphonic acid with water, or adding it to fuming sulphuric acid. It forms a *barium salt*, $[C^6H^3(OH)SO^3]^2Ba + 1\frac{1}{2}H^2O$, which crystallises in granular masses of microscopic prisms. The *potassium salt*, $C^6H^3(OH).SO^3K + \frac{1}{2}H^2O$, separates from boiling absolute alcohol as a yellowish crystalline powder, from aqueous alcohol in tufts of short needles. The acid fused with potash is converted into salicylic acid (Hayduck, *Ber.* vii. 552).

A cresolsulphonic acid, apparently identical with the above, is obtained as a potassium salt by fusing potassium toluenedisulphonate (p. 2009) with potassium hydroxide at 190° – 205° . The solution of the melt is acidulated with sulphuric acid; freed by means of ether from small quantities of salicylic acid; neutralised with potassium carbonate; freed from potassium sulphate by crystallisation; again acidulated to a pasty consistence; and mixed with ether-alcohol to complete the precipitation of the potassium sulphate. For further precipitation, the acid is converted into the barium salt, which crystallises with great facility, and separated therefrom by sulphuric acid.

The free sulphonic acid crystallises in feathery groups which retain $\frac{1}{2}$ mol. water at 100° ; it melts at 80° – 81° , and turns brown when heated above 100° ; it is hygroscopic, dissolves readily in alcohol and ether, and its aqueous solution gives with ferric chloride a coloration which disappears on addition of mineral acids or of alcohol. The *potassium salt*, $C^6H^3(OH)SO^3K + 2H^2O$, crystallises in well-defined prisms which dissolve readily in hot alcohol, swell up at 120° , melt without decomposition at 225° – 230° , and are decomposed by melting potash at 260° – 270° . The *sodium salt* forms plates or tablets containing 2 mol. H^2O . The *ammonium* and *cadmium salts* crystallise in prisms or needles. The *barium salt*, $[C^6H^3(CH^3)(OH)SO^3]^2Ba + H^2O$, crystallises readily in small prisms, insoluble in alcohol, and becoming anhydrous at 170° . The aqueous solution forms no precipitate with baryta-water, but is coloured blue by ferric chloride. The *calcium salt*, $(C^6H^3O^4S)^2Ca + 1\frac{1}{2}H^2O$, crystallises in stellate groups of needles which become anhydrous at 100° . The *lead salt*, $(C^6H^3O^4S)^2Pb + 3H^2O$, is readily soluble in water and in hot alcohol, and crystallises in silky needles, which give off their water at 160° . The *copper salt*, $(C^6H^3O^4S)^2Ca + 8H^2O$, crystallises in large square tablets; the *silver salt* in concentric groups of anhydrous needles, which are sensitive to light; the *zinc salt* in larger prisms, containing $10\frac{1}{2}$ mol. water, of which they lose $8\frac{1}{2}$ at 100° , the other 2 at 190° (C. Bruner, *Wien. Akad. Ber.* [2 A bth.], lxxviii. 665).

E. Baumann (*Ber.* xi. 1907) describes the potassium salt of an orthocresolsulphonic acid obtained by heating *o*-cresol with potassium hydroxide and water, leaving the solution to cool to 60°–70°, and digesting it at that temperature with potassium pyrosulphate. It crystallises in shining laminæ, somewhat more soluble in water and in alcohol than potassium paracresolsulphonate.

Potassium cresolsulphonate (a mixture of several modifications) occurs, together with the phenolsulphonate, in horse-urine. It is somewhat less soluble than the latter in water and in alcohol; reacts similarly with water, acids, and alkalis, but decomposes somewhat more quickly on keeping, and is gradually decomposed during the putrefaction of the urine. The dry potassium salts of the cresolsulphonic acids are converted at 140°–150° into sulphonic acids which give a deep blue coloration with ferric chloride (Baumann).

TOLUIC ACIDS, $C^6H^5O^2 = C^6H^4(CH^3).COOH$. The ethylic ether of *orthotoluic acid* is formed by the action of ethyl chlorocarbonate on ortho-iodotoluene (p. 1994). The acid separated from the ether thus obtained melts at 102·5°.

Orthotoluic acid in alkaline solution, heated with potassium permanganate, is oxidised to orthophthalic acid, $C^6H^4O^4$ (Weith, *Ber.* vii. 1057).

Bromoparatoluic Acid, $C^6H^3Br(CH^3).COOH$, is prepared by dropping bromoparaxylene into a solution of 5 to 10 g. chromic acid in 100 g. glacial acetic acid; heating the liquid on the water-bath for an hour; precipitating with water; distilling off the undecomposed bromoxylene with steam; and washing the precipitate with water. The acid thus produced appears to be identical with that which Landolph obtained from bromocymene (vii. 1175). It is easily soluble in alcohol and ether, insoluble in cold water, slightly soluble in boiling water, and crystallises therefrom in small shining needles melting at 203·5°–204°; sublimes in shining elongated laminæ. Its *barium salt*, $(C^6H^3BrO^2)^2Ba + 4H^2O$, crystallises in concentric groups of short capillary needles, very slightly soluble in cold, much more freely in hot water. The *calcium salt*, $(C^6H^3BrO^2)^2Cd + 3H^2O$, is somewhat more soluble, and crystallises in arborescent groups of short hard needles (Jannasch a. Dieckmann, *Liebig's Annalen*, clxxi. 83).

Nitrotoluic Acids. Fittica (*Liebig's Annalen*, clxxxi. 303; *Ber.* vi. 938; vii. 1357, 1529) distinguishes three mononitrotoluic acids, $C^6H^7(NO^2)O^2$, viz.: α . Produced by dropping cymene into red fuming nitric acid of sp. gr. 1·5. Kept in a state of gentle ebullition, this acid melts at 189°.— β and γ . Formed by oxidising liquid and solid nitrocymene (p. 622) respectively with chromic acid. These two acids resemble one another in subliming without previous fusion, in forming very similar salts, and in giving with lead, mercury, and silver salts white precipitates insoluble in alcohol. The γ -acid differs, however, from the β -acid in being very nearly insoluble in water whether cold or hot, and only slightly soluble in alcohol of 90 per cent. Moreover, the alcoholic solution of the β -acid remains clear when mixed with solution of platonic chloride, whereas that of the γ -acid gives after some time a yellow crystalline precipitate. Both acids are scarcely attacked by tin or zinc and hydrochloric acid, but sodium-amalgam converts them into the corresponding diazin-toluic acids.

Diazin-toluic Acids, $C^6H^4N^2O^4 = CQ^2H.C^7H^5.N=N.C^6H^4.CO^2H$. The nitro-acid in alkaline solution is left in contact with the sodium-amalgam for about a day, till the addition of acetic acid in excess no longer produces a precipitate, and the diazin-acid is then precipitated with hydrochloric acid, or extracted from the acetic solution by ether. The β -acid when recrystallised from boiling water forms yellowish microscopic needles, which melt at 182°–184°, dissolve readily in alcohol, ether, and acetic acid, with moderate facility in boiling water, scarcely at all in cold water. The same diazin-acid is formed in like manner from a nitrotoluic acid. γ -*diazin-toluic acid*, when purified by recrystallisation from boiling alcohol, forms tufts of yellowish-brown needles nearly insoluble in water whether hot or cold, moderately soluble in boiling alcohol and in acetic acid, still more soluble in ether. It sublimes at about 240° without previous fusion, blackening at the same time (Fittica, *loc. cit.*)

Hydroxytoluic Acids, $C^6H^3(OH)(CH^3)(COOH)$. *Oxytoluic*, *Homohydroxybenzoic*, or *Cresotic acids*.—These acids are formed: 1. By the action of carbon dioxide on the sodium-cresols (p. 583). 2. By oxidation of the corresponding aldehydes, most readily by introducing the aldehydes into fused potash containing a little water, continuing the fusion for a few minutes, then adding water and precipitating with hydrochloric acid (Tiemann a. Schotten, *Ber.* xi. 767). 3. By the action of carbon tetrachloride on a strongly alkaline solution of a sodium-cresol:

By this reaction, orthocresol is converted into orthohomo-orthohydroxybenzoic or

orthohomosalicylic and orthohomoparahydroxybenzoic acids.* As in other reactions in which ortho- and para-compounds are produced simultaneously, the ortho-compounds are formed most abundantly at high, and the para-compounds at low temperatures; and for this reason the carbon tetrachloride reaction is best adapted for preparing the homoparahydroxybenzoic acids, whereas the homo-orthohydroxybenzoic or homosalicylic acids are better prepared by the action of carbon dioxide on the sodium-derivatives of the cresols: for as this reaction takes place at about 200°, these ortho-compounds are produced by it in much larger quantity than the para-compounds (E. Schall, *Ber.* xii. 816).

The following hydroxytoluic acids, obtained by oxidation of the corresponding aldehydes, are described by Tiemann a. Schotten, *loc. cit.*

a. From Orthocresol:

Orthohomosalicylic acid, $[\text{OH} : \text{CH}^3 : \text{COOH} = 1 : 2 : 6]$, melting at 159°–160°, is identical with β -cresotic acid (p. 584).

Orthohomoparahydroxybenzoic acid, 1 : 2 : 4, is sparingly soluble in cold water and chloroform, easily soluble in boiling water, alcohol, and ether, and crystallises from water in small faintly flesh-coloured needles containing $\frac{1}{2}$ mol. crystallisation-water, and melting at 172°–173°.

b. From Metacresol:

Metahomosalicylic acid, 1 : 3 : 6, identical with γ -cresotic acid, melts at 173°.

Metahomoparahydroxybenzoic acid, 1 : 3 : 4, crystallises from water in small white needles containing $\frac{1}{2}$ mol. water, and melting at 177°–180°.

c. From Paracresol:

Parahomosalicylic acid, [1 : 4 : 6], identical with α -cresotic acid, melts at 151°.

The homosalicylic acids behave with solvents and reagents almost exactly like salicylic acid. They dissolve but sparingly in cold water, more readily in boiling water, easily in alcohol and chloroform. From water or weak spirit they crystallise in dazzling white needles, undistinguishable from crystals of salicylic acid. They also give the salicylic acid reaction with *ferric chloride*. In exactly neutralised solutions of the ammonium salts, *barium chloride* produces no precipitate, *cupric sulphate* a yellow-green crystalline precipitate of a neutral copper salt, soluble in a large quantity of hot water. In solutions containing excess of ammonia, basic compounds are formed in both cases. *Silver nitrate* produces in neutral solutions of the ammonium salts, white precipitates, very sparingly soluble in water, easily in ammonia; *lead acetate*, white precipitates easily soluble in acetic acid.

The homoparahydroxybenzoic acids are but sparingly soluble in cold water, still less in chloroform, but dissolve readily in hot water, alcohol, and ether. They do not give any characteristic colour-reactions with ferric chloride. The normal *barium* and *calcium salts* are easily soluble; the solutions treated with ammonia do not give precipitates of basic salts. In neutral solutions of the ammonium salts, *cupric sulphate* forms a blue-green precipitate very slightly soluble in water; but on adding cupric sulphate and a little ammonia to these same solutions, precipitates are formed consisting of basic salts which dissolve with blue colour in excess of ammonia. The *silver* and *lead salts* are white compounds sparingly soluble in water (Tiemann a. Schotten).

There are four possible homologues of metahydroxybenzoic acid, but the corresponding aldehydes are not produced by the chloroform reaction. One of these hydroxytoluic acids, viz. orthohomometahydroxybenzoic acid, [1 : 2 : 5], is formed: (1). Together with hydroxyterephthalic acid, $\text{C}^6\text{H}^3(\text{OH})(\text{CO}^2\text{H})(\text{CO}^2\text{H})$, [1 : 2 : 5], by fusing sulphotoluic acid, $\text{C}^6\text{H}^3(\text{CH}^3)(\text{SO}^2\text{H})(\text{CO}^2\text{H})$, with potash. The two acids thus produced cannot easily be separated by crystallisation, but the separation may be effected by the application of a gentle heat, the hydroxytoluic acid then subliming alone (Flesch, *Ber.* vi. 481). (2). By passing nitrous gas into a nitric acid solution of the amidotoluic acid (m. p. 184°), which Ahrens obtained by reduction of one of the nitrotoluic acids resulting from the action of nitric acid on coal-tar xylene (vii. 1180).

This acid crystallises in long needles having a silky lustre, sparingly soluble in cold, easily in hot water, alcohol, and ether, insoluble in chloroform. It melts at 203°–204° (corr. 206°–207°), volatilises with vapour of water, and does not give any coloration with ferric chloride. Its *lead salt* crystallises with $2\text{H}_2\text{O}$ in needles having a diamond lustre. The *calcium salt* contains $4\text{H}_2\text{O}$. The *ethylic ether* crystal-

* In the names of these hydroxytoluic acids, the positions of the side-chains are referred to the phenolic hydroxyl which stands in the position 1; the first prefix, ortho, &c. (standing before 'homo') refers to the CH^3 -group, and indicates the cresol from which the acid is derived, while the second prefix, o-, m-, or p-, coming after 'homo,' indicates the position of the CO^2H -group.

lises in wavellitic geodes, melts at 74°–75°, and solidifies at 60°–62°. The acid heated with methyl iodide and potassium hydroxide is converted into the *dimethylic ether*, $C^6H^3(CH^3)(OC^2H^3)(CO^2CH^3)$, and this latter boiled with potash yields methyl-hydroxytoluic acid, $C^6H^2(OH^2)(OH)(CO^2H)$, which crystallises in beautiful sublimable needles, melts at 156°, is insoluble in cold water, but dissolves readily in alcohol and in ether. Its *barium salt* contains $4H^2O$. Orthohomometahydroxybenzoic acid is not decomposed by hydrochloric acid, even at 270°, but its potassium salt, heated with quicklime, yields a liquid cresol which boils at 185°–187°, and when fused with potash, yields nothing but salicylic acid (E. v. Gerichten a. W. Rössler, *Ber.* xi. 705, 1586).

Methoxytoluic Acids, $C^6H^4O^3 = C^6H^3(OCH^3)(CH^3)(COOH)$ (C. Schall, *Ber.* xii. 816). The methylic ethers of these acids are best prepared by the action of methyl iodide on the sodium salts of the hydroxytoluic acids, $C^6H^3(ONa)(CH^3)COONa$. Those of the three meth-homosalicylic acids, $OCH^3 : CH^3 : COOH = 1 : 2 : 6, 1 : 3 : 6, 1 : 4 : 6$, are oily liquids smelling like winter-green oil, and decomposing partially when boiled.

Methylic Methoxy-orthomethylparabenzoate, or *Methylic Orthomoanisate*, $OCH^3 : CH^3 : COOCH^3 = 1 : 2 : 4$, crystallises in small plates melting at 67°, sparingly soluble in hot water, easily in alcohol, ether, benzene, and chloroform.

Methylic Methoxy-metamethylparabenzoate, or *Metahomoanisate* [$1 : 3 : 4$], is a thick oil.

These ethers, which are all volatile in steam, are converted into the corresponding acids by heating with excess of alkali:

OCH ³	CH ³	COOH	
1	2	6	Feathery needles, m. p. 81°
1	3	6	Groups of needles or plates, m. p. 103°
1	4	6	Long thin needles, m. p. 67°
1	2	4	Minute silky needles, m. p. 192°
1	3	4	Needles, m. p. 176°

These methoxytoluic acids are converted by oxidation with potassium permanganate in alkaline solution into the corresponding methoxyphthalic acids, $C^6H^3(OCH^3)(COOH)(COOH)$, and this transformation determines their constitutional formulæ, and therefore the constitution of the corresponding hydroxytoluic acids (p. 1531). The structure of these latter cannot well be determined by converting them into hydroxyphthalic acids by fusion with potash, as this process is apt to lead to transpositions in the side-chains; neither can the constitution of a hydroxytoluic acid be determined by direct oxidation with permanganate, as the benzene-nucleus is then attacked and not the CH^3 -group.

The following table exhibits the relations between the hydroxytoluic and methoxytoluic acids and the corresponding derivatives of phthalic acid:

1.	2.	3.
Orthohomosalicylic acid, $\overset{1}{C^6H^3}.\overset{2}{OH}.\overset{6}{CH^3}.COOH$ m. p. = 164°.	Metahomosalicylic acid, $\overset{1}{C^6H^3}.\overset{3}{OH}.\overset{6}{CH^3}.COOH$ m. p. = 173°.	Orthohomomet-hydroxybenzoic acid, $\overset{1}{C^6H^3}.\overset{2}{OH}.\overset{5}{CH^3}.COOH$ m. p. = 204°.
Methorthohomosalicylic acid, $\overset{1}{C^6H^3}.\overset{2}{OCH^3}.\overset{6}{CH^3}.COOH$ m. p. = 81°.	Meth-metahomosalicylic acid, $\overset{1}{C^6H^3}.\overset{3}{OCH^3}.\overset{6}{CH^3}.COOH$ m. p. = 103°.	Methoxyortho-methyl-metabenzoic acid, $\overset{1}{C^6H^3}.\overset{2}{OCH^3}.\overset{5}{CH^3}.COOH$ m. p. = 156°.
β -Methoxyisophthalic acid, $\overset{1}{C^6H^3}.\overset{2}{OCH^3}.\overset{6}{COOH}.COOH$ m. p. = 217°.	Methoxyterephthalic acid, $\overset{1}{CH^3}.\overset{2}{OCH^3}.\overset{5}{COOH}.COOH$ m. p. = 278°.	
β -Hydroxyisophthalic acid, $\overset{1}{C^6H^3}.\overset{2}{OH}.\overset{6}{COOH}.COOH$ m. p. = 239°.	Hydroxyterephthalic acid, $\overset{1}{C^6H^3}.\overset{2}{OH}.\overset{5}{COOH}.COOH$ m. p. above 300°.	

4.	5.	6.
Parahomosalicylic acid, $\text{C}^6\text{H}^1_3\text{.OH}^4\text{.CH}^6_3\text{.COOH}$ m. p. = 151°.	Orthohomoparahydroxy- benzoic acid, $\text{C}^6\text{H}^1_3\text{.OH}^2\text{.CH}^4_3\text{.COOH}$ m. p. = 172°.	Metahomoparahydroxy- benzoic acid, $\text{C}^6\text{H}^1_3\text{.OH}^3\text{.CH}^4_3\text{.COOH}$ m. p. = 178°.
Methparahomosalicylic acid, $\text{C}^6\text{H}^1_3\text{.OCH}^4_3\text{.CH}^6_3\text{.COOH}$ m. p. = 67°.	Methoxyorthomethyl- parabenzoic acid, $\text{C}^6\text{H}^1_3\text{.OCH}^2_3\text{.CH}^4_3\text{.COOH}$ m. p. = 192°.	Methoxymetamethylpara- benzoic acid, $\text{C}^6\text{H}^1_3\text{.OCH}^3_3\text{.CH}^4_3\text{.COOH}$ m. p. = 176°.
α -Methoxyisophthalic acid, $\text{C}^6\text{H}^1_3\text{.OCH}^2_3\text{.COOH}^4\text{.COOH}$ m. p. = 261°.		Methoxyorthophthalic acid, $\text{C}^6\text{H}^1_3\text{.OCH}^3_3\text{.COOH}^4\text{.COOH}$ m. p. = 138°-144°.
α -Hydroxyisophthalic acid, $\text{C}^6\text{H}^1_3\text{.OH}^2\text{.COOH}^4\text{.COOH}$ m. p. above 300°.		Hydroxyorthophthalic acid, $\text{C}^6\text{H}^1_3\text{.OH}^3\text{.COOH}^4\text{.COOH}$ m. p. = 181°.

Sulphotoluic Acid, $\text{C}^6\text{H}^3(\text{CH}_3)(\text{CO}^2\text{H})(\text{SO}^3\text{H})$. This acid is obtained by oxidation of thiocymene (from camphor) with nitric acid, and may be purified by conversion into the lead salt and decomposition of the latter with hydrogen sulphide, these operations being repeated several times. It crystallises from aqueous solution in long thin hydrated prisms (Flesch, *Ber.* vi. 481); in concentric groups of needles containing 1 mol. water, easily soluble in water, alcohol, and ether (Bechler, *J. pr. Chem.* [2], viii. 170). The *potassium salt*, $\text{C}^6\text{H}^3(\text{CO}^2\text{H})(\text{SO}^3\text{K}) + 3\text{H}_2\text{O}$, crystallises from a solution of the acid incompletely neutralised with potash, in well-defined prisms. The *lead salt*, $\text{C}^6\text{H}^3(\text{CO}^2)(\text{SO}^3)\text{Pb} + 3\text{H}_2\text{O}$, separates immediately as a granular powder on adding lead carbonate to the warm aqueous solution of the acid; by evaporating the solution it may be obtained in granular crusts (Flesch). According to Bechler (who, however, did not obtain it quite pure) it contains only 1 mol. H_2O . The *magnesium salt*, $\text{C}^6\text{H}^3(\text{CO}^2)(\text{SO}^3)\text{Mg} + 3\text{H}_2\text{O}$, crystallises in tufts of colourless needles, very easily soluble in water (Bechler).

By fusion with potash, this sulphotoluic acid is converted into a hydroxytoluic acid melting at 202°-203°, and therefore different from any of the five hydroxytoluic acids above described (Flesch).

Fittica (*Liebig's Annalen*, clxxii. 328; *Ber.* vi. 942) describes a sulphotoluic acid isomeric with the above, obtained by adding thiocymene from thymol to nitric acid of sp. gr. 1.2, and evaporating the solution to dryness on a water-bath, and purified by boiling the residue with alcohol, decanting the mother-liquor from the crystals which separate on cooling, and recrystallising the product several times. The acid thus prepared is insoluble in water, sparingly soluble in alcohol, and crystallises therefrom in stellate groups of anhydrous needles melting at 190°. It dissolves in ammonia; blackens, and yields sulphuric acid when boiled with aqueous potash, soda, or baryta; and is decomposed even by heating with water or calcined magnesia. Its *magnesium salt*, $\text{C}^6\text{H}^3(\text{CO}^2)(\text{SO}^3)\text{Mg}$, formed by boiling the alcoholic solution of the acid with magnesia, separates in yellowish crystals, which under the microscope exhibit rhombic forms.

Alphatoluic or Phenylacetic Acid, $\text{C}^6\text{H}_5\text{.CH}_2\text{.COOH}$. The amide of this acid is formed by prolonged heating of benzyl cyanide with an alcoholic solution of potassium hydrosulphide (p. 314), and when heated with alcoholic potash is converted into the acid melting at 66°-67°.

Potassium phenylacetate is decomposed by the electric current into the base and acid, but the acid is quickly oxidised by the oxygen and ozone evolved at the positive pole, to benzaldehyde and benzoic acid. A solution of the free acid is but slowly electrolysed, yielding the same products, together with two neutral substances, one melting at 90°-93°, the other at 115° (Slawik, *Ber.* vii. 1051). Phenylacetic acid in alkaline solution is oxidised by potassium permanganate to benzoic acid; and when

ozonised oxygen is passed into the same solution, benzaldehyde is given off, and benzylic phenylacetate, $\text{C}^6\text{H}_5\cdot\text{CH}_2\cdot\text{COOCH}_2^2(\text{C}^6\text{H}_5)$, is obtained as a light yellow liquid having a faint aromatic odour, a density of 1.101, and boiling at $317^\circ\text{--}319^\circ$ (Slawik).

Phenylacetic acid, heated with phthalic anhydride and sodium acetate, is converted into benzylidene-diphthalyl, $\text{C}^6\text{H}_4\cdot\text{C}^2\text{O}^2\cdot\text{CH}\cdot\text{C}^6\text{H}_5$ (p. 1620).

a-Tolunitril, *Phenylacetoneitril*, or *Phenyl-methyl Cyanide*, $\text{C}^6\text{H}_5\cdot\text{CH}_2\cdot\text{CN}$, is the chief constituent of the essential oils of the garden cress (*Lepidium sativum*) and the garden nasturtium (*Tropaeolum majus*). See CRESS-OILS (p. 584).

Parabromalphatoluic acid, $\text{C}^6\text{H}_4\cdot\text{Br}\cdot\text{CH}_2\cdot\text{COOH}$, formed by heating *p*-bromobenzyl cyanide at 100° , with hydrochloric acid in sealed tubes, crystallises in long white needles, which melt at 114.5° . It decomposes carbonates very slowly, but dissolves readily in ammonia and soda-ley, forming salts. By oxidation with chromic acid it is converted into parabromobenzoic acid.

Ammonium parabromalphatoluate forms white needles easily soluble in water. The *silver salt*, $\text{C}^6\text{H}_4\cdot\text{Br}\cdot\text{CO}_2^2\text{Ag}$, is a white precipitate nearly insoluble in water; the *copper salt*, $(\text{C}^6\text{H}_4\cdot\text{Br}\cdot\text{CO}_2)^2\text{Cu}$, a bluish-green nearly insoluble precipitate; the *calcium* and *barium salts* crystallise from water in needles (Jackson a. Lowery, *Ber.* x. 1209).

Para-iodalphatoluic acid, $\text{C}^6\text{H}_4\cdot\text{I}\cdot\text{CH}_2\cdot\text{COOH}$, formed in like manner from the corresponding cyanide (p. 2007), and purified by crystallisation from boiling water, forms white acuminate plates melting at 135° , sublimes in needles, dissolves readily in hot water, also in alcohol, ether, benzene, carbon sulphide, and glacial acetic acid. By chromic acid mixture, it is oxidised to *p*-iodobenzoic acid. Its *silver salt*, $\text{C}^6\text{H}_4\cdot\text{I}\cdot\text{CH}_2\cdot\text{COOAg}$, crystallises from boiling water, in which it is slightly soluble, in shining plates; the *barium salt*, $(\text{C}^6\text{H}_4\cdot\text{I}\cdot\text{CH}_2\cdot\text{COO})^2\text{Ba} + \text{H}_2\text{O}$, forms small white easily soluble needles; the *calcium salt*, easily soluble branching needles. With solutions of heavy metallic salts, *p*-iodalphatoluic acid forms variously coloured precipitates (Mabery a. Jackson, *Ber.* xi. 55).

TOLUIC ALDEHYDES, $\text{C}^6\text{H}_5\cdot\text{O} = \text{C}^6\text{H}_4(\text{CH}_3)\text{COH}$. *Orthotoluic Aldehyde* is prepared by heating orthoxyl chloride, $\text{C}^6\text{H}_5\text{Cl}$, for an hour with $\frac{1}{2}$ mol. lead nitrate and 6 or 7 pts. water:

It is a yellowish, strongly refracting liquid, smelling like bitter almond oil and cinnamon oil, boiling at 200° , and forming a crystalline compound with hydrogen-sodium sulphite (Lauth a. Grimaux, *Bull. Soc. Chim.* [2], vii. 233; Rayman, *ibid.* xxvii. 498). By sodium-amalgam and water it is converted into the corresponding xylyl alcohol, $\text{C}^6\text{H}_4(\text{CH}_3)_2\cdot\text{CH}_2\text{OH}$, which crystallises in needles soluble in alcohol, slightly soluble in water, melts at 54° , and boils at 210° . At the same time there is formed a body analogous to hydrobenzoin, melting at 173° (Rayman).

Hydroxytoluic Aldehydes, $\text{C}^6\text{H}_5\cdot\text{O}^2 = \text{C}^6\text{H}_3(\text{OH})(\text{CH}_3)\text{COH}$ (Tiemann a. Schotten, *Ber.* xi. 767). These compounds are prepared from the three isomeric cresols by the action of sodium hydroxide and chloroform:

20 pts. of the cresol are heated in a flask with inverted condenser with a solution of 50 pts. sodium hydroxide in 150 water, and 30 or 40 pts. of chloroform are gradually added. The mixture, which usually becomes cherry-red, is acidified at the conclusion of the reaction, and distilled in a current of steam. The aldehyde homologous with salicylic aldehyde then distils over, together with unaltered cresol. The remaining liquid, filtered from a resinous compound (rosolic acid), deposits on cooling crystals of a homologue of parahydroxybenzoic aldehyde, when ortho- or meta-cresol has been used; paracresol, on the other hand, does not yield a similar compound.

The homoparahydroxybenzaldehydes from *o*- and *m*-cresol, like parahydroxybenzaldehyde itself, form easily soluble compounds with hydrogen-sodium sulphite; the three homosalicic aldehydes, on the other hand, like salicylic aldehyde itself, form sparingly soluble compounds with that salt.

Orthocresol, treated as above, yields the two following compounds:

Orthohomosalicic aldehyde, $\text{C}^6\text{H}_3(\text{OH})(\text{CH}_3)(\text{COH}) = (1 : 2 : 6)$, melting at 170° to an oil, which boils at $208^\circ\text{--}209^\circ$; and

Orthohomoparahydroxybenzaldehyde, $\text{C}^6\text{H}_3(\text{OH})(\text{CH}_3)(\text{COH}) = (1 : 2 : 4)$, crystallising from water in long feathery prisms, which melt at 115° .

From metacresol have been prepared:

Metahomosalicic aldehyde, $\text{C}^6\text{H}_3(\text{OH})(\text{CH}_3)(\text{COH}) = (1 : 3 : 6)$, melting at 54° , boiling at $222^\circ\text{--}223^\circ$; and

*Meta*homoparaoxybenzaldehyde, $\text{C}^6\text{H}^3(\text{OH})(\text{CH}^3)(\text{COH}) = (1 : 3 : 4)$, which crystallises from water in white tabular plates, which melt at 110° .

Paracresol gives only *one* aldehyde, namely:

Parahomosalicyclic aldehyde, $\text{C}^6\text{H}^3(\text{OH})(\text{CH}^3)(\text{COH}) = (1 : 4 : 6)$, a bright yellow oil, solidifying at 40° . When crystallised from dilute alcohol, this aldehyde melts at 56° , and boils at $217^\circ\text{--}218^\circ$.

The three homosalicyclic aldehydes dissolve sparingly in water, easily in alcohol, ether, and chloroform. With ferric chloride, the ortho-aldehyde gives a bluish, the meta- a violet, and the para- a deep blue colour. They smell like salicylic aldehyde, which they further resemble in being coloured yellow by alkalis, and in the sparing solubility of their ammonium salts in excess of ammonia. Alcoholic solutions of these aldehydes, mixed with a little ammonia, give white precipitates with lead acetate and silver nitrate; with copper sulphate they give green precipitates, which are not dissolved by excess of ammonia.

The two homoparahydroxybenzaldehydes dissolve in hot water, easily in alcohol, ether, and chloroform. With ferric chloride the ortho-compound gives a bluish violet, the meta-compound a bright rose-red colour. Their alkaline solutions are colourless. With metallic salts they behave like the homologues of salicylic aldehyde, but their precipitates with cupric sulphate dissolve in excess of ammonia.

The hydroxytoluic aldehydes are converted by oxidation with potassium permanganate into the corresponding hydroxytoluic acids, very slowly when the aldehydes are simply dissolved in water, more readily in presence of acetic acid. The easiest way of effecting the conversion is to fuse the aldehydes with potassium hydroxide containing a little water, the fusion being continued for a few minutes, water then added, and the acids precipitated by hydrochloric acid (p. 2023).

Parahomosalicyclic aldehyde is remarkable for the facility with which it crystallises, and reacts with other bodies. By treating it, in quantities of a few grams, with excess of sodium-amalgam, for a day or two, neutralising *exactly* with sulphuric acid, and extracting with ether, *parahomosaligenin* (parahomosalicyclic alcohol), $\text{C}^6\text{H}^3(\text{OH})(\text{CH}^3)(\text{CH}^2\text{OH}) = (1 : 4 : 6)$, is obtained in colourless brilliant needles, melting at 105° , which may be purified by crystallisation from a small quantity of hot water. Parahomosaligenin dissolves easily in alcohol and ether, and in all proportions in boiling water. It reacts like saligenin. In neutralising as above with sulphuric acid, a small quantity of a compound is usually precipitated, which melts at $200^\circ\text{--}205^\circ$, and probably consists of a homologue of saliretin.

When parahomosalicyclic aldehyde is boiled for five hours with methyl iodide and a solution of potash in methyl alcohol, and the mixture poured into water, *methyl-parahomosalicyclic aldehyde* separates as an oil, which, after washing with water and soda-solution, boils at 254° ; it smells like creasote, and does not react either with ferric chloride or with caustic soda.

The potassium derivative of the aldehyde, when suspended in anhydrous ether and treated with acetic anhydride, gives a corresponding *acetyl*-derivative, which melts at 57° , and is also unaffected by ferric chloride. It combines with hydrogen-sodium sulphite, and unites directly with 1 mol. of acetic anhydride, to form a compound from which the aldehyde character has entirely disappeared. This compound melts at 94° , and is completely decomposed by boiling water and by soda-solution.

An attempt was made, by boiling the aldehyde for an hour with an equal weight of dry sodic acetate and excess of acetic anhydride, to obtain homologues of coumarin and coumaric acid:

The product was poured into water, and the oil which separated taken up with ether. The ethereal solution was shaken, first with sodium-hydrogen sulphite solution to remove unaltered aldehyde, and then with sodium carbonate to remove acetocoumaric acid, which is always formed in this reaction. On evaporating the remaining ethereal solution, a well-crystallised product was obtained, which smelt of coumarin, and gave on analysis numbers which pointed to its being a mixture of methyl-coumarin and the above-mentioned addition-compound of acetoparahomosalicyclic aldehyde with acetic anhydride; it melted between 60° and 88° . The acid extracted from the ethereal solution by sodium carbonate, having been boiled with alkalis to remove the acetyl-group, gave an acid which melted at 185° , and showed the crystalline form and reactions of orthocoumaric acid.

Parahomosalicyclic aldehyde and orthohomoparaoxybenzaldehyde, on nitration, yield only orthonitro-derivatives, the first melting at 141° , the second at 152° . Both are crystalline bodies, insoluble in cold, soluble in hot water, and both exhibit the

aldehyde character. Ordinary salicylic aldehyde, according to Mazzara, gives an ortho- and a para-nitro-derivative. But in the hydroxytoluic aldehydes above described, the para-position is already occupied, in the first by a methyl-group, in the second by a COH-group; these aldehydes, therefore, give only ortho-nitro-compounds (Schotten, *Ber.* xi. 784).

TOLUIDINES, $C^6H^4(NH^2).CH^3$. See **TOLUENES (AMIDO-)**, (pp. 1995, 2000).

TOLUQUINONE, $C^6H^6O^2 = C^6H^3(CH^3)O^2 = C^6H^3.O.H.H.O.H$ (Nietzky, *Ber.* x. 832, 1934). This compound is formed by the oxidation of paradiamidotoluene or of orthotoluidine dissolved in sulphuric acid, with manganese dioxide, potassium dichromate, or ferric salts; and in like manner, though less readily, from amidazotoluene. It crystallises in golden-yellow, sharply-pointed, rhombic laminae, having the characteristic odour of quinones, very volatile, melting at 67° , slightly soluble in cold, more readily in hot water, very easily in alcohol and ether. The aqueous solution has a golden yellow colour, and is turned brown by alkalis.

Chlorotoluquinones. The di- and tri-chloro-derivatives of toluquinone, which Graebe and Borgmann obtained by the action of potassium chlorate and hydrochloric acid on the mixture of cresols from coal-tar, have been further examined by Southworth (*Liebigs Annalen*, clxviii. 267), who has prepared them from the pure isomeric cresols.

*Meta*cresol treated with potassium chlorate and hydrochloric acid becomes first black, then red, and is ultimately converted into small yellow globules which quickly solidify and sink to the bottom; and by washing these with water and distilling them with steam, dichlorotoluquinone,* $C^6H^4Cl^2O^2$, is obtained as a yellow crystalline mass. This compound crystallises from alcohol in yellow, transparent tables, which become brown on exposure to light. It is slightly soluble in water, but dissolves in alcohol and ether. It may be sublimed, but decomposes partially at the same time. Solution of sulphurous acid converts it very readily into the corresponding quinol, $C^6HCl^2.CH^3.(OH)^2$, a colourless body, which, when crystallised from water, retains water of crystallisation, probably $2H^2O$. It melts between 167° and 169° , and may be sublimed without decomposition. By treatment with acetyl chloride it furnishes an acetyl-derivative which crystallises from alcohol in small clustering needles melting between 122° and 124° .

Dichlorotoluquinone is not reduced to toluquinol by the action of sodium-amalgam.

*Ortho*cresol similarly treated yields a mixture of di- and trichlorotoluquinone, convertible by reduction with sulphurous acid into the corresponding di- and trichloroquinols, which may easily be separated by distillation with water, the former volatilising readily with the steam, while the latter remains in the residue.

Dichlorotoluquinol, $C^6HCl^2.CH^3.(OH)^2$, melts at 119° – 121° , sublimes easily, and crystallises from hot water in feathery needles.

Trichlorotoluquinol crystallises from the solution left after distillation in long needle-shaped crystals. It melts at 211° – 212° . This was the melting point found by Borgmann for his trichlorotoluquinol obtained from coal-tar cresol, which also agrees with this compound in the rest of its properties. It would, therefore, appear that the two compounds are identical, and hence that orthocresol is an essential constituent of the cresol from coal-tar.

The trichlorotoluquinone above mentioned is identical with that which Hayduck obtained by oxidising orthotoluidine-para-sulphonic acid with potassium chlorate and hydrochloric acid (p. 2017).

*Para*cresol, on account of its structure, is incapable of conversion into a quinone; when treated with potassium chlorate and hydrochloric acid it yields nothing but dark-coloured uncrystallisable products.

Toluquinol, $C^6H^5O^2 = C^6H^3(CH^3)(OH)(OH)$ (Nietzki, *Ber.* x. 832, 1934; xi. 1278). This compound is formed by the action of sulphurous acid on the quinone, and crystallises from hot benzene in broad colourless needles, which melt at 124° and sublime partly without decomposition. It dissolves very readily in water (much more readily than the 6-carbon quinol), also in alcohol and ether, less readily in benzene. By slow oxidation it is converted into a quinhedrone, then into toluquinone. The quinhedrone is obtained in nearly black slender needles on mixing the aqueous

* In Southworth's paper these chlorinated quinones are distinguished as *chlor-ortho-* or *chlor-meta-*quinones, according to the cresol from which they are formed; but as there can be only one toluquinone, viz., that above formulated, these terms are not very appropriate.

solutions of molecular proportions of toluquinone and toluquinol, and agitating the yellow-brown liquid with ether. It melts at 52°.

Toluquinol heated with *acetyl chloride* yields a diacetyl-derivative, which crystallises in large colourless plates, melts at 52°, and is converted by oxidising agents into the toluquinone.

Methyl-toluquinols.—A mixture of 12 pts. toluquinol and 80 pts. methyl iodide, heated for 12 hours at 100° with 8 pts. sodium hydroxide and 100 pts. methyl alcohol (or better with a solution of the calculated quantity of sodium in methyl alcohol), yields, as chief product, dimethyltoluquinol, $C^6H^{12}O^2$, together with a small quantity of monomethyltoluquinol, $C^6H^{10}O^2$. The latter melts at 72°, boils at 245°, dissolves in benzene, is but slightly volatile with water-vapour, and is converted by oxidation into toluquinone. *Dimethyltoluquinol* is slightly soluble in water, insoluble in aqueous potash, boils at 214°–218°, and likewise volatilises with water-vapour. By oxidation in glacial acetic acid (1 pt. of the quinol in 12 pts. acetic acid and 8 pts. water) with potassium dichromate (1.3 pt.) and sulphuric acid (3 pts.), it is converted (like ethyl-pyrogallol) into dihydroxymethyl-ditolylquinone, $C^{16}H^{16}O^4 = C^6H^2(CH^2)(OCH^2).O—O.(OCH^2)(CH^2)C^6H^2$. This last compound is nearly insoluble in water, but dissolves easily and with deep yellow-red colour in alcohol, ether, glacial acetic acid, and benzene, and crystallises in light brick-red or brown needles which melt at 153°, and sublime when cautiously heated above the melting point. By heating with aqueous ammonium sulphide it is converted into the corresponding hydro-compound, $C^{16}H^{18}O^4$, which crystallises from alcohol or benzene in slender needles melting at 173°; is nearly insoluble in acids, and is reconverted by oxidation into the quinone-like body.

When dimethyltoluquinol is heated for several hours at 190° with eight or ten times its weight of strong hydrochloric acid, there is formed, together with methyl chloride, a substance having the composition

which is that of the anhydride of tetrahydroxyditolyl,

This anhydride is insoluble in water, soluble in alcohol and benzene, and crystallises from the latter in long flat needles containing benzene, from alcohol in colourless shining laminae which effloresce when heated. It unites with 1 mol. water, but it is not yet decided whether the water is taken up as water of crystallisation or whether the resulting hydrated body consists of *tetrahydroxyditolyl*. The anhydride heated with zinc-dust yields a semi-solid hydrocarbon having the odour of lemon-oil.

TOLUYL, $C^6H^7O = CH^3.C^6H^4.CO$. A monatomic acid radicle homologous with benzoyl, $C^6H^5.CO$. The same name is sometimes applied to the phenolic radicle, $C^6H^7 = CH^3.C^6H^4$, properly called **TOLYL**.

TOLUYL-BENZOIC ACID, $C^{15}H^{12}O^3 = CH^3.C^6H^4.CO.C^6H^4.CO^2H$. This acid is formed, together with ditolyl-ketone and diphenyl-ketone-dicarboxylic acid, $CO^2H.C^6H^4.CO.C^6H^4.CO^2H$, by the oxidation of ditolylmethane, $CH^3.C^6H^4.CH^2.C^6H^4.CH^3$, with a mixture of potassium chromate and dilute sulphuric acid (Weiler, *Ber.* vii. 1181); also, together with a dicarboxylic acid, $(C^6H^4.CO^2H)^2CO$, by oxidation of ditolyl-ketone with a mixture of chromic acid and glacial acetic acid (Ador a. Krafts, *Compt. rend.* lxxxv. 1163). It separates from the solutions of its salts on acidulation, as an extremely gelatinous precipitate, convertible by drying and trituration into a white powder, and crystallises from methyl alcohol or acetone in slender shining needles. It dissolves with great difficulty in cold, and only sparingly in hot water, but readily in methyl alcohol, ethyl alcohol, acetone, glacial acetic acid, potash, soda, and ammonia, less easily in benzene and in chloroform. Strong sulphuric acid dissolves it, even at ordinary temperatures, more readily at a gentle heat, forming a golden-yellow solution, from which it is thrown down by water as a white flocculent precipitate. It melts at 222°, and at a higher temperature undergoes partial carbonisation, and yields a white woolly sublimate (Weiler). According to Ador a. Krafts it melts at 228°, and sublimates without decomposition. Its *potassium salt*, $C^{15}H^{11}KO^3$, forms tufts of long white needles. The *sodium* and *ammonium salts* also crystallise well (Weiler).

TOLUYLENE. Syn. with **STILBENE** or **DIPHENYLETHYLENE**, $C^{14}H^{12} = C^6H^2(C^6H^5)^2$ (p. 675). The same name is sometimes applied in combination to the diatomic radicle C^7H^6 , more appropriately called *Tolyene* (*q.v.*)

TOLYL* or *Methyl-phenyl*, $C^7H^7 = C^6H^4(CH^3)$. A monatomic radicle, metameric with BENZYL or PHENYL-METHYL, $CH^2(C^6H^5)$.

On DITOLYL, $CH^3.C^6H^4.C^6H^4.CH^3$, and its derivatives, see pp. 691-693.

TOLYL ALDEHYDE. Syn. with Toluic Aldehyde (p. 2027).

TOLYL CYANIDE, $C^7H^7.NC$, is converted into tolyl-thiocarbimide, $C^7H^7.N=CS$, and tolylthiocarbamide, $CS[NH(C^7H^7)]^2$, in the same manner as phenyl cyanide into the corresponding phenyl-compounds (p. 1546).

TOLYL-AMIDOGLYCOLL-AMIDES, -ANILIDES, and -TOLUIDES. See GLYCOLLAMIDES (pp. 882, 883).

TOLYLAMINES, $C^6H^4(NH^2).CH^3$. Syn. with TOLUIDINES.

TOLYLARSENIC COMPOUNDS (La Coste a. Michaelis, *Ber.* xi. 1888). *Ortho-monotolylarsenious Chloride*, $AsCl^2.C^7H^7$, is obtained by the action of (ortho)-mercury-ditolyl on arsenious chloride. It is a colourless liquid of faint odour, boiling at 264° - 265° , and may be distilled unchanged in an atmosphere of carbonic anhydride. It is converted by chlorine-gas into the tetrachloride $AsCl^4.C^7H^7$, a yellow liquid, which is decomposed by water into hydrochloric and monotolylarsenic acids. The corresponding para-compound is similarly obtained from (para)-mercury-ditolyl (m. p. 235°). It crystallises in colourless plates, which melt at 31° , and distils unchanged in an atmosphere of carbonic anhydride at 267° . The tetrachloride solidifies at a slightly reduced temperature; water decomposes it similarly to the ortho-compound. Both the above chlorides are converted by aqueous sodium carbonate into monotolylarsenoxides, $AsO.C^7H^7$. These are white powders, resembling arsenious oxide, easily soluble in hot alcohol, insoluble in ether.

The ortho-compound fuses at 146° , the para-compound at 156° . On raising the temperature, both undergo decomposition, with liberation of arsenious anhydride, the latter yielding tritolylarsine crystallising in plates (m. p. 129° - 130°).

Orthomonotolylarsinic acid, $C^7H^7.AsO(OH)^2$, is the product of the action of water on the tetrachloride previously mentioned. It crystallises from its aqueous solution in slender needles, which melt at 160° to a colourless liquid. The para-compound, similarly prepared, crystallises from its aqueous solution in long needles, which on heating do not melt, but are decomposed at a temperature of 300° .

TOLYL-BUTYLENE, $C^{11}H^{14} = CH^3.C^6H^4.CH^2.C^3H^3$, is formed, together with diallyl- and dixylyl, by heating 1 mol. metaxylyl chloride, $CH^3.C^6H^4.CH^2Cl$, 1 mol. allyl iodide and 4 at. sodium on the water-bath till reaction begins, then cooling the mixture to prevent the action from becoming too strong, and again heating it on the water-bath for six or eight hours. The pure tolyl-butylene, separated from the crude product by filtration and fractional distillation, is a limpid liquid having a sweetish odour, boiling at 195° , and uniting with bromine to a colourless oil which does not solidify at -10° (Aronheim, *Ber.* ix. 1789).

TOLYL-CARBAMIDE, or **TOLYL-UREA**, $C^6H^{10}N^2O = NH^2.CO.NH(C^7H^7)$. Sell obtained a monotolyl-carbamide by the action of potassium cyanate on toluidine sulphate, and described it as crystallising in white needles, and decomposing at 158° into ammonia and ditolyl-carbamide (i. 872). Schwebel (*Ber.* xi. 1128) obtains a tolyl-carbamide, together with tolyl-hydantoic acid, tolyl-hydantoin (*q.v.*), and toluidine, by fusing tolylglycocine with urea. The tolyl-carbamide thus obtained crystallises in silvery needles, insoluble in water, not attacked by acids or alkalis, and decomposing at about 200° . Lastly, a tolyl-carbamide melting at 182° is obtained by the reaction described in the following article. As all these three products were obtained from ordinary *p*-toluidine, it is probable that the differences between them are due to different degrees of purity.

TOLYL-CARBINOL, $C^6H^{10}O = CH^3.C^6H^4.CH^2OH$. Syn. with XYLAL ALCOHOL (*q.v.*)

TOLYL-CARBODIIMIDOTHIA-ACETIC,

is formed, like the corresponding phenyl-compound (p. 1555), by the action of monochloroacetic acid on *p*-toluidine thiocyanate, or on a mixture of a metallic thiocyanate

* There is some confusion in the use of this term, as it is applied sometimes, as above, to the 7-carbon radicle, methyl-phenyl, $CH^3.C^6H^4-$, sometimes to the 8-carbon radicle, $C^8H^7 = CH^3.C^6H^4.CH^2-$; but this latter, being derived from xylene, is better called 'xylyl,' e.g. $C^8H^7Br = CH^3.C^6H^4.CH^2Br =$ bromoxylylene or xylyl bromide.

with toluidine. It melts at 176° – 182° , and is resolved by prolonged heating with sulphuric acid into thioglycollic acid and *p*-tolyl-carbamide, melting at 182° .

(Nencki, *J. pr. Chem.* [2], xvi. 1; Jäger, *ibid.* 17).

TOLYL-CHLORACETAMIDE, $\text{CH}^2\text{Cl}\cdot\text{CO}\cdot\text{NH}(\text{C}^6\text{H}^4\cdot\text{CH}^3)$. See ACETAMIDES (p. 7).

Di-TOLYLDIAZINS, $\text{C}^{14}\text{H}^{14}\text{N}^2 = \text{CH}^2\cdot\text{C}^6\text{H}^4\cdot\text{N}=\text{N}\cdot\text{C}^6\text{H}^4\cdot\text{CH}^3$. *Azotoluenes*.—The *ortho*- and *para*-modifications (α and β , vi. 265; vii. 1163) are formed by reduction of liquid and solid nitrotoluene respectively with sodium-amalgam. The *para*-compound is however more readily obtained in the pure state by oxidation of *p*-ditolyl-hydrazine (p. 1057). It melts at 144° – 145° , sublimes with decomposition, and is less soluble in alcohol than the *ortho*-compound (Petrieff, *Ber.* vi. 556). It may also be prepared in considerable quantity by oxidation of *p*-toluidine: (a). With bleaching powder in presence of chloroform (R. Schmitt, *J. pr. Chem.* [2], xviii. 196); (b). By drenching the toluidine with a quantity of hydrochloric acid not sufficient to dissolve it completely, and then treating it with a solution of potassium permanganate. The ethereal extract of the resulting mass leaves on evaporation a black mass, from which petroleum-ether extracts a substance crystallising in reddish needles, having the composition and melting point of ditolyl-*p*-diazin; and the second and third ethereal extracts of the crude product yield crystals melting at 244° – 245° , and having the composition of *ditolyl-ditolylene-tetrazin*, $\text{C}^{28}\text{H}^{28}\text{N}^4$ (Barsilowsky, *Ber.* vi. 1209; xi. 2153). See p. 2031.

Bromo-p-ditolyl-diazin, obtained by direct bromination, crystallises in concentric groups of needles, which dissolve with difficulty in alcohol and ether, easily in chloroform and benzene; it melts at 136° , and sublimes without decomposition at a higher temperature.

Mononitro-p-ditolyl-diazin (m. p. 76°) and the *dinitro-compound* (m. p. 1100° ?) are formed by heating the paradiazin with nitric acid of sp. gr. 1.4, the dinitro-compound separating from an alcoholic solution on cooling in yellow needles, and the mononitro-compound from this mother-liquor in white needles. Stronger nitric acid of sp. gr. 1.54 converts the paradiazin into a trinitro-ditoloxydiazin, $\text{C}^{14}\text{H}^{11}(\text{NO}_2)^3\text{N}^2\text{O}$, melting at 201° (Petrieff); compare vii. 1163.

Orthoditolyl-diazin may be advantageously prepared by oxidising *o*-toluidine with potassium permanganate, the yield amounting to 30 per cent. of the toluidine used. It is nearly insoluble in water, but dissolves readily in alcohol, ether, benzene, carbon sulphide, and chloroform, and crystallises in well-defined prisms having a fine red colour, and melting at 55° . It volatilises readily with water-vapour, is not attacked by boiling soda-ley, but dissolves in strong sulphuric acid, and is precipitated from the solution by water, apparently unchanged. It is not altered (neither is the *para*-compound) by further treatment with potassium permanganate (Hoogewerff a. van Dorp, *Ber.* xi. 1202).

Metaditolyl-diazin, prepared by reduction of metanitrotoluene with sodium-amalgam, or better with zinc-dust and alcoholic potash, separates from alcoholic solution in large orange-red crystals very much like those of diphenyl-diazin (azo-benzene). It melts at 54° (Barsilowsky, *Ber.* x. 2098, 2240). A. Goldschmidt (*ibid.* xi. 1625) obtains the same compound, together with metatoluidine, by distilling the crude product of the action of alcoholic potash on metanitrotoluene, and finds that it crystallises in large red tablets melting at 51° , insoluble in water, easily soluble in alcohol and benzene, deliquescent in ether into symmetrical metaditolyl-hydrazine.

Ortho-amidoditolyl-diazin, or *o*-Amidazotoluene,

This compound is formed by treating orthotoluidine floating on a saturated solution of common salt with nitrous acid; and on washing the resulting thick dark-brown oil with soda-ley, and treating it with hot dilute hydrochloric acid, the liquid on cooling, especially after addition of strong hydrochloric acid, deposits laminae of *amidoditolyl-diazin hydrochloride*, which after drying in a vacuum has the composition $\text{C}^{14}\text{H}^{13}\text{N}^3\cdot\text{HCl}$; it gives off hydrochloric acid at 100° , dissolves sparingly in cold water, easily in water acidulated with hydrochloric acid, and in alcohol. The base separated by ammonia forms thin laminae or tubular crystals having a golden lustre

and blue surface-shimmer, melts at 100° , and dissolves readily in alcohol and ether, but is insoluble in water. Its salts have an orange-yellow colour, and are decomposed by water; the *silver salt* forms golden-yellow easily decomposable laminæ; the *platinochloride*, thin brown plates, which when dried at 100° have the composition $(C^6H^4N^3, HCl)^2PtCl^4$ (Nietzky, *Ber.* x. 662, 1155).

is very much like ortho-amidotolyl-*o*-tolyldiazin; it melts at 127° – 128° , and forms salts which have a steel-blue lustre and exhibit a crimson colour in acid solution. The *hydrochloride*, $(C^6H^4N^3, HCl)^2PtCl^4$, crystallises in cinnamon-red needles; the *platinochloride* is insoluble in water, and contains 5 per cent. water, which it gives off at 180° .

Amidophenylparatolyldiazin, $C^6H^4(NH^2).N^2.C^6H^3$, crystallises in needles an inch long having a dark yellow colour and blue shimmer; melts at 147° ; forms a rose-coloured hydrochloride crystallising in nacreous rhombic tablets, and a platinochloride which crystallises in brown needles, and when dried at 180° has the composition $(C^6H^4N^3, HCl)^2PtCl^4$. The *silver salt*, $(C^6H^4N^3)^2AgOH$ (at 100°), crystallises in golden-yellow scales.

Metamidoditolyldiazin (metamidazotoluene) is easily formed by the action of nitrous acid on metatoluidine. Its salts are but slightly soluble in water; the hydrochloride crystallises from alcohol containing hydrochloric acid in long dark steel-blue needles which are decomposed by water; the acid solutions of the salts have a fine red colour. The base itself forms golden-yellow needles melting at 80° . The *platinochloride*, $(C^6H^4N^3, HCl)^2PtCl^4$ (at 130°), forms yellow, metallically lustrous laminæ, nearly insoluble in water and in alcohol. *Paratolyldiazin-tolylamide* and *metatoluidine hydrochloride* react in alcoholic solution, with elimination of *p*-toluidine, forming metamidotolylparatolyldiazin, which crystallises in yellow laminæ melting at 127° . The *hydrochloride* of this base consists of stellate groups of steel-blue laminæ; the *platinochloride*, $(C^6H^4N^3, HCl)^2PtCl^4$, of sparingly soluble needles having a bronze lustre.

Ortho-amidoditolyldiazin and aniline hydrochloride heated with alcohol at 160° yield a red dye-stuff resembling saffranin, which dissolves in water with red, in strong hydrochloric acid with deep blue colour, changing to red on dilution. The *p*-*o*-compound yields a violet colouring matter; the tolylphenyl-compound a violet colour with ortho-, a blue-violet with *p*-toluidine. These colouring matters are reduced by zinc, yielding colourless solutions, which quickly become coloured on exposure to the air.

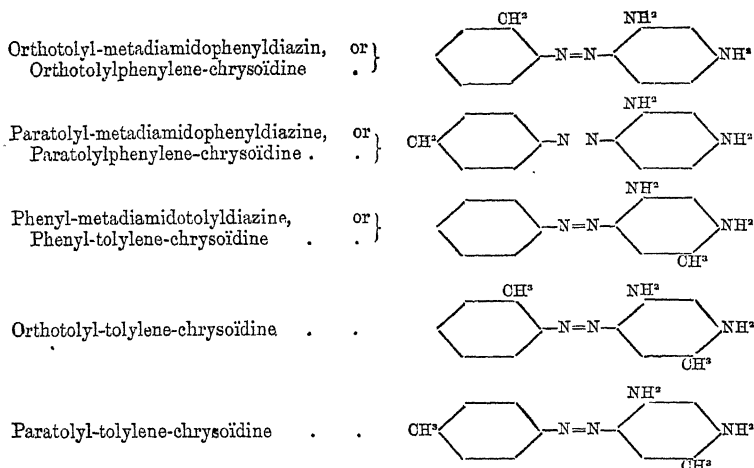

The mixture of bases obtained by reduction of metamidoditolyldiazin gave by oxidation, after addition of a small quantity of orthotoluidine, the green coloration characteristic of (*m*-*o*)-tolylenediamine (vii. 1180). Hence, in the bodies above described the substituted groups probably stand in the positions 1 (methyl), 2, 5 (Nietzki, *loc. cit.*)

Tolylamidotolyldiazin, $C^6H^4N^3 = C^6H^3N=N.NH(C^6H^3)$. *Diazotoluene-amidotoluene* (Nietzki, *Ber.* x. 662, 1155).—This compound is formed by dissolving 2 pts. paratoluidine and 1 pt. amyl nitrite in 8 to 10 pts. ether, and leaving the solution to evaporate in a moderately warm place. It then remains as a crystalline pulp, which may be purified by washing with alcohol. When mixed in alcoholic solution with hydrochloride of aniline or orthotoluidine (not of paratoluidine), it unites with those compounds, forming salts of diamidotolyldiazins—bodies homologous with *chrysoidine* or *phenyl-m-diamidophenyldiazin*, $C^6H^3N=N.C^6H^3(NH^2)^2$ (p. 469).

To prepare these compounds, a mixture of tolyl-tolylamido-diazin with somewhat more than the theoretical quantity of aniline hydrochloride or orthotoluidine hydrochloride is drenched an eight to ten-fold quantity of alcohol, whereupon the reaction takes place attended with rise of temperature, and is completed in three or four hours. The product boiled with dilute hydrochloric acid yields a solution which on cooling deposits the hydrochloride of the diamido-diazin compound. The reaction may perhaps be represented by the following equation:

The same compounds may be prepared (like *chrysoidine*) by the action of tolyldiazin salts (diazotoluene salts) on phenylene- and tolylene-diamines (p. 470). The following have been obtained by O. N. Witt (*Chem. Soc. J.* xxxv. 181):

The hydrochlorides of these bases form splendid yellow and orange dye-stuffs, known commercially as 'chrysoïdines.'

Phenyl-tolylene-chrysoïdinesulphonic acid is represented by the formula :

Ditolyl-ditolyldiazine, $C^{28}H^{26}N^4 = C^7H^7N=N.C^7H^7.C^7H^7.N=NC^7H^7$
 $C^7H^6.N.N.C^7H^7$
 or $\begin{array}{|c|} \hline C^7H^6.N.N.C^7H^7 \\ \hline \end{array}$ (Barsilowsky, *Ber.* xi. 2153). This is the compound formed,

together with *p*-ditolyl-diazin, by oxidation of *p*-toluidine with potassium permanganate (p. 1996). Its formation is explained by Barsilowsky as follows: 2 mols. toluidine are first converted into ditolyl-hydrazine, $C^7H^7.NH.NH.C^7H^7$, part of which is oxidised to *p*-tolyldiazin, while another portion is converted into the isomeric toluidine, $NH^2(C^7H^7).C^7H^7.NH^2$, a molecule of which unites either with 2 mols. toluidine, as indicated by the equation:

or with 1 mol. of symmetrical ditolyl-hydrazine:

This compound, treated with chlorine or bromine, yields nothing but resinous products. The *hydrazine*, $C^{28}H^{30}N^4$, prepared from it, is dissolved by acids and precipitated from the solutions by alkalis without alteration. Its alcoholic solution treated with acids forms saline precipitates, of which those formed by sulphuric, hydrochloric, and nitric acid cannot be obtained in the crystalline state. Those formed with organic acids are, however, more stable, the most characteristic being the *oxalate*, $C^{28}H^{30}N^4.C^2H^2O_4 + H^2O$, which is crystalline, slightly soluble in water, easily soluble in alcohol, especially with aid of heat, but decomposes when heated in an air-bath even below 100° , and gives up part of its acid even to water. With *methyl* or *ethyl iodide* the hydrazine forms only resinous products; with *acetyl chloride* it forms a crystallisable body, consisting either of $C^{14}H^{14}N^2(C^2H^3O)^2$ or $C^{28}H^{28}N^4(C^2H^3O)^4$.

Tolyl-oxytolyldiazin, or **Oxyazotoluene**, $C^7H^7.N=NC^7H^7$, formed, together with two other compounds, by the action of paratoluidine acetate on nitrosophenol, crystallises in orange-yellow prisms, somewhat soluble in hot water, and melting at 151° . It possesses acid properties, and forms a silver salt which crystallises in shining orange-coloured needles.

Ditolyl-oxydiazin, $C^4H^{14}N^2O = C^7H^7N.O.NC^7H^7$. *Azorytoluene*.—This compound, formed, together with ditolyldiazin, by the action of sodium-amalgam on nitrotoluene in alcoholic solution, crystallises, according to Melms, in yellow needles melting at 70° ; according to Petrieff, in large laminæ melting at 57° (see vii. 1163).*

Monobromo-p-ditolyl-oxydiazin (p. 1163), and the corresponding dibromo-compound, are obtained by dissolving *p*-ditolyl-oxydiazin in bromine not cooled. The latter is slightly soluble in alcohol, and crystallises in needles melting at 138° (Petrieff, *Ber.* vi. 556).

Mononitro-p-ditolyl-oxydiazin, melting at 84° , and the dinitro-compound at 145° , are obtained by heating *p*-ditolyl-oxydiazin (m. p. 59°) with nitric acid of sp. gr. 1.4. Both crystallise in yellow needles, and may be separated by alcohol, in which the dinitro-compound is insoluble (Petrieff, *loc. cit.*)

Azorytoluidine (E. Buckney, *Ber.* xi. 1451).—This base is formed as a thick pulp on gradually mixing a concentrated solution of nitro-*p*-toluidine in absolute alcohol with very small pieces of sodium-amalgam (50 g. substance being reduced in $1\frac{1}{2}$ to 2 days). It may be purified by recrystallisation from a large quantity of water, and then forms small yellow needles melting at 148° , slightly soluble in cold, more freely in hot water and alcohol. With strong hydrochloric acid it forms a sparingly soluble yellow-brown hydrochloride, $C^4H^{16}N^4O.2HCl$, from the aqueous solution of which platonic chloride throws down the yellow double salt, $C^4H^{16}N^4O.2HCl.PtCl_4$.

Diamidotolyldiazin, $\begin{array}{c} NH_2 \\ | \\ CH_3 \end{array} > C^6H^3.N=N.C^6H^3 < \begin{array}{c} NH_2 \\ | \\ CH_3 \end{array}$, and the corresponding *hydrazine*, $\begin{array}{c} NH_2 \\ | \\ CH_3 \end{array} > C^6H^3.NH.NH.C^6H^3 < \begin{array}{c} NH_2 \\ | \\ CH_3 \end{array}$, are formed simultaneously by the action of sodium-amalgam on the oxydiazin in alcoholic solution, and may be separated by their difference of solubility in alcohol. The *diazin*, also called *azotoluidine*, is easily soluble in alcohol, is precipitated from the alcoholic solution by water, and crystallises in red needles melting at 159° . The *hydrazine*, $C^4H^{18}N$ (hydrazotoluene), crystallises in small colourless plates melting at 180° , nearly insoluble in water, ether, and cold alcohol, sparingly soluble in hot alcohol, and easily oxidised in alcoholic solution (even by heating in contact with the air to diamidotolyldiazin).

Ditolyl-hydrazines, $C^4H^{16}N^2$. The symmetrical modifications of these compounds, $\begin{array}{c} C^7H^7.NH \\ | \\ C^7H^7.NH \end{array}$, also called *hydrazotoluenes*, are formed by the action of sodium-amalgam or ammonium sulphide on the corresponding ditolyldiazins or -oxydiazins (vii. 1163). The *ortho*-compound (m. p. 165°) is permanent in the dry state when kept from contact with the air, but is converted into ditolyldiazin or -oxydiazin when dissolved in alcohol or water. When dry chlorine oxide gas, Cl_2O , is passed into its ethereal solution, a white powder is formed, whose aqueous solution gives with the nitrates of silver and copper insoluble precipitates from which alkalis separate a body crystallising in nacreous laminæ, sparingly soluble in water, easily in alcohol and ether, and appearing from the analysis of its hydrochloride, $C^4H^{16}N^2.HCl$, to be an isomeric toluidine or diamidotolyl, $C^4H^{14}(NH_2)^2$ (vii. 1163). At the same time ditolyl-oxydiazin and an addition-product are formed, the reaction being represented by the equation:

(Petrieff, *Ber.* vi. 556).

Metaditolyl-hydrazine (symmetrical), obtained by the action of alcoholic ammonium sulphide on *m*-ditolyldiazin, is easily alterable in contact with the air, and is converted by addition of sulphuric acid to its solution in dilute alcohol, into *m*-toluidine sulphate, $[C^6H^3(CH_3)NH_2]^2H^2SO_4$, which is easily soluble in water, insoluble in alcohol, and crystallises in laminæ having a satiny lustre. *m*-Toluidine is separated from this salt by ammonia as an oil which solidifies at low temperatures, forms salts with hydrochloric and nitric acids, and is coloured blue by ferric chloride (A. Goldschmidt, *Ber.* xi. 1625).

* As both Melms and Petrieff operated on solid nitrotoluene, the great difference between the melting points of the ditolyldiazins which they obtained is not easy to account for, except on the supposition that Melms' product was contaminated with ditolyldiazin, which melts at 137° .

TOLYLDIPHENYL-METHANE, $C^{20}H^{18} = CH(C^7H^7)(C^6H^5)^2$ (E. and O. Fischer, *Liebig's Annalen*, xciv. 282). This hydrocarbon is prepared by the action of boiling alcohol on diazoleucaniline chloride (p. 1178). When recrystallised from methyl alcohol, it forms spherical groups of prisms easily soluble in ether, benzene, and ligroin, less easily in cold alcohol and wood-spirit; it melts at 59° – 59.5° , and boils without decomposition at a temperature above 360° . Nitric acid converts it into a number of nitro-compounds, one of which, when treated with zinc-dust and glacial acetic acid, yields leucaniline.

Tolyldiphenyl Carbinol, $C^{20}H^{18}O = (C^7H^7)(C^6H^5)^2COH$, obtained by oxidising the hydrocarbon dissolved in glacial acetic acid with chromic acid, crystallises from ligroin in six-sided prisms or tables, melts at 150° , dissolves easily in ether, alcohol, and benzene, less easily in ligroin, and boils without decomposition.

TOLYLENE-CARBAMATE, ETHYLIC or **TOLYLENE-URETHANE**, $C^{10}H^{18}N^2O^4 = C^7H^7 \begin{smallmatrix} NH.CO.O^2C^2H^5 \\ NH.CO.O^2C^2H^5 \end{smallmatrix}$, is formed, together with tolylene-diamine hydrochloride, by the action of ethylic chlorocarbonate on tolylene-diamine:

On dissolving the product in water, the urethane separates first in fine crystals, which may be purified by treatment with animal charcoal and recrystallisation from alcohol. It forms dazzling white needles having a silky lustre, soluble in ether, and melting at 137° . On distillation, the greater part passes over unaltered, but the remainder is decomposed into alcohol and tolylene isocyanate, $C^7H^7(NCO)^2$. The same compound is obtained more abundantly by distilling the urethane with phosphoric anhydride, and passes over as a strongly refractive liquid having a fearfully pungent and tear-exciting odour. In contact with ether, this liquid quickly solidifies, and therefore appears, like many other cyanates, to pass into a polymeric modification. The solid body thus formed consists of stellate groups of yellow transparent crystals melting at 95° , and reconverted by alcohol into tolylene-urethane.

TOLYLENE-DIAMINES, $C^7H^7(NH^2)^2.CH^2$. Syn. with DIAMIDO-TOLUENES (pp. 2003–2005).

TOLYLENE - DICARBAMIDE, or **TOLYLENE - DIUREA**, $C^7H^7(NH.CO.NH^2)^2$, which Strauss obtained, by adding tolylene-diamine to a cooled solution of potassium cyanate (vi. 1117), is also formed by the action of ammonia on tolylene-isocyanate. It forms shining crystalline scales sparingly soluble in alcohol and in boiling water, melting at 220° . When heated with ethyl iodide at 110° , it is converted into diethyl-tolylene-carbamide, a yellowish body soluble in alcohol and ether, melting at 175° (Lussy, *Ber.* viii. 201).

TOLYLENE-THIOCARBAMIDE, $C^7H^7N^2S = N^2(C^7H^7)(CS)H^2$, is formed by the action of potassium thiocyanate on a warm aqueous solution of tolylene-diamine, the immediate product of the reaction being tolylene-diamine thiocyanate, which is subsequently converted into the thiocarbamide (Lussy, p. 2003).

On **TOLYLENE-DITHIOCARBAMIDE**, $C^7H^7(NH.CS.NH^2)^2$, and its Ethyl- and Phenyl-derivatives, see **CARBAMIDES** (p. 399).

TOLYL-GLYCOCINE, $C^9H^{11}NO^2 = C^7H^7.NH.CH^2.COOH$. This compound, which P. J. Meyer obtained by heating *p*-toluidine with monochloroacetic acid (p. 881), may also be prepared by prolonged heating of toluidine chloracetate with water. When purified by recrystallisation from hot water (which is attended with partial decomposition), it crystallises in slender colourless felted needles, and after a further crystallisation in long straw-yellow needles which melt, with decomposition, at 166° – 168° (Meyer's product melted at about 145° , and decomposed at about 170°). Its solution in strong hydrochloric acid gives a crystalline precipitate with platinum chloride, amorphous precipitates with mercuric chloride and stannous chloride, green with cupric sulphate (Schwebel, *Ber.* x. 2045).

TOLYL-HYDANTOIC ACID, $\begin{smallmatrix} CH^2.N(C^7H^7).CO.NH^2 \\ COOH \end{smallmatrix}$, and **TOLYL-HYDANTOIN**, $\begin{smallmatrix} CH^2.N(C^7H^7) \\ CO-NH \end{smallmatrix} \rangle CO$. See **HYDANTOIC ACID** (p. 1046).

TOLYL-HYDRAZINE, $CH^2.C^6H^4.NH.NH^2$. See **HYDRAZINES** (p. 1057).

TOLYL-OXAMETHANE, $CH^2.C^6H^4.CO.NH.CO^2C^2H^5$. See **OXAMIC ETHERS** (p. 1457).

TOLYLPHENYLACETIC ACID, $C^{16}H^{14}O^2 = \text{CH}^3.C^6H^4.C^6H^5 > \text{CH}.COOH$ (Tanisch, *Ber.* x. 996). This acid, homologous with diphenyl-acetic acid (p. 665), is produced by the action of toluene and zinc-dust on phenyl-bromacetic acid, the product consisting mainly of *p*-tolyl-phenyl-acetic acid, with a smaller quantity of the ortho-acid.

Paratolyl-phenylacetic acid dissolves sparingly in cold water, a little more freely in boiling water, readily in alcohol, ether, chloroform, and carbon sulphide, and crystallises in nearly rectangular plates, melting at 115° , and subliming, when more strongly heated, in oily drops, which gradually solidify and then melt at 108° – 110° .

The *potassium salt* crystallises from a concentrated solution in clear monoclinic plates, containing 4 mol. of water. The *sodium salt* is very soluble, and forms needles with 6 mol. of water. The *barium salt* could be obtained only as a resinous mass, and the *calcium salt*, which is well adapted for the purification of the acid, is very sparingly soluble in cold and hot water, and crystallises from dilute hot alcohol in glistening needles containing 2 mols. of water. The salts of *lead*, *copper*, *silver*, and *zinc* are precipitates; the first crystallises from hot alcohol in needles; the copper and zinc salts dissolve also in alcohol, and more freely in ether-alcohol, separating in viscid drops, which gradually solidify. The *methyl-ether* is a thick oil, and the *ethyl-ether* crystallises from alcohol in plates melting at 34° . The *amide* forms needles, which are grouped in warty masses and melt at 151° . The soluble salts of the acid are decomposed by carbon dioxide. Chromic acid solution oxidises the acid to paratolylphenyl ketone and parabenzoylbenzoic acid.

On purifying the crude acid by crystallisation from alcohol, a mother-liquor is obtained, containing an oily acid, which cannot be crystallised, and consists of a mixture of the para- and ortho-acids. A separation of these could not be effected, but their presence was proved by oxidation, a mixture of para- and ortho-benzoylbenzoic acid being thereby produced.

p-**TOLYLPHENYL-CARBINOL**, $C^{14}H^{14}O = \text{CH}^3.C^6H^4.CHOH.C^6H^5$, obtained by the action of sodium-amalgam on *p*-tolylphenyl ketone (p. 1154), forms, when purified by crystallisation from ligroin, concentric groups of colourless needles having a silky lustre and melting at 52° – 53° . A mixture of tolylphenyl-carbinol and benzene heated with phosphoric anhydride yields tolyldiphenyl-methane (p. 2036):

(E. and O. Fischer, *Liebigs Annalen*, xciv. 265).

TOLYLPHENYL-CARBOXYLIC ACID,

produced by incomplete oxidation of solid ditolyl with chromic acid, melts at 243° – 244° (Carnelley: see *DITOLYL*, p. 691).

TOLYLPHENYL-GUANIDINE, $\text{CH}^3(C^6H^5)(C^6H^7)N^3$, and **DITOLYL-GUANIDINE**, $\text{CH}^3(C^6H^7)^2N^3$. See *GUANIDINES* (p. 909).

TOLYLPHENYL KETONES, $C^{14}H^{12}O = \text{CH}^3.C^6H^4.CO.C^6H^5$ (Plascuda a. Zincke, *Ber.* vii. 375). The preparation and properties of the para- and ortho-modifications of these bodies and their chlorinated derivatives have already been described (pp. 1154–1156); also their oxidation to para- and ortho-benzoylbenzoic acid respectively (p. 309).

Nitro-derivatives.—*Mononitrotolylphenyl Ketone*, $\text{CH}^3.C^6H^4.CO.C^6H^4(NO^2)$, produced by the action of fuming nitric acid on solid tolylphenyl ketone, is identical with the nitromethylbenzophenone obtained by the action of dilute nitric acid on benzyl-toluene (vii. 183). It crystallises from hot alcohol in broad shining laminae or groups of needles, melts at 126° – 127° , and sublimes easily in shining laminae or groups of needles, dissolves readily in chloroform, benzene, and hot acetic acid. By boiling its solution in glacial acetic acid with chromic acid, it is oxidised to benzoic acid and metanitrobenzoic acid (m. p. 140°). The greater part of the nitro-ketone is, however, completely burnt in this process, and the first product of the oxidation, viz. *mononitrobenzoylbenzoic acid*, has not been obtained.

Dinitrotolylphenyl Ketone, $C^{14}H^{10}(NO^2)^2O$, is produced by prolonged boiling of dinitrobenzyl-toluene (p. 183) with nitric acid of sp. gr. 1.4, or by heating its solution in glacial acetic acid with chromic acid. It crystallises from acetic acid in thick yellowish needles, from alcohol in silky laminae; melts at 126° – 127° ; decomposes at a higher temperature, without subliming; dissolves with moderate facility in benzene

and in chloroform, less easily in ether. By oxidation it yields paranitrobenzoic acid and dinitrobenzoylbenzoic acid, $C^{14}H^8(NO^2)_2O^3$.

Trinitrotolylphenyl Ketone, $C^{14}H^8(NO^2)_3O$, obtained by adding solid tolylphenyl ketone or its mono- or di-nitro-derivative to a mixture of nitric and sulphuric acids, crystallises from alcohol or from glacial acetic acid in small well-defined yellowish prisms, melts at 165° , and decomposes without subliming at a higher temperature.

The nitro-derivatives of orthotolylphenyl ketone are uncrystallisable resins.

TOLYLPHENYL PINACOLINS, $C^{28}H^{21}O$. See KETONES (p. 1155).

TOLYLPHENYL-SULPHONE, $C^7H^7.SO^2.C^8H^8$. See SULPHONES (p. 1855).

TOLYL-SILICONIC ACID, $C^7H^7.SiO^2H$. An acid produced by the action of ammonia on silico-tolyl chloride, $C^7H^7SiCl^3$ (p. 1794).

TOLYL-SULPHOXIDES (p. 1856).

TOLYL-THIOHYDANTOÏN, $CS \begin{matrix} \text{NH} & \text{---} & \text{CH}^2 \\ & \diagdown & \diagup \\ & \text{N}(C^7H^7) & \text{---} & \text{CO} \end{matrix}$. See HYDANTOÏN (p. 1047).

TOLYL-TOLYLENE-CHRYSOÏDINE, $C^{14}H^{16}N^4 = C^7H^7.N = N.C^7H^7(NH^2)^2$. A homologue of chrysoïdine, more properly called *Diamidazotoluene* or *Tolyldiamidotolyldiazin* (p. 470). It crystallises in stellate groups of orange-coloured needles, easily soluble in alcohol and ether, almost insoluble in water. The *hydrochloride*, $C^{14}H^{16}N^4.HCl$, crystallises in red needles, and yields a crimson platinochloride (Hofmann, *Ber.* x. 218).

TOPAZ. The following analyses of topaz have been published by H. Klemm (*Jahrb. f. Min.* 1874, 189).

1. Pyrohasite. 2. Topaz from Miask. 3. From Freiberg. 4. Values deduced from the formula $5Al^3O^3SiO^2 + SiF^4$, the fluorides being reckoned as the equivalent quantities of oxides:

	¹	²	³	⁴
F	17.106	17.167	17.447	17.50
SiO ²	33.643	33.469	33.323	33.16
Al ³ O ³	56.218	56.529	56.350	56.70

On the Crystalline forms of Topaz, see E. Bertrand (*Zeitschr. Kryst.* i. 297); Laspeyres (*ibid.* 347); Jeremejew (*ibid.* ii. 504); Seligmann (*ibid.* iii. 30); also *Jahresb. f. Chem.* 1877, 1305; 1877, 1237. On Minerals enclosed in Topaz, see Hartley (*Chem. Soc. J.* xxxi. 241). On Corrosion-figures of Topaz, see Baumhauer (*Jahrb. f. Min.* 1876, 1).

On the Decomposition of Topaz at high temperatures, see SILICATES (p. 1792).

TOPAZOLITE. Crystals of this mineral (a variety of garnet) from the trap-rocks of New Haven, Connecticut, are described by E. S. Dana (*Sill. Am. J.* [3], xiv. 215; *Jahresb. f. Chem.* 1877, 1313).

TORBANITE. On the supposed formation of this carbonaceous mineral from petroleum, see W. Skey (*Chem. News*, xxxi. 16).

TOURMALIN. Green tourmalin from Campolongo has been analysed by Th. Engelmann (*Zeitschr. Kryst.* iii. 312) with the following result:

Fl	SiO ²	Al ³ O ³	Be ² O ³	FeO	MnO	MgO	Na ² O	K ² O	H ² O
0.60	39.26	38.33	9.40	4.51	1.12	1.02	2.43	0.38	2.41 = 99.46

Sp. gr. of opaque crystals from Campolongo, 2.802; of transparent crystals from the same locality, 2.969; of crystals from the Binnenthal, 2.925.

Intergrowths between tourmalin and orthoclase are described by E. H. Williams (*Sill. Am. J.* [3], xi. 273). The tourmalin crystals, which are imbedded in quartz or orthoclase, were found in a quarry near Port Henry, New York.

The Corrosion-figures of tourmalin and topaz have been examined by H. Baumhauer (*Jahrb. f. Min.* 1876, 1).

TRACHYTE. *Analyses*. 1. From Gladstone in Queensland, resembling that of the Puy-de-Dôme (Daintree, *Geol. Soc. Qu. J.* xxviii. 271). (2-5). *Augitic trachytes* from the Andes. 2. From Tunguragua: black, very finely crystalline ground-mass enclosing plagioclases, augite and magnetite. 3. Tunguragua: red, porous ground-mass enclosing numerous plagioclases and short prismatic augites; magnetite is wanting, having probably been converted into ferric oxide: hence the red coloration. 4. Pichincha, 4,860 meters above the sea-level: greenish-black, finely crystalline ground-mass, enclosing small augites and magnetite, also plagioclases containing

cavities and enclosed liquids. 5. Cachofruto, near Marmato: grey, very hard ground-mass enclosing tabular plagioclases, with small quantities of augite and magnetite (Artopé, *Jahrb. f. Min.* 1874, 93). 6. Trachyte from Wolferdingen, in the Westerwald (Hilger, *ibid.* 1877, 421). (7-9). Trachytes from the neighbourhood of Gleichenberg (E. Ludwig, *Min. Mitth.* 1877, 276). 7. *Quartz-trachyte* from the Schaufelgraben, near Gleichenberg, analysed by H. Frisch; sanidine and quartz in a dull, somewhat porous ground-mass; on decomposition it yielded 27·14 per cent. quartz. 8. Trachyte, north of Gleichenberg, analysed by L. Smita. 9. Trachyte from the Schuh Villa, Gleichenberg, distinguished from No. 2 by a small amount of spathic iron ore; analyses by J. Utschik. 10. *Quartz-trachyte* from the Tardree Mountain, County of Antrim, Ireland. The analyses and the microscopic examination indicate the presence of 62 per cent. sanidine and 38 per cent. quartz and tridymite. The sanidine contains exactly equivalent quantities of potassium and sodium (A. v. Lasaulx, *Min. Pet. Mitth.* [2], i. 410). 11. *Sanidine-plagioclase trachyte* from the Volcano of Ferra in Sardinia. 12. *Sanidine-augite trachyte* from the same locality (C. Dölter, *Jahresb. f. Chem.* 1878, 1287). 13. *Quartziferous Sanidine-trachyte* from Nagy-Kövesd: red-brown ground-mass, much decomposed and rich in ferric oxide; contains numerous quartz-grains and felspars enclosing laminae of mica and hornblende (Dölter, *Jahrb. f. Min.* 1875, 95). 14 and 15. Hornfelstrachyte from Markt Tüffer in Styria. 14. Red. 15. Green; sp. gr. 2·75 (E. v. Drasche (*ibid.* 1873, 768). 16. Trachyte-tufa from Wöllan in Styria, sp. gr. 2·51 (v. Drasche, *loc. cit.*)

(¹) P²O⁵. (²) Loss on ignition. In 12 and 13, traces of Mn and P²O⁵.

S. de Luca (*Compt. rend.*, lxxxvii. 174) has detected lithium in the waters and certain earthy decomposition-products of the trachytic rocks of the Solfatara of Puzzuoli.

On the Classification of Trachytes, see Doelter (*Verh. geol. Reichsanst.* 1873, 172) and Szabo (*ibid.* 310). On the Trachytes of the Visegrad range near Budapest, see A. Koch (*Zeitschr. geol. Ges.* xxviii. 293; *Jahresb. f. Chem.* 1876, 1289).

TRAP-ROCKS. The trap-rocks of Connecticut consist, according to G. W. Hawes (*Sill. Am. J.* [3], ix. 185), partly of diabases, partly of chloritic dolerites. The latter are metamorphosed dolerites, but the alteration has been produced, not by contact with the atmosphere (as in that case they would contain no ferrous oxide) but at the moment of eruption, by assumption of subterranean water and carbonic acid. For analyses, see the paper above cited; also *Chem. Soc. J.* xxix. 350; *Jahresb. f. Chem.* 1875, 1272).

On *Trap-granulite*. See GRANULITE (vii. 578).

TRAUTWEINITE. This name is applied by E. Goldsmith (*Sill. Am. J.* [3], v. 313) to microscopically small hexagonal crystals, implanted on chrome-iron ore from California. Qualitative analysis showed the presence of chromium, iron, and manganese.

TREHALOSE or **MYCOSE**, C¹²H²²O¹¹ (iii. 1068). On the occurrence of this kind of sugar, together with glucose and mannitol, in the higher kinds of fungi, see MANNITOL (p. 1267).

TREMOLITE. This mineral has been found in veins in the granulite limestone, to the east of Friedberg, in Austrian Silesia (Neminar, *Min. Mitth.* 1875, 111).

2040 TRIACETYL-EMODIN—TRIAZO-COMPOUND, $C^{36}H^{29}N^5$.

TRIACETONALKAMINE, $C^9H^{19}NO$, and **TRIACETONAMINE**, $C^9H^{17}NO$. See ACETONAMINES (pp. 29, 32).

TRIACETYL-ANTHRAPURPURIN, $C^{30}H^{14}O^8 = C^{14}H^5(C^2H^3O)^3O^5$. See ANTHRAPHURPURIN (vii. 89).

TRIACETYL-EMODIN, $C^{18}H^7(C^2H^3O)^3O^5$. Emodin (p. 732) treated with glacial acetic acid yields, according to the temperature, mono- or tri-acetyl-emodin. The former crystallises from glacial acetic acid in golden-yellow laminae melting at about 180° ; the latter in light yellow needles melting at 190° . Both are easily reconverted into emodin by heating with alkalis (Liebermann, *Ber.* viii. 970).

TRI- and DI-ACETYL-FLAVOPURPURIN. The *diacetyl*-derivative, $C^{14}H^8(C^2H^3O)^2O^5$, is the chief product obtained by boiling flavopurpurin (p. 111) with acetic anhydride. When recrystallised from glacial acetic acid, it forms golden-yellow laminae, very slightly soluble in that liquid, still less soluble in alcohol. It sublimes at 125° , melts at 238° , and is readily decomposed by potash, sodium carbonate, and ammonia.

Triacetyl-flavopurpurin is found in the mother-liquors of the diacetyl-compound, and may be formed from the latter or from flavopurpurin by heating acetic anhydride at 180° – 200° . From glacial acetic acid, in which it is much more soluble than the diacetyl-compound, it crystallises in sulphur-yellow needles, which melt at 195° – 196° , and are decomposed by potash or by sodium carbonate only at the boiling heat.

TRIACETYL-HYDROCYANROSAURIN, and **TRIACETYL-LEUCO-ROSAURIN**. See ROSAURIN (p. 1762).

TRIACETYL-PURPURIN, $C^{14}H^8(C^2H^3O)^3O^5$. See PURPURIN (p. 111).

TRIACETYL-TRIISOXYLENE, $C^{11}H^{16}O^8 = C^6H(CH^3)^2(O.C^2H^3O)^3$. See XYLOQUINONES.

TRIAMIDOBENZENE, $C^6H^2N^3 = C^6H^2(NH^2)^3$ [1 : 1 : 5]. This compound, originally obtained by the dry distillation of triamidobenzoic acid (vii. 147), is also produced by the reduction of dinitraniline with tin and hydrochloric acid. It is most readily separated from the resulting hydrochloride by distillation with lime from short combustion-tubes bent downwards. The product thus formed is however not so pure as that which is obtained from triamidobenzoic acid, the former boiling at 340° , whereas the latter boils at 330° , though the two are theoretically identical (H. Salkowski, *Ber.* vi. 139). By oxidation it yields a colouring matter, which is also formed by heating chrysoidine with dilute hydrochloric acid at 150° – 160° (Hofmann, *Ber.* x. 213).

Acetyl-ethenyl-triamidobenzene, $C^{10}H^{11}N^3 = C^6H^2(NH.C^2H^3O)(N^2H.C^2H^3)^2$, formed by heating triamidobenzene with twice its weight of glacial acetic acid for ten hours, then adding water and evaporating down, crystallises with $2H^2O$ in godes of prismatic crystals; melts at 85° – 90° ; gives off its water, and resolidifies at 100° ; dissolves readily in hot water, very sparingly in cold water. The anhydrous compound when distilled gives off a small quantity of acetic acid; its boiling point is above that of mercury.

Acetyl-ethenyl-triamidobenzene is converted by hydrochloric acid, with separation of acetic acid, into *ethenyl-triamidobenzene hydrochloride*, $C^6H^2(NH^2)(N^2H.C^2H^3).2HCl + 1\frac{1}{2}H^2O$, which forms easily soluble, highly lustrous crystals, mostly having a faint reddish colour and apparently belonging to the triclinic system. At 100° they give off their water and part of the hydrochloric acid (H. Salkowski a. C. Rudolph, *Ber.* x. 1692).

TRIAMIDOPHENOL, $C^6H^2(NH^2)^3OH$. On the action of bromine and water on this compound, see PHENOLS (p. 1523).

TRIAMYL-PHOSPHINE, $(C^5H^{11})^3P$. See PHOSPHINES (vii. 955).

TRIAZO-COMPOUND, $C^{36}H^{29}N^5$. Aniline and diphenyl-nitrosamine act strongly on one another, forming water, diazo-amidobenzene, amidazobenzene, diphenylamine, and the compound $C^{36}H^{29}N^5$, which is sparingly soluble in alcohol, and crystallises from aniline in flat, ruby-coloured, shining needles, melting at 236° . It is best prepared by heating 10 pts. diphenylnitrosamine, 10 aniline hydrochloride, and 200 dry aniline for an hour and a half at 120° – 125° , mixing the product cooled to 60° with an equal volume of alcohol, washing the crystals which separate with alcohol,

drying them, and recrystallising from a ten-fold quantity of aniline. The body thus obtained has probably the constitution

and may be called a triazo-compound, as it contains 3 atoms of nitrogen linked together. It dissolves in strong sulphuric acid with violet coloration, and turns violet without dissolving when heated with hydrochloric acid. It is also formed when 10 pts. amidazobenzene, 10 diphenylamine, 10 aniline hydrochloride, and 200 aniline are treated as above (O. N. Witt, *Ber.* x. 1309).

TRIBENZHYDROXYLAMINE, $\text{N}(\text{C}^6\text{H}^5\text{O})^3$. See **HYDROXYLAMINE** (p. 1079).

TRIBENZOYL-ANTHRAPURPURIN, $\text{C}^{14}\text{H}^5(\text{C}^6\text{H}^5\text{O})^3\text{O}^5$. See **ANTHRAPURPURIN** (vii. 90).

TRIBENZOYL-DIAMIDOPHENOL, $\text{C}^6\text{H}^3(\text{OH})^2 < \begin{array}{c} \text{N}(\text{C}^6\text{H}^5\text{O})^2 \\ \text{NH}(\text{C}^6\text{H}^5\text{O}) \end{array}$. See **PHENOL** (p. 1523).

TRIBENZOYLENE-BENZENE, $\text{C}^{22}\text{H}^{12}\text{O}^3 = \text{C}^6(\text{C}^6\text{H}^4\text{CO})^3$. This appears to be the constitution of the yellow body ($\text{C}^9\text{H}^4\text{O}$), which Gabriel a. Michael obtained by the action of dehydrants on phthalyl-acetic acid (p. 1622). It does not take up either hydrogen or bromine, does not melt at 450° , and is not attacked even by hot potash-ley. Melting potassium hydroxide, however, converts it into phenenyl-tribenzoic acid, $\text{C}^6\text{H}^3(\text{C}^6\text{H}^4\text{CO}^2\text{H})^3$, which may be purified by separating it from the fused mass, converting it into ammonium salt, exhausting this with alcohol, and repeating these operations several times upon the residue. The phenenyltribenzoic acid may then be separated from the residue by hydrochloric acid, and crystallised from alcohol or glacial acetic acid by mixing the solutions with hot water. Phenenyltribenzoic acid thus obtained forms prisms which dissolve easily in alcohol, ether, and glacial acetic acid, sparingly in benzene and carbon sulphide; it melts at 259° – 261° , and undergoes partial carbonisation at 447° . The *silver salt* contains $\text{C}^{22}\text{H}^{15}\text{Ag}^3\text{O}^8$ or $\text{C}^{22}\text{H}^9\text{AgO}^3, 3\text{H}^2\text{O}$. The acid is not altered by nascent hydrogen, but when distilled over red-hot potassium hydroxide, it yields triphenylbenzene (Gabriel a. Michael, *Ber.* xi. 1007, 1679).

TRIBENZYLAMINE, $\text{N}(\text{CH}^2\text{C}^6\text{H}^5)^3$. The crystalline forms of this base and of some of its salts have been determined by R. Panebianco (*Gazz. chim. ital.* 1878, 854). The base itself and the platinochloride crystallise in the monoclinic system; the hydrochloride in the hexagonal system. The *sulphate* forms colourless monoclinic crystals, insoluble in water and in ether, soluble in alcohol, and melting with incipient decomposition at 106° – 107° . *Tribenzylamine-alum*, $\text{Al}(\text{C}^6\text{H}^7)^3\text{NH}(\text{SO}^4)^3, 12\text{H}^2\text{O}$, crystallises in cubo-octohedrons, with octohedral cleavage; it is soluble in water, insoluble in alcohol and ether, melts in its water of crystallisation at about 110° , and decomposes at about 120° . *Tribenzylamine nitrate*, $(\text{C}^6\text{H}^7)^3\text{N} \cdot \text{HNO}^3$, crystallises in the orthorhombic system, is slightly soluble in water and in alcohol, insoluble in ether, and melts with decomposition at 120° .

Tribenzylamine, subjected to exhaustive chlorination in presence of iodine, is converted into perchlorobenzene and perchloromethane (Ruoff, *Ber.* ix. 1483). Heated in a salt-water bath with *ethyl iodide*, it yields a crystallised iodide which dissolves in alcohol, melts at 190° , and is resolved into its components by the action of silver oxide (G. Vasca-Lanza, *Ber.* vii. 82).

TRIBROMACETAMIDE, $\text{NH}^2\text{C}^6\text{Br}^3\text{O}$, is formed, together with dibromacetamide and other brominated products, by the action of bromine on asparagine suspended in water. The action is very energetic, and on exhausting the resulting red liquid with ether, leaving the ether to evaporate, placing the residue over sulphuric acid till it solidifies, and recrystallising it from water, tribromacetamide separates out first, while dibromacetamide (melting at 156° – 157° , resolidifying at about 125°) crystallises from the mother-liquors after neutralisation with ammonia (Guareschi, *Gazz. chim. ital.* 1876, 375). Tribromacetamide is also formed by the action of ammonia on hexbromacetone (Weidel a. Grüber, p. 1524).

Tribromacetamide crystallises in shining white lamellæ, which melt at 119° – 121° , and are reproduced at 96° . It dissolves sparingly in alcohol, ether, and cold water, and is resolved by boiling with alkalis into bromoform, carbon dioxide and ammonia (Guareschi). Sulphuric acid converts it into ammonium sulphate and tribromacetic acid (Weidel a. Grüber).

TRIBROMACETANILIDE, $\text{C}^6\text{H}^2\text{Br}^3\text{NH}(\text{C}^6\text{H}^5\text{O})$. See **ACETAMIDES** (**BROMOPHENYL**), p. 5.

TRIBROMACETIC ACID, CBr_3COOH (p. 18). This acid is formed, together with ammonium sulphate, by heating tribromacetamide for several hours in a reflux apparatus at 128° – 130° , with a mixture of 3 pts. sulphuric acid and 2 pts. water (Weidel & Gruber, *loc. cit.*); also, together with dibromacetic acid (which remains in the mother-liquors), by the action of bromine on a strong solution of malonic acid (Petrieff, *Ber.* viii. 355).

Ethyl Tribromacetate, $\text{CBr}_3\text{COOC}^2\text{H}_5$, is formed by heating the dibromacetic ether with 1 mol. bromine at 120° . When freed from absorbed hydrogen bromide by heating in a stream of carbon dioxide, it forms an oily liquid which fumes strongly in the air and decomposes partly when distilled. It is decomposed by water and alcohol, the products of decomposition containing bodies which reduce an ammoniacal silver solution (Kessel, *Ber.* xi. 1917).

TRIBROMACETOPHENONE-*o*-CARBOXYLIC ACID, $\text{CBr}_3\text{CO.C}^6\text{H}^4\text{CO}^2\text{H}$. See PHENYL-KETONES (p. 1565).

TRIBROMALOÏN, $\text{C}^6\text{H}^3\text{Br}^3\text{O}^7$, is formed, together with small quantities of more or less highly brominated products, by the action of bromine-water on barbaloin (p. 63). It crystallises in yellow needles (E. Schmidt, *Arch. Pharm.* [3], viii. 496).

TRIBROMAMIDOBENZENESULPHONIC ACID. See BENZENESULPHONIC ACIDS (p. 233).

TRIBROMAMIDOBENZOIC ACID, $\text{C}^6\text{H}(\text{NH}^2)\text{Br}^3\text{CO}^2\text{H}$ [$\text{CO}^2\text{H} : \text{NH}^2 = 1 : 3$], is formed by the action of bromine on metamidobenzoic acid, and yields a tribromobenzoic acid melting at 186.5° (H. Vollbrecht, *Ber.* x. 1904).

TRIBROMANHYPDOPYRURIL, $\text{C}^8\text{H}^3\text{Br}^3\text{N}^4\text{O}^2$. See PYRORACEMIC UREIDES (p. 1721).

TRIBROMANTHRAQUINONE, $\text{C}^{14}\text{H}^3\text{Br}^3\text{O}^2$. One modification of this compound is obtained by heating anthraquinone with bromine containing iodine to 275° . When purified by boiling it with soda-ley, and crystallising the residue from glacial acetic acid, it forms needles having a faint yellow colour, melting at 186° , and subliming at a higher temperature. It dissolves readily in toluene, nitrobenzene, chloroform, carbon sulphide, and ligroin. Strong sulphuric acid dissolves it without decomposition. Heated with bromine at 320° , it is converted into a tetrabromanthraquinone, which, after purification as above, crystallises in yellow scales melting at 295° – 300° . The tribromo-compound (1 pt.) is converted by heating with sodium hydroxide (2 pts.) at 200° – 210° into purpurin; with potassium hydroxide at a lower temperature into hydroxypurpurin, $\text{C}^{14}\text{H}^6\text{O}^6$ (Diehl, *Ber.* xi. 179, 183).

Another modification of tribromanthraquinone is formed by oxidising pentabromanthracene with chromic acid dissolved in glacial acetic acid. This product melts at 365° , sublimes in broad flat needles, dissolves with moderate facility in the homologues of benzene and in glacial acetic acid, only sparingly in carbon sulphide, chloroform, and benzene, and is nearly insoluble in alcohol and in ether (Hammer-schlag, *Ber.* x. 1212).

TRIBROMETHANE, $\text{C}^2\text{H}^3\text{Br}^3$. The α -modification, CH^3CBr^3 (b. p. 187° – 188°), appears to exist, together with α -dibromethane, CH^3CHBr^2 (b. p. 109° – 110°), by the action of bromine on ethyl bromide (Denzel, *Ber.* xi. 1739).

TRIBROMETHYLENE, C^2HBr^3 . On the formation of the liquid and solid modifications of this compound from acetylene tetrabromide, see ACETYLENE (p. 35). Liquid tribromethylene, agitated with oxygen gas, is converted into dibromacetyl bromide, $\text{C}^2\text{HBr}^2\text{O.Br}$ (Demole, *Compt. rend.* lxxxvi. 542).

Tribromethylene Dibromide, $\text{C}^2\text{HBr}^3\text{Br}^2$, is one of the compounds formed by heating mucobromic acid with bromine and water in sealed tubes, its formation being especially abundant when the two substances act on one another in molecular proportion. It crystallises in long colourless needles melting at 50° – 52° , and is converted by alcoholic potash into tetrabromethylene, C^2Br^4 , melting at 50° (*Liebig's Annalen*, clxv. 297).

TRIBROMETHYL-PHTHALIMIDE. See PHTHALIMIDE (p. 1619).

TRIBROMHYDROCOTARNINE HYDROBROMIDE, $\text{C}^{12}\text{H}^4\text{Br}^3\text{N}^3\text{O}^3\text{HBr}$. See NARCOTINE, OXIDATION-PRODUCTS OF (p. 1382).

TRIBROMOBAPHINITONE, $\text{C}^{26}\text{H}^{23}\text{Br}^3\text{O}^6$. See BAPHINITONE (p. 141).

TRIBROMOBENZENES, $\text{C}^6\text{H}^3\text{Br}^3$. See BENZENES (BROMO-), (pp. 166–169).

TRIBROMOBENZENESULPHONIC ACIDS, $C^6H^2Br^3.SO^3H$. See BENZENESULPHONIC ACIDS (pp. 240-243).

TRIBROMOBENZOIC ACIDS, $C^6H^2Br^3.COOH$. A tribromobenzoic acid, melting at 234° - 235° , was obtained by Reinecke by heating benzoic acid with bromine and water (vi. 310). Another, melting at 186.5° , is produced by the action of nitrous acid and alcohol on the tribromamidobenzoic acid which is obtained by treating metamidobenzoic acid with bromine. This tribromobenzoic acid is sparingly soluble in water and crystallises in needles. Its *barium salt* forms tabular crystals containing $5\frac{1}{2}$ mol. H^2O (H. Vollbrecht, *Ber.* x. 1704).

TRIBROMOBILIRUBIN, $C^{32}H^{33}Br^3N^4O^6$ (Maly). See BILE-PIGMENTS (p. 325).

TRIBROMODIACETANILIDE, $C^8H^2Br^3.N(C^2H^3O)^2$. See ACETAMIDES (p. 5).

TRIBROMODIMETHYLETHYLBENZENE, $C^6Br^3(CH^3)^2(C^2H^5)$. See MESITYLENE, HOMOLOGUES OF (p. 1285).

TRIBROMODINITRODIPHENYLAMINE, $C^{12}H^6Br^3(NO^2)^2N$. See PHENYLAMINES (p. 1550).

TRIBROMODINITROPROPIONIC ACID, $CBBr^3.C(NO^2)^2.COOH$, is produced by the action of strong nitric acid on tribromophloroglucol:

It forms white, scaly, inodorous crystals having a fine silky lustre, insoluble in cold water and in acids, easily soluble in alcohol and ether. When a few drops of water are added to its recently prepared alcoholic solution, it separates in stellate groups of slender needles. When boiled with water it yields oxalic acid and bromopicroin:

By *sodium-amalgam* it is resolved into methylamine, oxalic acid, and hydrocyanic acid:

(R. Benedikt, *Liebigs Annalen*, clxxxiv. 255).

TRIBROMOFLAVOPURPURIN, $C^{14}H^2Br^3O^2(OH)^3$, is formed by adding bromine to a solution of flavopurpurin (p. 111) in glacial acetic acid, and separates in orange-yellow needles melting with decomposition at 284° , sparingly soluble in glacial acetic acid, and dissolving, with yellow-red colour, in soda-ley (Schunck a. Roemer, *Ber.* x. 1225).

TRIBROMOFLUORENE, $C^{13}H^7Br^3$. See FLUORENE (p. 673).

TRIBROMOGLYOXALINE, $C^8HBr^3N^2$. See GLYOXALINE (p. 890).

TRIBROMOGUANAMIDINE, $C^4N^3H^4Br^3O^3$. See GUANAMIDE (p. 900).

TRIBROMOLACTIC ACID, $C^3H^3Br^3O^3$, is formed by prolonged digestion of bromal hydrocyanide, $C^2HBr^3O.HCN$, with dilute hydrochloric acid (Pinner, *Ber.* vii. 1499).

TRIBROMOMETHYL-DIPHENYLAMINE, $C^{13}H^{10}Br^3N$, is formed, together with tetrabromomethyl-diphenylamine and tetrabromodiphenylamine, by the action of bromine on methyl-diphenylamine (p. 1550) dissolved in glacial acetic acid. On treating the resulting crystalline pulp with alcohol, the two brominated methyl-diphenylamines are dissolved out, while tetrabromodiphenylamine remains in the residue. Tribromomethyl-diphenylamine forms colourless transparent needles insoluble in water, easily soluble in alcohol and in benzene. Fuming nitric acid converts it into *tetranitrodibromodiphenylamine*, which crystallises from glacial acetic acid in yellow nacreous laminae or rhombohedral tables, but does not appear to have been obtained pure (R. Gnehm, *Ber.* viii. 1040).

TRIBROMONAPHTHALENE, $C^{10}H^6Br^3$. See NAPHTHALENE-DERIVATIVES (p. 1351).

TRIBROMONITROBENZENESULPHONIC ACIDS, $C^6HBr^3(NO^2)SO^3H$. See BENZENESULPHONIC ACIDS (p. 247).

TRIBROMOPHENANTHRENE, $C^{14}H^7Br^3$ (p. 1514).

TRIBROMOPHENOL, $\text{C}^6\text{H}^3\text{Br}^3\text{O}$, is formed, together with free phenol-disulphonic acid and other products, by the action of bromine in excess on potassium phenol-disulphonate:

(M. v. Schmidt, *Ber.* xi. 852). It is also formed, together with tribromoresorcinol, by the action of pentabromoresorcinol on aniline (Benedikt, *Ber.* xi. 1559). On its reactions, see PHENOLS (p. 1525).

TRIBROMOPHENYL-GLYCOCINE,

is obtained on adding bromine water to an aqueous solution of phenyl-glycoccine (p. 1563) till a permanent coloration is produced, as a white precipitate, insoluble in water, acids, and alkalis, easily soluble in hot alcohol, from which, however, it does not crystallise. From hot glacial acetic acid it crystallises in colourless microscopic needles (Schwebel, *Ber.* xi. 1131).

TRIBROMOPHLOOROGLUCOL, $\text{C}^6\text{H}^3\text{Br}^3\text{O}^3$. On the conversion of this compound into tribromodinitropropionic acid, see p. 1571.

TRIBROMOPROPIONIC ACID, $\text{C}^3\text{H}^3\text{Br}^3\text{O}^2$. An acid of this composition is obtained, together with a large quantity of oxalic acid, by the action of nitric acid in excess on acrolein bromide. It crystallises from boiling benzene, and melts at 93° (Linnemann a. Penl, *Ber.* viii. 1097).

TRIBROMOPYROGALLOL, $\text{C}^6\text{Br}^3(\text{OH})^3$. See PYROGALLOL (p. 1709).

TRIBROMOQUINONE, $\text{C}^6\text{HBr}^3\text{O}^2$, is formed, together with tetrabromoquinone (bromanil) and other brominated derivatives of quinone, by acidulating an alkaline solution of ethylic succinyl-succinate (see ADDENDA) with sulphuric acid, and mixing it with excess of bromine (F. Herrmann, *Ber.* x. 107).

TRIBROMOPYRORACEMIC ACID, $\text{CBr}^3\cdot\text{CO}\cdot\text{CO}^3\text{H}$. See PYRORACEMIC ACID (p. 1718).

TRIBROMORESORCINOL, $\text{C}^6\text{H}^3\text{Br}^3\text{O}^2$, is formed by the action of bromine on an aqueous solution of resorcinoldisulphonic acid, the sulpho-groups being oxidised to sulphuric acid and thereby removed. It crystallises in colourless needles having a silky lustre.

TRIBROMOSTRUTHIN, $\text{C}^{14}\text{H}^{14}\text{Br}^3\text{O}^2$. See OSTRUTHIN (p. 1449).

TRIBROMOTOLUENES, $\text{C}^6\text{H}^2\text{Br}^3\cdot\text{CH}^3$. See TOLUENE (p. 1990).

TRIBROMO-*p*-TOLUENESULPHONIC ACID, $\text{C}^6\text{HBr}^3(\text{CH}^3)(\text{SO}^3\text{H})$. See TOLUENESULPHONIC ACIDS (p. 2012).

TRIBROMOTOLUIDINE, $\text{C}^6\text{HBr}^3(\text{NH}^2)(\text{CH}^3)$. See TOLUENES, BROMAMIDO- (p. 1998).

TRIBROMOXYLENES, $\text{C}^6\text{HBr}^3(\text{CH}^3)^2$. See XYLENE.

TRIBUTYLAMINE (normal), $[\text{CH}^3(\text{CH}^2)^3]^3\text{N}$ (b. p. 211° – 215°). See BUTYLAMINES (vii. 222).

TRIBUTYL(ISO)ARSINE. A red crystalline compound of tri-isobutylarsine with arsenic iodide is formed by heating isobutyl iodide with powdered arsenic at 175° – 180° (Cahours, *Compt. rend.* lxxvii. 1403).

TRIBUTYLENE (ISO-), $\text{C}^{12}\text{H}^{24}$. This hydrocarbon is obtained, together with isodibutylene (p. 1128) by saturating trimethyl-carbinyl iodide with isobutylene, and heating the liquid with calcium oxide at 100° in a sealed tube for three hours. The product, after being freed from lime by digestion with dilute hydrochloric acid, is distilled in a current of steam; and the oily distillate is freed from remaining traces of the iodide by digestion for a few hours with moist silver oxide, then washed, dried, and rectified over an alloy of sodium and potassium. The liquid thus obtained may be separated by fractional distillation into isodibutylene boiling at 102° – 105° , and isotributylene, boiling at 177° – 178° . The same isotributylene is obtained by the action of trimethylcarbinyl iodide on isodibutylene in presence of calcium oxide in sealed tubes at 100° (Julie Lermontoff, *Ber.* xi. 1255).

Tri-isobutylene appears also to be contained in the oily condensation-products formed in the preparation of trimethylcarbinol.

TRIBUTYL(ISO)PHOSPHINE. See PHOSPHINES (vii. 955).

TRIBUTYLSULPHINE-COMPOUNDS. See SULPHINES (p. 1850).

TRICARBALLYLIC ACID,

This acid, originally obtained by the action of potash on allyl tricyanide, $\text{CH}^2(\text{CN})\cdot\text{CH}(\text{CN})\cdot\text{CH}^2(\text{CN})$ (v. 879) is also produced: α . Together with hydroxycrotonic acid, $\text{C}^4\text{H}^4\text{O}^3$, by the action of a boiling slightly alkaline solution of potassium cyanide on dichloroglycide, $\text{C}^3\text{H}^3\text{Cl}^2$. Claus a. Kölver, who discovered this reaction (*Ber.* v. 358; *Liebig's Annalen*, clxx. 131), explain it by supposing that a cyanochloroglycide is first formed and then converted in the slightly alkaline solution, with evolution of ammonia, into chlorocrotonic acid:

This acid then decomposes a further quantity of potassium cyanide, forming hydrogen cyanide, which is added on; at the same time the second chlorine-atom is replaced by cyanogen, and both the cyanogen-groups thus introduced are converted into carboxyl-groups, the final product being tricarballic acid. β . Together with a bibasic acid, by the action of potassium cyanide on ethylic monochlorocrotonate (Claus, *Ber.* ix. 223). γ . Ethylic acetosuccinate is converted by the action of sodium into ethylic acetotricarballic acid, $\text{CH}^2\cdot\text{CO}\cdot\text{C}(\text{CH}^2\cdot\text{COOC}^2\text{H}^3)^2\cdot\text{COOC}^2\text{H}^3$, and this compound saponified by alcoholic potash or baryta-water yields tricarballic acid (G. Miehle, *Liebig's Annalen*, exc. 322). 4. Tricarballic acid appears to be one of the products formed by the action of chlorine on gallic acid (Schreder, *ibid.* clxxvii. 282). δ . Tricarballic acid has been found in a precipitate formed during the evaporation of the juice of very unripe beet; the juice of ripe beet does not yield it (v. Lippmann, *Ber.* xi. 707).

TRICHLORACETAL, $\text{C}^6\text{H}^1\text{Cl}^3\text{O}^2 = \text{C}^2\text{HCl}^3(\text{OC}^2\text{H}^3)^2$, is formed, together with mono- and dichloroacetal, by the action of chlorine at various temperatures on alcohol of 50 to 75 per cent. It is described by Paternò (vi. 4) and by Krey (viii. 1) as crystallising in colourless needles melting at 72° , and boiling with slight decomposition at 230° (Paternò), melting at 83° , and beginning to decompose at 190° (Krey). H. Byasson, on the other hand (*Compt. rend.* lxxxvii. 26), describes it as a mobile liquid having a density of 1.288, and boiling at 197° . This product probably contained mono- and dichloroacetal.

TRICHLORACETAMIDE, $\text{NH}^2\cdot\text{C}^2\text{Cl}^3\text{O}$. This compound, heated with phosphorus pentachloride, yields tetrachlorethylidene-imidochlorophosphenyl, $\text{C}^2\text{Cl}^3\text{ONP}$, which appears to be formed by the following series of reactions:

- (1). $\text{CCl}^3\cdot\text{CO}\cdot\text{NH}^2 + \text{PCl}^3 = \text{CCl}^3\cdot\text{CCl}^2\cdot\text{NH}^2 + \text{POCl}^3$
- (2). $\text{CCl}^3\cdot\text{CCl}^2\cdot\text{NH}^2 + \text{POCl}^3 = \text{CCl}^3\cdot\text{CCl}^2\cdot\text{NH}\cdot\text{POCl}^2 + \text{HCl}$
- (3). $\text{CCl}^3\cdot\text{CCl}^2\cdot\text{NH}\cdot\text{POCl}^2 = \text{CCl}^3\cdot\text{CCl}^2\cdot\text{N}=\text{N}\cdot\text{POCl}^2 + \text{HCl}$

Tetrachlorethylidene-imidochlorophosphenyl distils at 255° – 259° , and solidifies at 70° – 80° to a crystalline mass. Its vapours strongly irritate the eyes and mucous membranes. It is very unstable, and cannot be kept without change; its decomposition yields, amongst other products, trichloroacetonitril (Wallach, *Ber.* viii. 299).

TRICHLORACETANILIDE, or **TRICHLOROPHENYLACETAMIDE**, $\text{C}^6\text{H}^2\text{Cl}^3\cdot\text{NH}\cdot\text{C}^2\text{H}^3\text{O}$, is formed, together with *dichloroacetanilide*, by passing dry chlorine into a solution of 1 pt. acetanilide in 4 pts. acetic acid of 90 per cent. till the weight of the liquid is increased to the amount of 1.05 per cent. It crystallises in needles melting at 204° , dissolves sparingly in ether, carbon sulphide, and ligroin, more readily in alcohol and acetic acid (Beilstein a. Kurbatow, *Ber.* viii. 1655). The metameric compound, *Phenyl-trichloroacetamide*, $\text{C}^6\text{H}^3\cdot\text{NH}\cdot\text{C}^2\text{Cl}^3\text{O}$, which Tommasi a. Meldola obtained by pouring aniline into trichloroacetyl chloride, crystallises in rhomboidal plates, melts at 94° , and is extremely soluble in ether and in carbon sulphide (p. 6).

TRICHLORACETIC ACID, $\text{CCl}^3\cdot\text{COOH}$. See ACETIC ACID (p. 19). *Potassium trichloroacetate*, heated with bromine in closed vessels at 110° – 120° , is converted into potassium bromide, carbon dioxide, and bromotrichloromethane, CCl^3Br . Chlorine acts much less strongly, and only on addition of iodine, producing in the first instance hexachlorethane, C^2Cl^6 (van't Hoff, *Ber.* x. 678).

Ethylic Trichloroacetate is decomposed by potassium cyanide in alcoholic solution, yielding, if water is present, potassium chloride, carbon dioxide, ammonia, and acetic acid; and, if water is absent, carbon dioxide and chloroform (Claus, *Liebig's Annalen*, cxc. 58). A trichlorinated acetic ether, probably $\text{CH}^3\cdot\text{COO}\cdot\text{CHCl}\cdot\text{CHCl}^2$, is formed by

the action of chlorine at 120° in presence of iodine on ethylidene acetochloride, $\text{CH}^3\text{.CH} < \begin{smallmatrix} \text{Cl} \\ \text{OC}^2\text{H}^2\text{O} \end{smallmatrix}$ (Kessel, *Ber.* x. 1994).

Trichloroacetic Anhydride, $(\text{C}^2\text{Cl}^3\text{O})^2\text{O}$, is formed by the action of trichloroacetyl chloride on trichloroacetic acid (Anschütz, *Ber.* x. 325); also by heating trichloroacetic acid for two days with excess of phosphorus trichloride. It is a colourless liquid, which has a faint odour, boils at 222°–224°, rapidly absorbs moisture from the air, and is thereby decomposed (Buckney a. Thomsen, *Ber.* x. 698).

TRICHLORACETONE, $\text{CCl}^3\text{.CO.CH}^3$. This compound is obtained by direct chlorination of acetone (p. 26), and, together with other products, by the action of chlorine on the sodium salt of citraconic acid (p. 814).

TRICHLORACETONIC ACID, $\text{CH}^3 > \begin{smallmatrix} \text{CH}^3 \\ \text{CCl}^3 \end{smallmatrix} \text{COH.COOH}$, formed by the action of strong hydrochloric acid at the heat of the water-bath on trichloroacetone-cyanhydrin (p. 26), is a syrupy liquid which is easily decomposed by alkalis, and does not form definite salts (C. Bischoff, *Ber.* viii. 1329).

TRICHLORACETONITRIL, $\text{CCl}^3\text{.CN}$ (p. 33), is decomposed by boiling with milk of lime and more completely by potash, yielding carbon dioxide and chloroform (Beckurts a. Otto, *Ber.* ix. 1591).

TRICHLORACETOPHENONE-ORTHO-CARBOXYLIC ACID, $\text{COCCl}^3\text{.C}^6\text{H}^4\text{.COOH}$, is formed by the action of chlorine on phthalylacetic acid suspended in glacial acetic acid (p. 1621).

TRICHLORACETYL BROMIDE, $\text{CCl}^3\text{.CO.Br}$ (b. p. 143°). See **ACETYL BROMIDE** (p. 21).

TRICHLORACETYL CARBAMIDE, $\text{NH}^2\text{.CO.NH.C}^2\text{Cl}^3\text{O}$, is formed by heating trichloroacetyl chloride with urea (Tommasi a. Meldola, p. 392), also by heating the trichloroacetate of urea with phosphorus pentachloride (Clermont, *Compt. rend.* lxxviii. 848). According to Tommasi a. Meldola, it crystallises from alcohol in needles melting at 150°; according to Clermont in micaceous laminae, subliming for the most part without decomposition, insoluble in cold, and only slightly soluble in hot water.

TRICHLORACETYL CHLORIDE, $\text{CCl}^3\text{.CO.Cl}$, originally obtained by the action of trichloride or pentachloride of phosphorus on trichloroacetic acid, or of the pentachloride on acetyl chloride (vi. 22; vii. 19), is also formed by the action of chlorine in sunshine on paradichloraldehyde dissolved in carbon tetrachloride (viii. 54); and, according to Friederici (*Ber.* xi. 1970), by passing dry hydrogen chloride over a heated mixture of trichloroacetic acid and phosphorus pentoxide. It boils at 118°. By the action of phosphine (PH^3) it is converted into trichloroacetyl phosphide, $\text{C}^2\text{Cl}^3\text{O.PH}^2$ (Steiner, *Ber.* viii. 1178). With *trichloroacetic acid*, it forms the anhydride, $\text{C}^2\text{Cl}^3\text{O.O.C}^2\text{Cl}^3\text{O}$ (Anschütz, *Ber.* x. 1881).

TRICHLORAL HYDROCYANIDE, $\text{C}^6\text{H}^4\text{Cl}^3\text{NO}^3$ (Cech, *Ber.* ix. 1020). This compound, called by Cech *trichloral cyanide*, is formed on mixing a saturated solution of chloral hydrate with a very small quantity of a concentrated solution of potassium cyanide. Crystalline spangles then separate after some time, and on subsequently adding an excess of water, a bulky white precipitate is formed, consisting of microscopic needles, and containing the elements of 3 mol. chloral and 1 mol. hydrogen cyanide, $3\text{C}^2\text{HCl}^3\text{O} + \text{HCN} = \text{C}^6\text{H}^4\text{Cl}^3\text{NO}^3$. This compound is insoluble in water (though extremely hygroscopic), but dissolves in alcohol and benzene, very easily in ether, and crystallises from the last two solvents in white prisms melting at 123°; from the alcoholic solution it separates in nodules. When heated a few degrees above its melting point, it partly sublimes undecomposed, and when subjected to dry distillation, it yields a sublimate of chloralide, leaving an abundant carbonaceous residue. It is not acted upon by dilute acids in the cold, but when boiled therewith it yields chloral. Heated with soda-lime it gives off ammonia, together with vapours having the odour of 'propane-ethyl.' Heated with *aniline* and potassium cyanide, it gives off hydrogen cyanide, and yields chloral-monoanilide, $\text{CCl}^2(\text{NH.C}^6\text{H}^5)\text{CHO}$.

TRICHLORALOLIN, $\text{C}^{16}\text{H}^{15}\text{Cl}^3\text{O}^2$, is formed, together with products containing larger and smaller proportions of chlorine, by the action of chlorine on barbaloin (E. Schmidt, *Arch. Pharm.* [3], viii. 496).

TRICHLORANGELACTIC ACID. See **TRICHLOROVALEROLACTIC ACID**, under **BUTYRIC CHLORAL** (p. 444).

TRICHLORANILINES, $C^6H^2Cl^3.NH^2$. See pp. 196 and 1549.

TRICHLORANTHRACENE, $C^{14}H^2Cl^3$. When chlorine is passed into a solution of anthracene in chloroform till the viscid mass at first formed becomes thin and transparent, the chloroform then distilled off, and the residual crystalline mass washed with ether and recrystallised from chloroform, dichloranthracene dichloride, $C^{14}H^2Cl^2.Cl^2$, is obtained in transparent colourless prisms melting at 149° – 150° ; and on heating this compound to 170° , trichloranthracene is obtained, together with a small quantity of dichloranthracene. The same decomposition takes place gradually when the dichloride is kept in closed vessels. The trichloranthracene thus produced crystallises from alcohol in long yellow needles melting at 162° – 163° , and yielding an alcoholic solution which exhibits a blue fluorescence; it is but slowly attacked by nitric acid. It is perhaps identical with that which Graebe & Liebermann obtained (vii. 90) by the action of phosphorus pentachloride on anthraquinone (F. Schwarzer, *Ber.* x. 376).

TRICHLORANTHRAQUINONE, $C^{14}H^2Cl^3O^2$, is formed by heating anthraquinone with antimony pentachloride in a sealed tube at 180° , and purified by boiling the crude product with hydrochloric acid and crystallising the residue from a mixture of alcohol and benzene. It forms yellow needles, which sublime with decomposition, melt between 284° and 290° , and dissolve in glacial acetic acid, chloroform, and toluene, sparingly also in benzene (Diehl, *Ber.* xi. 179).

TRICHLORETHYLIDENIC ETHERS. See CHLORALIDE (p. 445).

TRICHLORHYDRIN, $C^3H^3Cl^3$. See TRICHLOROPROPANES.

TRICHLORHYDROXYFULMPLATINUM, $Pt^4O^{12}N^2H^2Cl^3(OH)$. See PLATINUM-COMPOUNDS (p. 1651).

TRICHLOROBENZENES, $C^6H^3Cl^3$. See BENZENE-DERIVATIVES (p. 173).

TRICHLOROBILIRUBIN, $C^9H^6Cl^3NO^2$ (Thudichum). See BILE-PIGMENTS (p. 325).

TRICHLOROBUTYLIDENIMIDE, $C^4H^3Cl^3NH$, is formed by heating acetyl-butyl-chloral hydrocyanide, $C^4H^3Cl^3(OC^2H^3O)CN$, for an hour with excess of dry ammonium acetate, and separates gradually on addition of water. It dissolves readily in alcohol, ether, hot benzene, and hot water, less readily in glacial acetic acid, melts at 164° – 165° , and decomposes at 192° , also on exposure to sunshine (Pinner & Klein, *Ber.* xi. 1488).

TRICHLOROCHRYSENE, $C^{18}H^9Cl^3$. See CHRYSENE (p. 464).

TRICHLOROLACTIC ACID, $CCl^3.CHOH.CO^2H$. The ethylic ether of this acid is converted by the action of zinc and hydrochloric acid into ethylic monochloracrylate, $CHCl=CH.CO^2C^2H^3$ (Pinner, p. 45). According to W. Rudneff, on the other hand (*Ber.* viii. 434), the chief product of the reduction of ethylic trichlorolactate is ethylic dichlorolactate.

On the Action of Trichlorolactic Acid on Chloralide, see p. 445.

TRICHLOROLACTIC BROMALIDE, $CCl^3.CH<\overset{O}{\underset{COO}{\parallel}}>CH.CBr^3$. On the crystalline form of this compound, see Wallach (*Liebigs Annalen*, xciii. 1; *Jahresb. f. Chem.* 1878, 690).

TRICHLOROMETHYLSULPHONIC CHLORIDE, $CCl^3.SO^2Cl$, which Kolbe obtained by the action of moist chlorine on carbon disulphide (v. 559), is also produced by the action of water on the chloride, $SO^2Cl.CHCl.CO^2Cl$, resulting from the action of phosphorus pentachloride on sulphacetic acid. On treating this chloride with water, the greater part dissolves, and trichloromethylsulphonic chloride remains as a white substance melting at 137° , and agreeing in other respects with the product obtained by Kolbe (R. Siemens, *Ber.* vi. 659).

TRICHLORONAPHTHALENES, $C^{10}H^3Cl^3$. See NAPHTHALENE (p. 1350).

TRICHLOROPHENOL, $C^6OH.Cl.H.Cl.H.Cl$. See PHENOL (p. 1525).

TRICHLORONITROBENZENES, $C^6H^2(NO^2)Cl^3$. The modification $C^6.NO^2.Cl.Cl.H.H.Cl$ is prepared as follows:—The acetyl-derivative of paradichloroaniline, $C^6.NH^2.Cl.H.H.Cl.H$, yields by nitration two dichloronitracetanilides, of which the one least soluble in benzene and melting at 204° – 205° may be transformed into a dichloronitraniline, $C^6.NH^2.NO^2.Cl.H.H.Cl$, convertible by Griess's reaction into the trichloronitrobenzene, $C^6.Cl.NO^2.Cl.H.H.Cl$, which is identical with that above formulated. This trichloronitrobenzene crystallises from ligroin in colourless needles melting at 88° – 89° , and is converted by reduction and replacement of the amido-

3 TRICHLOROPHENOMALIC ACID—TRICODEINE.

p by chlorine into consecutive tetrachlorobenzene (p. 174), (Beilstein a. Kurbatow, *ig's Annalen*, xcii. 228).

The trichloronitrobenzene, $C^6H^3Cl^3H^2NO^2$, obtained from *symmetrical* tri-benzene, is converted by heating for several days with alcoholic ammonia at 2° into *chloronitro-m-phenylenediamine*, $C^6H^3NO^2NH^2.H.Cl.H.NH^2$, which when purified by crystallisation from carbon sulphide or ligroin, forms red needles melting at 2° – 194° , easily soluble in alcohol, less soluble in acetic acid of 50 per cent. or in benzene, very sparingly soluble in ligroin (Beilstein a. Kurbatow).

The trichloronitrobenzene melting at 56° , which is formed by nitration of *convective* trichlorobenzene (p. 173), is converted by heating with alcoholic ammonia at 1° into a dinitraniline, which melts at 162° – 163° , and may be converted by nitrous acid into ortho-dichloronitrobenzene (p. 187), (Beilstein a. Kurbatow).

TRICHLOROPHENOMALIC ACID. The substance so named by Carius (917), obtained by the action of chlorous acid on benzene, and supposed to have the composition $(C^6H^3Cl^3O^2)$, has been shown by Krafft (*Ber.* x. 797) to be identical with chloroquinol.

TRICHLORPHENYL-GUANIDINE, $CH^2(C^6H^3Cl^3)^3N^3$. See GUANIDINE (907).

TRICHLOROPHTHALIC ACID, $C^6HCl^3(COOH)^2$, is formed, together with other compound, probably a quinone, by the action of strong nitric acid on β -pentachloronaphthalene. It is a yellowish-white mass, converted by heat into an anhydride which crystallises in long needles melting at 157° (Atterberg a. Widman, *Ber.* 1841).

TRICHLOROPROPANES, $C^3H^3Cl^3$. Three of these compounds are known, viz.:

	B. p.	Sp. gr.
-Trichloropropane or Trichlorhydrin, $CH^2Cl.CHCl.CH^2Cl$	155°	1.41 at 0°
-Trichloropropane, $CH^3.CHCl.CHCl^2$	140°	1.402 at 4°
-Trichloropropane, $CH^3.CCl^2.CH^2Cl$	123°	1.350 at 0°

respecting the first, see i. 894; vi. 433; vii. 319. According to Belohoubek (*Ber.* x. 924), it is formed, together with the γ -modification and other products, by the action of chlorine on propylene (from allyl iodide, glacial acetic acid, and zinc), and may be separated by fractional distillation. It is decomposed by aluminium iodide, with formation of allyl iodide, aluminium chloride, and free iodine (Gustavson, *Ber.* ix. 1607).

β -Trichloropropane is formed by the action of chlorine on propylene chloride in sunshine; also, together with trichlorhydrin and a trace of a tetrachloride, by heating propylene chloride (from allyl iodide) with dry iodine chloride in small portions at 160° , and may be separated by treating the product with potash-ley and with sodium sulphate, washing it with water, drying over calcium chloride, and fractional distillation (Friedel a. Silva, *Compt. rend.* lxxiv. 805).

γ -Trichloropropane, or Monochloromethylchloracetol, is formed by the action of chlorine in sunshine on methylchloracetol, $CH^3.CCl^2.CH^3$ (vii. 1018), also by treating the same compound with iodine chloride. When heated with alcoholic potash at 100° , it yields, together with products which reduce ammoniacal silver solution, an ether which gives a white precipitate with silver solution. When heated with water in sealed tubes, it dissolves more readily than trichlorhydrin, leaving a small quantity of black liquid. The water contained, not glycerol, but a non-volatile body which resinised when the water was evaporated by heat, reduced ammoniacal silver solution, and remained as a yellow amorphous mass when its solution was evaporated in a vacuum. Its analysis gave numbers leading to the formula $CH^3.CO.CHO$. By oxidation with nitric acid it yielded a body having an odour like that of pyracemic acid. The black residue above mentioned yielded on fractional distillation two dichloropropylenes boiling at 75° and 94° (Friedel a. Silva, *loc. cit.*)

TRICHLORORESORCINOL, $C^6HCl^3(OH)^2$. See RESORCINOL (p. 1749).

TRICHLOROTOLUENES, $C^7H^3Cl^3$. See TOLUENE (p. 1993).

TRICHLOROTOLUQUINOL, $C^7H^3Cl^3O^2$, and **TRICHLOROTOLUQUINONE**, $C^7H^3Cl^3O^2$. See TOLU-QUINOL and -QUINONE (p. 2029).

TRICHLOROVALEROLACTAMIDE, $C^4H^5Cl^3(OH)CONH^2$. See VALERIC ACIDS.

TRICODEINE, $C^{108}H^{126}N^6O^{18}$. This polymeride of codeine is formed by heating codeine with a strong solution of zinc chloride for a short time and at a comparatively

low temperature; by longer heating at higher temperatures a mixture of tricodeine and tetracodeine, $C^{14}H^{16}N^2O^2$, is obtained (Wright, *Chem. Soc. J.* xxvii. 107). See further, vii. 373–375.

TRIDYMITE. On the occurrence of tridymite in volcanic rocks, see H. Möhl (*Jahrb. f. Min.* 1873, 453; *Jahresb. f. Chem.* 1873, 1150); in the lava of Santorin, Fouqué (*Compt. rend.* lxxxii. 1141; *Jahresb. f. Chem.* 1876, 1291). On twin-formations of tridymite, G. vom Rath (*Pogg. Ann.* clii. 1; *Jahresb. f. Chem.* 1874, 1242).

TRIETHYLAMIDACETOCHLORIDE, $C^6H^5ClNO^2 = \begin{array}{c} (C^2H^5)^3N-Cl \\ | \\ CH^2.COOH \end{array}$

is produced by the action of triethylamine on ethyl monochloracetate, and may be separated from triethylamine hydrochloride formed at the same time by boiling with baryta-water. It is not decomposed by strong bases, even at a rather high temperature. When treated with silver oxide it is converted into triethylglycocine (Brühl, *Ber.* viii. 1406).

TRIETHYLAMINE, $(C^2H^5)^3N$. On the formation of this base from dichlor-ethylamine, and its reactions with methylene iodide and ethyl chloropropionate, see ETYLAMINES (p. 748). By oxidation with permanganate it yields carbonic and acetic acids (Wallach a. Claisen, *Ber.* viii. 1237).

TRIETHYLAZONIUM IODIDE, $(C^2H^5)^3N^2H^2.C^2H^5I$ (p. 1061).

TRIETHYLBENZENE, $C^6H^5(C^2H^5)^3$. See MESITYLENE, HOMOLOGUES OF (p. 1285).

TRIETHYLBENZYLAMMONIUM IODIDE, $(C^2H^5)^3N(C^2H^7)I$. See BENZYLAMINES, under TOLUENES (AMIDO-), (p. 2001).

TRIETHYL-DICARBOPYRROLAMIDE, $C^{12}H^{19}N^2O^2$, formed, together with other products, by dry distillation of ethylamine mucate, is insoluble in water and melts at 229° – 230° . See PYRROLINE (p. 1728).

TRIETHYLENE-BORIC ETHER, $B(OC^2H^4OH)^3$. See TRIHYDROXYETHYL BORATE (*infra*).

TRIETHYLENE-TRITOLYLTRIAMINE, $N^3(C^2H^4)^3(C^6H^4.CH^3)^3$, is formed, together with ethylene-ditolyldiamine, by the action of ethylene bromide on toluidine at 150° . The two bases may be separated by means of alcohol, in which the former is very sparingly, the latter freely soluble. The triethylene-base crystallises in very beautiful needles melting at 186° ; its hydrochloride forms needles melting at 189° . *Ethylene-ditolyldiamine*, $N^2(C^2H^4)(C^6H^4.CH^3)^2H^2$, is best purified by separation from its salts. It forms crystals melting at 97.5° . Its hydrochloride is very soluble in water, and crystallises in long white needles (Gretillat, *Monit. scient.* [3], iii. 383).

TRIETHYL-GLYCOCINE, $\begin{array}{c} (C^2H^5)^3N . CH^2 \\ | \quad | \\ O - CO \end{array}$, formed by the action of silver

oxide on triethylamidacetoehloride (*supra*), is a liquid which begins to boil at 210° , and is partly resolved by distillation into triethylamine and carbonaceous products (Brühl, *Ber.* viii. 479).

TRIETHYL-METHYSTIBINE, $Sb(C^2H^5)^3(CH^3)$. The hydroxide of this radicle (i. 347), which, according to Friedländer, is optically active, has been shown by Le Bel (*Bull. Soc. Chim.* [2], xxvii. 444) not to possess this property when pure.

TRIETHYLNAPHTHYLPHOSPHONIUM IODIDE, $P(C^{10}H^7)(C^2H^5)^3I$, formed by the combination of diethylnaphthylphosphine with ethyl iodide, crystallises from water in colourless laminae melting at 209° .

TRIETHYLPHENYLARSONIUM IODIDE, $As(C^2H^5)^3(C^6H^5)I$. See PHENYL-ARSENIC COMPOUNDS (p. 1554).

TRIETHYLPEENYLPHOSPHONIUM IODIDE, $P(C^2H^5)^3(C^6H^5)I$. See PHOSPHINES (p. 1580).

TRIETHYLPHOSPHINE OXIDE, $P(C^2H^5)^3O$. In connection with the method of preparing this compound given by Carius and by Crafts a. Silva (vii. 953), F. A. Emmerton (*Amer. Chem.* 1873, iv. 9) observes that when 1 mol. phosphorus triiodide is treated with 3 mol. ethyl iodide, free iodine is given off, and a body is formed which, after treatment with solid potash, yields on distillation triethylphosphine oxide.

TRIETHYLSELENONIUM COMPOUNDS, $(C^2H^5)^3SeI$, &c. See SELENIUM-COMPOUNDS, ORGANIC (p. 1788).

TRIETHYLSILICOL, $(C^2H^5)_3SiOH$. See SILICON-ETHYL (p. 1794).

TRIETHYLSULPHINE-COMPOUNDS. See SULPHINES (p. 1850).

TRIETHYLTELLURIUM-COMPOUNDS. See TELLURIUM-COMPOUNDS, ORGANIC (p. 1900).

TRIHYDROXYETHYL BORATE, $B(OC^2H^4OH)^3$. *Triethylene-monoboric Ether*.—This compound is formed by treating ethylene alcohol with an excess, first of gaseous and then of liquid boron chloride:

The product crystallised from chloroform is a solid yellowish mass consisting of microcrystalline laminae, nearly insoluble in ether, melting at about 161.7° , and decomposing in moist air (C. Counciler, *Ber.* xi. 1106).

TRI-IODOMETHYL-ROSANILINE. See TRIMETHYL-ROSANILINE (p. 2053).

TRI-IODORESORCINOL, $C^6H^3I^3O^2$. See RESORCINOL (p. 1749).

TRI-ISOBUTYLENE, $C^{12}H^{24}$, appears to be contained in the oily condensation-products formed in the preparation of trimethylcarbinol by treating isobutylene with a mixture of 3 pts. sulphuric acid and 1 pt. water (Gorainow a. Butlerow, *Liebigs Annalen*, clxix. 146).

TRIMELLITIC ACID, $C^6H^3(CO^2H)^3$ [1 : 2 : 4]. See MELLITIC ACID (p. 1274). This acid is formed, together with isophthalic acid, by oxidising colophony with dilute nitric acid. 100 g. pulverised colophony and 2 litres of nitric acid (1 vol. commercial acid to 2 vol. water) are introduced into a retort with its beak directed upwards, and the liquid is heated to boiling, whereupon the colophony melts, and is quickly attacked, with copious evolution of red vapours, and converted into an orange-yellow viscid mass. After the boiling has been continued for six or eight hours, fresh resin and strong nitric acid are added alternately, till about 1 kg. resin has been introduced, the contents of the retort being kept in constant ebullition; this process takes about a fortnight. The resulting wine-yellow liquid, which on addition of water should merely show turbidity, and not yield any lumpy precipitate, is then distilled off till the remaining liquid begins to froth; and this liquid, while still hot, is poured into a tenfold volume of cold water, decanted after twenty-four hours from the varnish-like resin which separates, and evaporated to a syrupy consistence. The whole then solidifies after a while to a thick crystalline pulp, which may be freed from the syrupy mother-liquor by means of an aspirator and porous earthenware plates, and afterwards boiled with water. The extract on cooling deposits isophthalic acid in slender needles, and on further concentration, first a little more of the same acid and then trimellitic acid, which may be purified by solution in alcohol and crystallisation from water.

Trimellitic acid thus obtained (about 30 g. from 500 g. colophony) melts at 218° ; its anhydride, obtained by heating it to fusion, melts at 157° . When evaporated down with milk of lime and then heated, it yields benzene. Its air-dried barium salt contains $(C^6H^3O^6)^2Ba^2 + 4H^2O$ (comp. vi. 813), and gives off $3H^2O$ at 160° . The silver salt, $C^6H^3O^6Ag^3$ (dried at 120°), is a white precipitate, not much altered by exposure to light, soluble in a large quantity of water.

The syrupy mother-liquor of the trimellitic acid did not yield any other crystallised body, but on further treatment with nitric acid it gave a smaller quantity of a crude crystallisation containing a small proportion of trimellitic acid, but consisting mainly of terebic acid (J. Schreder, *Liebigs Annalen*, clxxii. 93).

TRIMESIC ACID, $C^6H^3(CO^2H)^3$ [1 : 3 : 5]. The symmetrical disposition of the carboxyl-groups in this acid is shown by its formation by oxidation of mesitylenic acid (vi. 811; viii. 1286); and as it is also produced from the phenol-tricarboxylic acid, $C^6H^2(OH)(CO^2H)^3$, obtained by heating disodic salicylate in a stream of carbon dioxide, by converting this tribasic acid into the chlorinated acid, $C^6H^2Cl(CO^2H)^3$, and reducing the latter with zinc and a dilute acid, it follows that this phenol-tricarboxylic acid must have the constitution of hydroxytrimesic acid, $[OH : CO^2H : CO^2H : CO^2H = 1 : 2 : 4 : 6]$. (See p. 1535.)

Trimesic acid is also formed by oxidation of triethylbenzene with chromic acid (p. 1286), and in very small quantity by fusion of sulphometabromobenzoic acid with sodium formate (p. 295).

TRIMETAPHOSPHORIC ACID, $P^3O^6H^3$, probably = $\begin{matrix} HO & & PO.O \\ & \diagdown & / \\ & O & \\ & / & \diagdown \\ HO & & PO.O \end{matrix} PO.OH$ (iv.

539). Several salts of this acid have been prepared and analysed by C. G. Lindbom (*Ber.* viii. 122). The sodium salt was prepared by heating ordinary sodium-ammonium phosphate in a platinum dish over a gas-lamp, the heat being gradually raised till the

pasty mass became crystalline like sugar, the whole then pulverised and again strongly heated, with stirring, but so as carefully to avoid fusion, which would result in the formation of the insoluble hexphosphate. In this manner, 95 per cent. of the sodium-ammonium phosphate is obtained as sodium trimetaphosphate. The following are the formulæ of the salts examined :

Double Salts :

The weaker bases do not appear to form trimetaphosphates of definite composition. With mercurous nitrate, a basic salt was obtained having the composition $5\text{Hg}^2\text{O} \cdot 3\text{P}^3\text{O}^9$.

TRIMETHOXY-TRIHYDROXYDIPHENYL, or **TRIMETHYLHEX-HYDROXYDIPHENYL**, $\text{C}^{12}\text{H}^{14}\text{O}^6 = \text{C}^{12}\text{H}^4(\text{OCH}^3)^3(\text{OH})^3$. This is the brown substance which O. Fischer obtained by the action of sulphuric acid on cœrulignone (p. 549). It differs from hydrocœrulignone, $\text{C}^{12}\text{H}^4(\text{OCH}^3)^3(\text{OH})^2$, by CH^2 . It yields a triacetyl-derivative having the composition $\text{C}^{12}\text{H}^4(\text{OCH}^3)(\text{O} \cdot \text{C}^2\text{H}^3\text{O})^3$ (O. Fischer, *Ber.* viii. 158).

TRIMETHYLACETIC ACID, $(\text{CH}^3)^3\text{C} \cdot \text{CO}^2\text{H}$. *Pivalic acid*. See **PENTOIC ACIDS** (p. 1501).

TRIMETHYLACETONITRIL, $(\text{CH}^3)^3\text{C} \cdot \text{CN}$. Syn. with Tertiary Butyl Cyanide (p. 360).

TRIMETHYLAMINE, $(\text{CH}^3)^3\text{N}$. This base occurs, together with methylamine, in *Mercurialis annua* (E. Schmidt, *Ber.* x. 2226). According to Selmi (*Gazz. chim. ital.* 1876, 468), it is obtained in considerable quantity by the distillation of putrid brain. (On its industrial preparation from the spent wash of the stills in which the molasses of beet-root is distilled for the production of alcohol, and its conversion into methyl chloride, see pp. 1305, 1306).

Reactions.—1. By oxidation with *potassium permanganate*, trimethylamine yields carbonic and oxalic acids (Wallach a. Claisen, *Ber.* viii. 1237).

2. Trimethylamine heated for twelve hours in a sealed tube on the water-bath with *monochlorhydrin*, is converted into trimethyl-glyceramine (Hanriot, *Compt. rend.* lxxxvi. 1335).

3. Trimethylamine passed in a stream of hydrogen through a red-hot tube yields ammonia, cyanogen, hydrocarbons, hexmethylenamine, $\text{N}[\text{N}(\text{CH}^2)^2]^3$ (iii. 151; vi. 829), which separates from the distillate in crystalline form, and methylene-methylamine, $\text{C}^2\text{H}^3\text{N} = \text{CH}^2 \cdot \text{N} = \text{CH}^2$. This last compound is resolved by heating with dilute hydrochloric acid into methyl aldehyde and methylamine, $\text{CH}^3 \cdot \text{N} = \text{CH}^2 + \text{H}^2\text{O} = \text{CH}^2\text{O} + \text{CH}^3\text{NH}^2$. It appears, however, from its vapour-density to have the molecular formula $(\text{C}^2\text{H}^3\text{N})^2$ (J. Romeny, *Ber.* xi. 835).

4. When trimethylamine is added to a solution of *aldehyde* in anhydrous ether, water is separated, and condensation-products of aldehyde are formed (N. Lubawin, *Ber.* viii. 1684).

5. With *ethyllic α-chloropropionate*, trimethylamine forms α-propio-betaine,

A compound of trimethylamine with *carbon disulphide*, $(\text{CH}^3)^3\text{N} \cdot \text{CS}^2$, is formed by passing trimethylamine-vapour through a mixture of equal parts of carbon disulphide and alcohol. It crystallises in white-needles melting at 125° , moderately soluble in chloroform and dilute alcohol, nearly insoluble in absolute alcohol, carbon sulphide, ether, and benzene, and producing a milky turbidity with water. It splits up into its components even at ordinary temperatures, but nevertheless unites with acids (employed in the dilute state) and with salts. With hydrochloric acid it forms the compounds $(\text{CH}^3)^3\text{NCS}^2 \cdot \text{HCl}$ and $2(\text{CH}^3)^3\text{NCS}^2 \cdot 3\text{HCl}$, and analogous compounds with nitric acid and with sulphuric acid. With phosphoric acid it forms the compound $2(\text{CH}^3)^3\text{NCS}^2 \cdot \text{H}^2\text{PO}^4$ (A. Bleunard, *Compt. rend.* lxxxvii. 1040).

TRIMETHYLANISBETAINÉ, $C^3H^3N(CH^3)^3O^3$, and **TRIMETHYLBENZBETAINÉ**, $C^7H^4N(CH^3)^3O^2$; better called *Anisbetaine* and *Benzbetaine*. See BETAINES (vii. 187).

TRIMETHYLBENZENE, $C^6H^3(CH^3)^3$. See MESITYLENE and PSEUDOCUMENE (pp. 1282–1285).

TRIMETHYL-BUTYLACTIC (AMIDO-), or **AMIDOTRIMETHYL-HYDROXYBUTYRIC ACID**, $C^7H^{12}NO^3 = CH^3C(OH)(COOH).CH^2.C(CH^3)^2.NH^2$ (W. Heintz, *Liebig's Annalen*, xcii. 329). This acid is formed by boiling amido-trimethyl-butylactide, $C^7H^{12}NO^2$ (*infra*) with baryta-water, a considerable quantity of the lactide, however, remaining unaltered. On mixing the resulting solution with cupric sulphate, the copper salt of amidotrimethylbutylactic acid is obtained, and this salt decomposed by hydrogen sulphate yields the acid, which is moderately soluble in water, nearly insoluble in alcohol and ether, and when slowly separated from the aqueous solution, crystallises in monoclinic prisms. When heated, it is resolved into water and the lactide. Its silver salt is a stiff gummy mass, the aqueous solution of which is not precipitated by alcohol. The *normal sulphate of amidotrimethylbutylactic acid*, obtained by dissolving 16 pts. of the amido-acid in water containing 10 pts. of hydrogen sulphate, forms concentric groups of prismatic crystals. The *hydrochloride*, $C^7H^{12}NO^3.HCl$, obtained by dissolving the amido-acid in hydrochloric acid, forms microscopic needles or square plates. The corresponding *nitrate* also forms microscopic crystals which are either flat needles, laminæ, or six-sided tablets.

Liebig's Annalen, clxxxix. 231; xcii. 339). To prepare this compound, hydrochloride of diacetonamine (p. 28) is heated with aqueous hydrocyanic acid at 120° for ten hours; the brown product mixed with fuming hydrochloric acid, which throws down sal-ammoniac; the solution is boiled for six hours in a reflux apparatus and then evaporated; the residue is exhausted with alcohol, the same process being repeated several times upon the extract; and the alcoholic solution is finally dechlorinated with silver sulphate, freed from silver and sulphuric acid by baryta-water, and evaporated down. Amidotrimethylbutylactide thus obtained forms shining prismatic crystals, neutral to litmus, melting above 180° , easily soluble in water and hot alcohol, nearly insoluble in ether, and indifferent to cupric hydroxide and platinum chloride. When heated with hydrochloric acid, it is decomposed with formation of basic products. Nitrous acid converts it into the corresponding alcohol, or *trimethyl-*

crystals easily soluble in water, alcohol, and ether, and undergoes alteration at 100° , becoming less soluble, and yielding a solution which deposits only small colourless crystalline granules. By boiling with barium hydrate, it is converted into an acid which Heintz regards as *trimethyldihydroxybutyric acid*.

The action of hydrocyanic acid on diacetonamine hydrochloride likewise gives rise to three other bodies, viz. *amidobutyric acid*, $C^4H^8NO^2$; *amidotrimethylhydroxybutyronitril*, or *nitridodiacetonamine*, $C^7H^{14}N^2O$, and the isomeric base, *amidotrimethylhydroxypropylcarbilamine* or *carbyldiacetonamine*.

TRIMETHYL-CARBINOL, $(CH^3)^3C.OH$. *Tertiary Butyl Alcohol*.—According to Pawlow (*Liebig's Annalen*, clxxxviii. 118), this compound is best prepared by the action of 1 mol. acetyl chloride on $1\frac{1}{2}$ mol. zinc-methyl, the yield amounting to 79.6 per cent. of the calculated quantity. When heated with dehydrated oxalic acid, it gives up water and yields butylene (Cahours a. Demarçay, *Compt. rend.* lxxxvi. 991).

TRIMETHYL-CARBINYL IODIDE, $(CH^3)^3CI$. On the reaction of this compound with isobutylene in presence of calcium oxide, see TRIBUTYLENE (Iso-) (p. 2044).

TRIMETHYL-CARBINYLAMINE, $(CH^3)^3C.NH^2$, is formed, together with isobutylamine, by heating isobutyl iodide with silver cyanate (R. Brauner, *Liebig's Annalen*, xcii. 65).

TRIMETHYLENE BROMIDE, $CH^2Br.CH^2.CH^2Br$. *Normal Propylene Bromide*.—Julie Lermontoff prepares this compound by saturating allyl bromide at -10° to -15° with dry hydrogen bromide, then heating it for twenty-four hours to 165° – 170° , and repeating the treatment (*Ber.* ix. 1441). (*Comp.* p. 1672).

TRIMETHYLETHYLAMMONIUM CHLORIDE and **HYDROXIDE** are decomposed by distillation in the manner represented by the following equations:

(Lossen, *Liebig's Annalen*, clxxxi. 364).

TRIMETHYL-GLYCERAMINE is formed by heating trimethylamine with monochlorhydrin on the water-bath for twelve hours. Its *platinochloride*, $[\text{C}^2\text{H}^5\text{O}(\text{CH}^3)^3\text{NCl}]^2\text{PtCl}_4$, forms orange-coloured, apparently quadratic tables, which give off hydrogen chloride in a vacuum, and are easily soluble in water, but insoluble in alcohol (Hanriot, *Compt. rend.* lxxxvi. 1335).

TRIMETHYL-MELAMINE, $\text{C}^3\text{H}^3(\text{CH}^3)\text{N}^6$, is formed on heating methylcyanamide for a short time in aqueous or alcoholic solution, also when the same compound is exposed to the air, especially to moist air. This reaction explains the production of trimethyl-melamine by desulphuration of methyl-thiocarbamide, as observed by Hoffmann (p. 1271), (E. Baumann, *Ber.* vi. 1371).

TRIMETHYLNAPHTHYLAMMONIUM IODIDE, $\text{C}^{10}\text{H}^7\text{N}(\text{CH}^3)^3\text{I}$. See NAPHTHALENES (AMIDO-), (p. 1370). The corresponding *hydroxide*, obtained by agitating the aqueous solution of the iodide with moist silver oxide, is deliquescent, strongly basic, and forms well-crystallised salts (Landshoff, *J. pr. Chem.* [2], xvii. 286).

TRIMETHYLPHENYLAMMONIUM IODIDE, $(\text{CH}^3)^3(\text{C}^6\text{H}^5)\text{NI}$. This compound, exposed to the action of a stream of dry hydrogen chloride, is converted into dimethylaniline and methyl iodide:

(N. F. Merrill, *J. pr. Chem.* [2], xvii. 286).

TRIMETHYLPHOSPHINE HYDRIDIODE, $\text{P}(\text{CH}^3)^3\text{HI}$. On the formation of this compound from PH^3I and CS^2 , see PHOSPHINES (p. 1579).

TRIMETHYL- α -PROPIOBETAINE, $\text{C}^6\text{H}^{13}\text{NO}^2$; better called *α -Propiobetaine* (pp. 187, 324).

TRIMETHYL-ROSANILINE, $\text{C}^{23}\text{H}^{25}\text{N}^3 = \text{C}^{20}\text{H}^{16}(\text{CH}^3)^3\text{N}^3$ (A. W. Hofmann, *Ber.* vi. 352). The methochloride of this base is obtained by oxidising dimethylaniline with potassium chlorate and cupric sulphate, or with cupric nitrate and common salt, the ingredients being worked up with sand to a homogeneous mass, and heated, in the first case, in a water-bath for several days, in the second for forty-eight hours at a temperature not exceeding 50° . The free base, the meth-hydroxide of trimethyl-rosaniline, $\text{C}^{20}\text{H}^{16}(\text{CH}^3)^3\text{N}^3\text{CH}^3\text{OH}$, separated from the crude product by means of caustic soda-solution, is a blue crystalline precipitate which dries up to a red-brown powder, insoluble in water and in ether, but dissolving with fine violet colour in alcohol. It is also readily dissolved by dilute acids, forming salts which are decomposed by ammonia. The *methiodide* obtained from the meth-hydroxide by solution in alcohol and addition of aqueous hydriodic acid, consists of microscopic needles, sparingly soluble in water and in alcohol. The *methylpicrate* forms fine bronze-coloured needles easily soluble in boiling, less easily in cold alcohol. The *leuco-compound*, analogous to the meth-hydroxide of trimethyl-rosaniline, obtained by the action of alcoholic ammonium sulphide on the violet base at 100° under pressure, forms large flattened needles, which acquire a violet tinge in drying, dissolve but sparingly in water, either cold or hot, readily in alcohol and in ether. The results of its analysis agree approximately with either of the formulæ $\text{C}^{20}\text{H}^{16}(\text{CH}^3)^3\text{N}^3\text{CH}^3\text{H}$ or $\text{C}^{20}\text{H}^{16}(\text{CH}^3)^3\text{N}^3\text{H}^2$.

To decide the question whether the violet dye obtained as above from dimethylaniline is identical or isomeric with the methyl-violet prepared on the manufacturing scale from rosaniline, an attempt was made to convert the former into the diiodomethylate. If the two bodies are identical, the diiodomethylate thus produced will be the well-known iodine-green (vi. 162), and convertible by further introduction of methyl iodide into the splendidly crystallised violet tri-iodomethylate. Experiment showed that the bodies in question are identical (Hofmann).

Trimethyl-rosaniline may also be prepared by oxidising a mixture of methylaniline and dimethylaniline with cupric chloride. Rosaniline and trimethylrosaniline

dimethylate act on one another in alcoholic solution at ordinary temperatures, according to the following equations :

and

The colour of the liquid passes from blue through red into violet-red, the last colour changing on addition of hydrochloric acid to leaf-brown (Girard a. Willm, *Bull. Soc. Chim.* [2], xxv. 100).

Triodomethylrosaniline is prepared by heating a mixture of 10 pts. rosaniline-base, 12 methyl iodide, and 20 methyl alcohol—all as pure as possible—in an enamelled autoclave for three or four hours at a temperature not exceeding 115°. The excess of methyl iodide is then distilled off, and the crystals are purified by recrystallisation (Hofmann, *loc. cit.*)

TRIMETHYLSELENONIUM IODIDE, $(\text{CH}^3)^3\text{SeI}$, is formed when dibenzyl-diselenide (p. 316) is left for two days in a closed vessel with methyl iodide; and on decanting the aqueous solution of the product from a black residue, evaporating slightly, digesting the liquid with silver chloride, and treating the filtrate with platinic chlorides, *trimethylselenonium platinochloride*, $[(\text{CH}^3)^3\text{SeCl}]^2\text{PtCl}_4$, is formed, which crystallises from water in dark red octohedrons (C. L. Jackson, *Ber.* vii. 1277).

TRIMETHYLSULPHINE, $(\text{CH}^3)^3\text{S}$. See SULPHINES (p. 1849).

TRIMETHYL-TOLYLAMMONIUM IODIDE, $(\text{CH}^3)^3(\text{C}^6\text{H}^4\cdot\text{CH}^3)\text{NI}$. See TOLUENES, AMIDO- (p. 2000).

TRINAPHTHALENE-DIAMINE, $(\text{C}^{10}\text{H}^8)^2\text{N}^2$, is formed by heating naphthylamine, naphthylamine hydrochloride, and nitronaphthalene, in molecular proportion, in a sealed tube at 190°–220° for three or four hours. The resulting black mass is pulverised, treating with hot water, and then, after addition of potash-ley, with superheated steam, and the residual base is dissolved in hot alcohol and precipitated by water. It may also be prepared by heating the above mixture in open vessels, the reaction beginning, on addition of a trace of ferric chloride, at 150°. For purification it may be dissolved in chloroform and separated therefrom by evaporation. The base thus obtained contains 1 mol. water, which it gives off slowly at 120°–125°. It is an amorphous blue-black powder, insoluble in water and in ether, dissolving with red colour in warm benzene. Heated at 180° in contact with the air, it begins to decompose. The *hydrochloride*, prepared by passing hydrogen chloride into the chloroform solution, evaporating the chloroform, and washing the residue with hot water, is a violet amorphous powder, dissolving in the same solvents as the base, but more readily and with finer colour. Both the salt and the base produce red-violet colours in dyeing (Salzmann a. Wichelhaus, *Ber.* ix. 1107).

TRI- α -NAPHTHOLPYROMELLITEIC ACID. See NAPHTHOLS (vii. 840).

TRINITRANILINE, $\text{C}^6\text{H}^2(\text{NO}^2)^3\text{NH}^2$ [1 : 2 : 4 : 6, NH^2 in 1]. *Picramide*. See BENZENES, NITRAMIDO- (p. 198).

TRINITROAZOXYBENZENE, $\text{C}^{12}\text{H}^7(\text{NO}^2)^3\text{N}^2\text{O}$. See AZOXYBENZENE (p. 215).

TRINITROBENZANILIDE, $\text{C}^{13}\text{H}^8\text{N}^4\text{O}^7 = \text{C}^6\text{H}^3(\text{NO}^2)^3\text{NH}\cdot\text{CO}\cdot\text{C}^6\text{H}^4(\text{NO}^2)$, formed by nitration of paranitrobenzanilide, melts at 165°, and is resolvable into metanitrobenzoic acid and [1 : 2 : 4] dinitraniline (p. 198): hence its constitution may be represented by the formula :

The same trinitrobenzanilide is formed from orthonitrobenzanilide (m. p. 94°). Metanitrobenzanilide (m. p. 154°) gives three trinitrobenzanilides melting respectively at 178°, 202°, and 212°. The first of these is resolvable into [1 : 2 : 4] dinitraniline and probably orthonitrobenzoic acid (H. Hubner, *Ber.* x. 1708).

TRINITROBENZENE, $C^6H^3(NO^2)^3$, is obtained by enclosing metadinitrobenzene (p. 175) in proportions of 2 grams each with 20 g. of a mixture of 2 vol. fuming sulphuric acid and 1 vol. highly concentrated nitric acid in strong tubes, and heating the tubes first for a day at 80° , afterwards for two or three days at 130° – 140° . On pouring the contents into water, a precipitate is formed, consisting of trinitrobenzene, which may be purified by crystallisation from alcohol or acetic acid, and then forms white laminae or needles melting at 121° – 122° , slightly soluble in water, more soluble in ether and in hot alcohol (P. Hepp, *Ber.* ix. 402).

Trinitrobenzene forms crystallised compounds with benzene, naphthalene, aniline, and dimethylaniline. By crystallising it from benzene, large prismatic crystals are obtained having the composition $C^6H^3(NO^2)^3 \cdot C^6H^6$. With naphthalene in alcoholic solution it yields the compound $C^6H^3(NO^2)^3 \cdot C^{10}H^8$, which melts at 152° – 153° , and is somewhat unstable, being partly decomposed by recrystallisation from alcohol. The aniline-compound, $C^6H^3(NO^2)^3 \cdot C^6H^5NH^2$, prepared like the last, forms red needles melting at 123° – 124° , nearly insoluble in cold alcohol, and likewise unstable. The homologous dimethylaniline-compound forms long dark violet needles melting at 106° – 108° . By nitrating paradinitrobenzene (m. p. 171°) and treating the product (? an isomeric trinitrobenzene) with aniline and alcohol, a body is obtained melting at 153° , and probably having the composition $C^6H^3(NO^2)^2NHC^6H^5$, together with diazoamidobenzene (Hepp, *Bull. Soc. Chim.* [2]. xxx. 4).

TRINITROBENZOIC ACID, $C^6H^2(NO^2)^3 \cdot COOH$, obtained by prolonged digestion of trinitrotoluene with fuming nitric acid at 100° , forms large prismatic crystals melting at 100° , and subliming without decomposition. Its silver salt is sparingly soluble in water (Tiemann & Judson, *Ber.* iii. 223). According to Friedländer (*Zeitschr. f. Kryst.* i. 623), the crystals of trinitrobenzoic acid are orthorhombic. $a : b : c = 0.8870 : 1 : 0.5715$. Combination $\infty P \cdot \infty \bar{P} \infty$ (predominant). $\bar{P} \infty$. Angle $\bar{P} \infty : \bar{P} \infty = 59^\circ 30'$. No distinct cleavage. The plane of the optic axes coincides with OP. The axis b is the first median line. Double refraction positive. Apparent angle of axes in air for Li-red $90^\circ 25'$, for Na-yellow $84^\circ 36'$, for Tl-green $78^\circ 5'$.

TRINITROBENZYLNAPHTHALENE. See NAPHTHALENE (p. 1346).

TRINITROCRESOL, $C^6H(NO^2)^3OH \cdot CH^3$. See CRESOLS (p. 583).

TRINITRO- α -DICHLORONAPHTHALENE, $C^{10}H^3Cl^2(NO^2)^3$, obtained by the action of a mixture of strong sulphuric acid and nitric acid (sp. gr. 1.48) on α -dichloronaphthalene, crystallises from glacial acetic acid in brittle yellow prisms, freely soluble in chloroform, sparingly in alcohol, and melting at 178° (O. Widman, *Bull. Soc. Chim.* [2], xxviii. 505).

TRINITRODIETHYLQUINOL, $C^6H(NO^2)^3(OC^2H^5)^2$. See QUINOL (p. 1739).

TRINITRODIMETHYLCATECHOL, $C^6H(NO^2)^3(OH)^2$. See NITROVERATROLS under VERATROL.

TRINITRODIMETHYLETHYLBENZENE, $C^6(NO^2)^3(CH^3)^2(C^2H^5)$. See MESITYLENE, HOMOLOGUES OF (p. 1285).

TRINITRODIMETHYLQUINOL, $C^6H(NO^2)^3(OCH^3)^2$. See QUINOL (p. 1738).

TRINITRODIMETHYLRESORCINOL. See RESORCINOL (p. 1751).

TRINITRODIPHENYL, $C^{12}H^7(NO^2)^3$. This appears to be the composition of a compound formed on dissolving dinitrodiphenyl (p. 661) in a mixture of sulphuric and fuming nitric acids. It separates from solution in benzene in yellowish crystals (Büchner, *Ber.* viii. 22).

TRINITROGLYCERYL is the name given (not very appropriately) by Brackebusch to trinitrin or trinitropropane, $C^3H^3(NO^2)^3$. See GLYCEROL (p. 876).

TRINITROINOSITE, $C^6H^9(NO^2)^3O^6$. See INOSITE (p. 1091).

TRINITROISOXYLENE, $C^8H^7(NO^2)^3$. See XYLENES.

TRINITROMESITYLENE, $C^9H^9(NO^2)^3$. According to Ladenburg (*Liebigs Annalen*, clxxix. 176), this compound, when reduced with tin and hydrochloric acid, yields, not triamidomesitylene, but diamidomesitylene, with separation of ammonia.

TRINITRONAPHTHALENES, $C^{10}H^3(NO^2)^3$. See NAPHTHALENE (p. 352).

TRINITROPARADIPHENYLBENZENE, $C^{16}H^{11}(NO^2)^3$, obtained by the action of fuming nitric acid on paradiphenylbenzene (p. 665), crystallises from glacial acetic acid in long white needles melting at 190° . If the nitration be performed in glacial acetic acid, the chief product is dinitrodiphenylbenzene, which melts at 264° , and is

but sparingly soluble in the ordinary solvents and in glacial acetic acid, even when hot (H. Schmidt a. G. Schultz, *Ber.* xi. 1755).

TRINITROPHENETOIL, $C^6H^2(NO^2)^3.O^2C^2H^5$. See PHENOL-ETHERS (p. 1522).

TRINITROPHENOL, $C^6H^2(NO^2)^3.OH$. See PHENOL (p. 1528).

TRINITROPHENOLSULPHONIC ACID, $C^6H(NO^2)^3(OH)(SO^3H)$. The mother-liquor of barium metabromobenzenesulphonate (p. 236) contains an uncrystallisable barium phenolsulphonate, the acid of which is converted by strong nitric acid into a trinitrophenolsulphonic acid which remains on evaporation as a crystalline mass. Its salts explode violently when heated. The *potassium salt*, $C^6H(NO^2)^3(OH)SO^3K + H^2O$, forms small orange-red rhombic prisms, moderately soluble in water. The *barium salt*, $[C^6H(NO^2)^3(OH)SO^3]^{1/2}Ba + 3H^2O$, forms small yellow to reddish-yellow crystals, often grouped in nodules, and moderately soluble in water (Berndsen, *Liebig's Annalen*, clxxvii. 92).

α -TRINITROPHENYLMETANITRANILINE, $NH \begin{Bmatrix} C^6H^1(NO^2) \\ C^6H^2(NO^2)^3 \end{Bmatrix}$. Syn. with PARAPICRYLMETANITRANILINE. See BENZENES (NITRAMIDO-) (p. 199).

TRINITROPHENYLMETHANE, $CH(C^6H^1.NO^2)^3$. See TRIPHENYLMETHANE (p. 2058).

TRINITRORESORCINOL, $C^6H^2(NO^2)^3(OH)$. See RESORCINOL (p. 1751).

TRINITROSOPHLOOROGLUCOL, $C^6(NO^2)^3(OH)^3$. See PHLOOROGLUCOL (p. 1571).

TRINITROTOLUENE, $C^6H^2(NO^2)^3.CH^3$. See TOLUENE (p. 1994).

TRINITROTOLYPHENYL KETONE, $C^{14}H^2(NO^2)^3O$. See TOLYL KETONES (p. 2038).

TRINITROTRIBROMOBENZENE (symmetric), $C^6.NO^2.Br.NO^2.Br.NO^2.Br$, is formed by the action of a mixture of fuming nitric and sulphuric acids on dinitro-*m*-bromobenzene (p. 181).

TRIPHANE. Pisani (*Compt. rend.* lxxxiv. 1509) has examined a triphane from Brazil, consisting of imperfect crystals which cleave parallel to a prism of $86^\circ 45'$, but do not exhibit the cleavage parallel to $\infty P\infty$, which is so distinct in other triphanes. Hardness = 1; sp. gr. = 3.16. Analysis gave:

SiO ²	Al ² O ³	FeO	MnO	CaO	Li ² O	Na ² O
63.80	27.93	1.05	0.12	0.46	6.75	0.89 = 101.00.

TRIPHENYLACETIC ACID, $(C^6H^5)^3C.O^2COOH$, is formed, together with ammoniac, by the action of fuming hydrochloric and glacial acetic acid on triphenyl-acetonitril (*infra*). It is moderately soluble in alcohol and ligroin, less soluble in glacial acetic acid, and separates from the latter in compact colourless crystals or in thin six-sided laminæ or prisms. It softens at 230° , but does not fuse till heated to 260° . It yields a *nitro-derivative* which dissolves with brown colour in alkalis (E. and O. Fischer, *Liebig's Annalen*, cxciv. 242).

TRIPHENYLACETONITRIL, TRIPHENYLCARBINYL CYANIDE, or **TRIPHENYLCYANOMETHANE**, $(C^6H^5)^3C.CN$, is formed by the action of dry mercuric cyanide at 150° – 170° on triphenylchloromethane (p. 2057). It crystallises from ligroin or glacial acetic acid in well-defined colourless triangular prisms, which melt at 127.5° , and dissolve readily in hot benzene and glacial acetic acid, less easily in ligroin. Alcoholic potash converts it into a colourless indifferent body, probably a polymeric nitril, which crystallises in colourless needles melting at 210° (E. and O. Fischer).

TRIPHENYLAMINE, $N(C^6H^5)^3$. See pp. 209, 1552.

TRIPHENYLARSINE, $As(C^6H^5)^3$. See PHENYLARSENIC COMPOUNDS (p. 1553).

TRIPHENYL-BENZENE, $C^{24}H^{18} = C^6H^3(C^6H^5)^3$. This hydrocarbon is formed by heating methylphenyl ketone with alcoholic ammonia, and remains undissolved on treating the product with hydrochloric acid. Its formation is a simple process of dehydration, and is analogous to that of mesitylene (trimethylbenzene) from acetone: $3(C^6H^5.CO.CH^3) = 3H^2O + C^6H^3(C^6H^5)^3$. It is also produced by the action of phosphoric anhydride on phenylmethyl ketone (Engler a. Heiner, *Ber.* vi. 638), and by distilling phenyltribenzoic acid over red-hot potassium hydroxide: $C^6H^3(C^6H^5.CO^2H)^3 = 3CO^2 + C^6H^3(C^6H^5)^3$ (Gabriel a. Michael, *Ber.* xi. 1007). Engler a. Berthold (*Ber.* vii. 1123) prepare it by saturating phenylmethyl ketone with dry hydrogen chloride and leaving the liquid at rest for several days at a lukewarm temperature, whereupon

triphenylbenzene separates in considerable quantity. A further quantity may be obtained by treating the decanted liquid with hydrogen chloride, and by repeating the operation, a solid product may be obtained amounting in all to about 60 per cent. of the phenylmethyl ketone employed. From the last mother-liquors a further quantity may be precipitated by dilute alkalis.

Triphenylbenzene forms orthorhombic crystals having the axial ratio $a : b : c = 0.56616 : 1 : 0.7663$, exhibiting the combination $\infty P \infty . \infty \bar{P} \infty . \infty P . \infty \bar{P} 3 . \infty \bar{P} \infty$, also (in crystals from another source), $\frac{1}{2}P$ and $\frac{1}{2}\bar{P}$. Fundamental and normal angles, $\infty P : \infty \bar{P} \infty = 60^\circ 29'$; $\bar{P} \infty : \infty P = 72^\circ 33' 30''$. Fracture flat conchoidal, approximating to a cleavage parallel to OP . Plane of optic axes $\infty \bar{P} \infty$. A plate cut parallel to OP showed in air: $2E$ for Li-light $= 17^\circ 48'$; for Na-light $= 18^\circ 25'$; for Ti-light $= 19^\circ 27'$. The double refraction of triphenylbenzene is stronger than that of any other substance yet examined (Arzruni, *Zeitschr. Kryst.* i. 445). On the crystalline form of triphenylbenzene, see also Engler a. Berthold (*loc. cit.*)

Triphenylbenzene melts at 169° – 170° , and boils at a temperature above the boiling point of sulphur. It dissolves sparingly in aqueous alcohol, more readily in absolute alcohol, ether, and carbon sulphide, most readily in benzene (Engler a. Berthold).

Monobromotriphenylbenzene, $C^{24}H^{17}Br$, is formed on leaving a solution of triphenylbenzene and bromine in carbon sulphide at rest for several days, and remains on evaporating the solvent, as a resin which, by crystallisation from alcohol, may be obtained in colourless needles melting at 104° (Engler a. Berthold).

An isomeride of the triphenylbenzene just described is formed, together with resinous products, by the action of strong nitric acid on benzerythrene (vi. 304). Chrysene (vi. 459; vii. 338; viii. 463) has also the same percentage composition (G. Schulz, *Ber.* xi. 95).

TRIPHENYLCARBAMIDE, $NH(C^6H^5).CO.N(C^6H^5)^2$ (see CARBAMIDES, p. 391). It is resolved by heat into phenyl isocyanate and diphenylamine (Michler, *Ber.* ix. 715).

TRIPHENYL-CARBINOL, $C^{19}H^{16}O = (C^6H^5)^3COH$ (Hemilian, *Ber.* vii. 1203). This tertiary alcohol is formed: 1. By boiling trimethylmethane with chromic acid mixture till the oily layer which floats on the surface solidifies to a crystalline crust; it may be purified by washing with boiling water and recrystallisation from benzene. 2. By adding 1 mol. bromine to a solution of 1 mol. triphenylmethane in carbon sulphide. On evaporating the solvent, there remains a brown oil, solidifying when treated with water to a brown mass of the carbinol, which may be freed from brown greasy bodies, and obtained colourless by solution in light petroleum and evaporation of the solvent.

Triphenyl-carbinol melts at 157° , boils at a temperature above 360° , dissolves readily in alcohol, ether, and benzene, and crystallises from these solvents by slow evaporation in shining hard six-sided plates. These crystals, according to measurements by Hintze, belong to the monoclinic system. $a : b : c = 0.75188 : 1 : 0.62971$. Angle $a : c = 119^\circ 41' 50''$. Combination $\infty \bar{P} . P . OP . -3P \infty . -2P \infty$.

Triphenyl-carbinol is not altered by distillation with soda-lime, or by treatment with alkalis, dilute mineral acids, or sodium-amalgam. It dissolves readily in strong sulphuric acid, even at ordinary temperatures, forming a yellow solution from which it is precipitated by water in its original state. With bromine and nitric acid it forms substitution-products difficult to purify. With acetyl chloride or acetic anhydride, and with benzoyl chloride, it yields ethers which are immediately decomposed by water or by alcohol. The acetic ether when distilled is partially carbonised and yields acetic acid and triphenylmethane. When a solution of the carbinol in anhydrous toluene is boiled with sodium, hydrogen is evolved, and an insoluble, pulverulent, very hygroscopic sodium-derivative is formed, which is immediately resolved by water into sodium hydroxide and triphenyl-carbinol. Triphenyl-carbinol, heated with benzene and phosphoric anhydride, yields triphenylmethane and diphenyl, according to the equation:

Trinitrotriphenyl-carbinol, $C^{19}H^{12}(NO^2)^3.OH$, is formed by oxidising trinitrotriphenylmethane with chromic acid and glacial acetic acid, and separates from hot benzene in nearly colourless crystals melting at 171° – 172° , sparingly soluble in alcohol, ether, and carbon sulphide, more freely in benzene and glacial acetic acid (E. and O. Fischer, *loc. cit.*)

TRIPHENYLCARBINYL CHLORIDE, or **TRIPHENYLCHLOROMETHANE**, $(C^6H^5)^3CCl$, is formed on mixing triphenyl-carbinol with phosphorus pentachloride, the mixture becoming warm and liquefying, giving off hydrogen chloride

and a distillate of POCl_3 , and leaving a residue of triphenylcarbinyl chloride, which solidifies on cooling to a radio-crystalline mass. At 150° this chloride begins to decompose and give off hydrogen chloride. It is slowly decomposed by cold water, instantly by boiling water, yielding hydrochloric acid and triphenyl-carbinol. When heated above 200° , it is resolved into hydrogen chloride and diphenylenephenyl-

methane, $\begin{array}{c} \text{C}^6\text{H}^5 \\ | \\ \text{C}^6\text{H}^5 \end{array} \text{CH.C}^6\text{H}^5$. By zinc-ethyl, dissolved in benzene, the chloride is converted into triphenylmethane (E. and O. Fischer). Heated to 150° – 170° with dry mercuric cyanide, it yields triphenylacetoneitril, $(\text{C}^6\text{H}^5)_3\text{C.CN}$ (p. 2056).

Ethyllic Triphenylcarbinylate, or Triphenyl-ethoxymethane, $(\text{C}^6\text{H}^5)_3\text{C}(\text{OC}^2\text{H}^5)$, is formed by boiling trimethylcarbinyl chloride with absolute alcohol, and separates, on mixing the cooled product with water, as a colourless oil which solidifies after long standing. It is easily soluble in ether, benzene, and hot alcohol, and separates from the latter in small indistinct crystals which distil without decomposition in a current of air (Hemilian).

TRIPHENYLENE, $\text{C}^{18}\text{H}^{12}$. See CHRYSENE (p. 463).

TRIPHENYLENE-DIAMINE, $(\text{C}^6\text{H}^4)_3\text{N}^2$. This compound is formed, together with sal-ammoniac, by heating 2 mol. aniline with 1 mol. nitrobenzene and dry hydrochloric acid in exhausted tubes for six hours at 230° ; also by heating diphenylamine with nitrobenzene and dry hydrochloric acid at the same temperature for an hour; and by the action of dry hydrochloric acid at 215° on azodiphenyl-blue; it appears to be identical with the colouring matter known as Staedeler's blue (*J. pr. Chem.* xvi. 63; *Jahresb. f. Chem.* 1865, 410). At the same time an intermediate product, $\text{C}^{18}\text{H}^{13}\text{N}^3$, is formed, which may also be produced by heating aniline hydrochloride with nitrobenzene at 210° (v. Dechen a. Wichelhaus, *Ber.* viii. 1609).

TRIPHENYLETHYLCARBAMIDE, $\text{N}(\text{C}^6\text{H}^5)_2.\text{CO.N}(\text{C}^2\text{H}^5)(\text{C}^6\text{H}^5)$. See CARBAMIDES (p. 391).

TRIPHENYL-GUANIDINE, $\text{C}^{18}\text{H}^{17}\text{N}^3 = \text{CH}^2(\text{C}^6\text{H}^5)_3\text{N}^3$. The two known modifications of this compound, α and β , are described under GUANIDINE (p. 906). A body having the same constitution as α -triphenyl-guanidine, but differing from it in physical properties, is described by Sell a. Zierold (*Ber.* vii. 1228) as produced by the action of aniline on isocyanphenyl chloride:

The hydrochloride of this base crystallises from aqueous alcohol in small white laminae melting at 207° , whereas the hydrochloride of α -triphenyl-guanidine obtained by Weith (p. 907) melts at 241° – 242° .

TRIPHENYL-METHANE, $(\text{C}^6\text{H}^5)_3\text{CH}$. This compound, which Kekulé a. Franchimont obtained by heating benzylene dichloride with mercury-diphenyl (vii. 948), is also produced by the following reactions: α . By heating a mixture of benzhydrol, benzene, and phosphoric anhydride at 130° – 140° for four hours. To purify it, the contents of the tube are washed with water and then distilled, whereupon the hydrocarbon passes over at a temperature above 360° as a light yellow oil, solidifying after a while to a mass of crystals, which may be freed from adhering oil by washing with cold, and recrystallisation from boiling alcohol (Hemilian, *Ber.* vii. 1208). β . By heating β -benzpinacolin with soda-lime at about 300° , benzoic acid being formed at the same time (Thörner a. Zincke, *Ber.* xi. 65):

γ . By treating a mixture of benzene and chloroform with aluminium chloride, ferric chloride, or zinc chloride at ordinary temperature, or with ferrous chloride aided by heat (Friedel a. Crafts, *J. pr. Chem.* [2], xvi. 233).

E. and O. Fischer (*Liebig's Annalen*, cxciv. 202) prepare triphenyl-methane by mixing 200 g. chloroform and 700 g. dry benzene with aluminium chloride, whereupon a brisk evolution of hydrogen chloride takes place, and afterwards heating the mixture, the reaction being then completed in about thirty hours. On pouring the two resulting layers of liquid into water and applying heat, diphenyl-methane passes over between 200° and 300° , and afterwards triphenyl-methane, which may be purified by crystallisation from alcohol; the pure product amounts to 200 grams.

Triphenyl-methane separates from alcoholic solution in brilliant well-defined crystals, melts at 92.5° , and boils at about 355° .

Trinitrotriphenyl-methane, $(\text{C}^6\text{H}_4.\text{NO}_2)_3\text{CH}$.—Triphenyl-methane dissolves readily in fuming nitric acid at ordinary temperatures, and on mixing the solution with water, a thick yellow oil is precipitated, which, when treated with chloroform, leaves

the trinitro-compound in the form of a light yellow powder. It is very sparingly soluble in alcohol and ether, easily in boiling acetone and benzene; crystallises therefrom in small yellow scales; melts at 203°, and decomposes without detonation at a higher temperature (Hemilian, *Ber.* vii. 1203). According to E. and O. Fischer (*loc. cit.*) it melts at 206°–207°.

TRIPHENYLMETHANETRISULPHONIC ACID, $\text{CH}(\text{C}^6\text{H}_4\text{SO}_3\text{H})_3$, formed by the action of sulphuric acid on triphenyl-methane, is very soluble in water, and yields a very soluble barium salt, which is precipitated by alcohol from its aqueous solution, and when air-dried has the composition $[\text{CH}(\text{C}^6\text{H}_4\text{SO}_3)_3]_2\text{Ba} + 3\text{H}_2\text{O}$. The sulpho-acid, fused with potassium hydroxide, yields a phenolic body easily soluble in ether, and crystallising in colourless needles which, when exposed to the air, quickly turn red and partially resinise (Hemilian).

TRIPHENYL-ROSANILINE, $\text{C}^{20}\text{H}^{16}(\text{C}^6\text{H}_5)^3\text{N}^3$. A body exhibiting the behaviour of this compound is formed, together with HBr and NH_4^+Br , on gradually adding bromine (6 mol.) to a solution of diphenylamine and toluidine (2 mol. each) in glacial acetic acid, then distilling off the acid, heating the product for some hours at 150°, and afterwards at 180°, till it solidifies and assumes a coppery lustre. The triphenyl-rosaniline may be extracted from the crude product by aniline; purified by dissolving it in 40 pts. alcohol and 2 pts. soda-ley of 20 per cent., and filtering the resulting solution from a brown base formed at the same time; and separated from the filtrate by hydrochloric acid. It dissolves in alcohol with blue colour, and dyes silk like the commercial product 3B. By successive treatment with strong sulphuric acid and caustic soda, it is converted into the form which is soluble in water (A. Weber, *Ber.* x. 760).

On *Triphenylrosaniline-sulphonic acids*, see vii. 77.

TRIPHLORETIDE, $\text{C}^{27}\text{H}^{26}\text{O}^7 = 3\text{C}^6\text{H}^{10}\text{O}^3$ (phloretic acid) $- 2\text{H}_2\text{O}$. Phloretic acid, heated at about 60° with phosphorus oxychloride, dissolves, with evolution of hydrogen chloride, and after about an hour the whole solidifies to a white mass. On washing the product with ether, alcohol, and water, and then dissolving it in glacial acetic acid at the boiling heat, the solution on cooling yields white crystals of triphloretide (H. Schiff, *Ber.* vi. 759).

TRIPHOSPHENYLIC ACID, $(\text{C}^6\text{H}_5)_3(\text{PO})_3\text{O}^2(\text{OH})^2$. See PHOSPHENYLIC ACIDS (p. 1576).

TRIPHOSPHENYL SULPHIDE, $(\text{C}^6\text{H}_5\text{P})_3\text{S}$, is produced, together with phenylphosphine sulphide, $\text{C}^6\text{H}_5\text{PH}_2\text{S}$, by heating phenylphosphine with sulphur at 100° in a stream of hydrogen. It forms crystals which melt at 138°, are insoluble in ether, but dissolve with violent reaction in nitric acid (Köhler a. Michaelis, *Ber.* x. 807).

TRIPHYLIN. This mineral occurs in a granite vein at Grafton, New Hampshire, in masses of various weight up to 20 kilograms and more; frequently decomposed on the outside, but fresh in the interior. The following analyses by S. L. Penfield (*Sill. Am. J.* [3], xiii. 425) lead to the formula $10\text{R}^3\text{PO}^4 + 11\text{R}^3\text{P}^2\text{O}^3$, which does not differ much from that given by Rammelsberg (*Mineralchemie*, 2 Aufl. 307), $\text{R}^3\text{PO}^4 + \text{R}^3\text{P}^2\text{O}^3$:

P^2O^3	FeO	MnO	CaO	MgO	Li^2O	K^2O	Na^2O	H^2O
44.18	26.09	18.17	0.89	0.56	8.77	0.32	0.16	1.47 = 100.61
43.88	26.38	18.24	0.99	0.61	8.81	0.32	0.09	1.47 = 100.79

TRIPLATOCTONITROSILIC ACID, $\text{Pt}^3\text{O}(\text{NO}^2)^3\text{H}^4$. See PLATONITRITES (p. 1655).

TRIPLITE. This mineral has been found by Stelzner (*Jahrb. f. Min.* 1874, 304) in the granitic quartz-veins of the Sierra de Cordoba, Argentine Republic, forming masses of the size of the fist without any indication of crystallisation. The analyses, performed by M. Sievert, differ considerably from other analyses of triplite (iv. 571), and are referred by him to the formulæ $(\frac{3}{8}\text{Mn}, \frac{5}{8}\text{Ca})\text{F}^2 + 2[\frac{3}{8}\text{MnO}, \frac{1}{8}\text{FeO}]\text{P}^2\text{O}^3$, for A, and $10[(\frac{3}{8}\text{Mn}, \frac{1}{8}\text{Ca})\text{F}^2 + 3(\frac{3}{8}\text{MnO}, \frac{1}{8}\text{FeO})\text{P}^2\text{O}^3] + \text{Fe}^2\text{O}^3$ for B. Sp. gr. of A = 3.24 to 3.86; of B = 3.83 to 3.90.

	X ⁽¹⁾	P^2O^3	FeO	Fe^2O^3	MnO	Mn	CaO	Ca	MgO	F

⁽¹⁾ Gangue. ⁽²⁾ Equivalent to 3.30 MnO. ⁽³⁾ 4.42 CaO. ⁽⁴⁾ After deduction of gangue. ⁽⁵⁾ 7.69 MnO. ⁽⁶⁾ 6.14 CaO.

TRIPLOÏDITE (G. J. Brush a. E. S. Dana, *Sill. Am. J.* [3], xvi. 33, 114). A ferroso-manganous phosphate, occurring, together with several others, in a granite vein rich in albite, near the village of Branchville, Redding District, Fairfield County, Connecticut. It usually forms crystalline aggregates mostly parallel-fibrous to columnar or divergent, sometimes confusedly fibrous to nearly massive. Occasionally distinct crystals are found imbedded in quartz, from which they cannot be separated without breaking into small pieces; rarely crystals may be found projecting into cavities in the massive mineral. Hardness = 4·5–5. Sp. gr. = 3·697. Lustre vitreous to greasy-adamantine. Colour yellowish to reddish-brown; crystals topaz- to wine-yellow, sometimes hyacinth-red. Streak nearly white. Transparent to translucent. Fracture sub-conchoidal.

The crystals are monoclinic and homœomorphous with wagnerite; they are much striated, and occasionally exhibit false planes. Observed faces: $0P$, ∞R , ∞P , ∞P , ∞P , $2P$. Habit prismatic. Axial ratio $a : b : c = 1·8571 : 1 : 1·4944$. Angle $ac = 71^\circ 46'$. Of the two axes of elasticity which lie in the plane of symmetry, one nearly coincides with the principal crystallographic axis; the other is almost normal to the orthopinacoid.

Analyses by S. L. Penfield: 1. Mean of two analyses of crystals; 2. A darker variety, richer in iron:

	P ² O ⁵	FeO	MnO	CaO	H ² O	Quartz
1.	32·11	14·88	48·45	0·33	4·08	— = 99·85
2.	32·24	18·65	42·96	not det.	4·09	1·09

These analyses lead to the formula $\hat{R}^4P^2O^4 + H^2O = \hat{R}^3(PO)^2 + \hat{R}H^2O^2$, which for Mn : Fe = 3 : 1 requires the values 31·91 P²O⁵, 16·18 FeO, 47·86 MnO, 4·05 H²O. Triploïdite being isomorphous with wagnerite, and the composition of the latter being analogous to that of triplite, the relations between these three minerals may be represented by the following formulæ:

Wagnerite	Mg ³ P ² O ⁸ + MgF ²
Triplite	(Fe,Mn) ³ P ² O ⁸ + (Fe,Mn)F ²
Triploïdite	(Mn,Fe) ³ P ² O ⁸ + (Mn,Fe)(OH) ²

that is to say, triploïdite is triplite having the fluorine replaced by hydroxyl.

TRIPOLI. This name is given in commerce to a porous, easily friable mineral produced by transformation of hornstone; it occurs in large quantities in South-west Missouri, and is used for making whetstones (A. Schmidt, *Jahrb. f. Min.* 1878, 719).

TRIPROPYLARSINE, (C²H³)³As. See PROPYL-COMPOUNDS (p. 1677).

TRIPROPYLPHOSPHINES, (C²H³)³P. Normal tripropylphosphine is obtained by the action of phosphorus trichloride on zinc-propyl: $3(C^2H^3)^2Zn + 2PCl^3 = 3ZnCl^2 + 2(C^2H^3)^3P$ (Cahours, *Compt. rend.* lxxvi. 1383).

On *Tri-isopropylphosphines*, see PHOSPHINES (vii. 955).

TRIPROPYLSULPHINE IODIDE, (C²H³)³SI. See PROPYL-COMPOUNDS (vii. 1014).

TRIPSEUDOTOLYL-GUANIDINE (see p. 2062).

TRISULPHETHYL-METHANE, or **METHYLTRIMERCAPTIDE**, CH(S.C²H³)³, formed by the action of chloroform on sodium-mercaptide, is an oily liquid, partially decomposing when boiled, and oxidised by nitric acid to ethylsulphonic acid (Niederist, *J. pr. Chem.* [2], xv. 174).

TRISULPHYDROXYBENZOIC ACID, C⁶(OH)H(SO³H)³COOH, syn. with OXY- (or rather HYDROXY-) BENZOTRISULPHONIC ACID (p. 1467).

TRISULPHONETHYL-NITROSYL, C⁶H¹⁵S³O²N = (C²H³.SO²)³NO. This compound, which Wischin obtained (*Liebig's Annalen*, cxxxix. 364), together with ethylsulphonic acid, by the action of nitric acid on ethylsulphonic acid, C²H³.SO.OH (produced by the action of sulphurous acid on zinc-ethyl), has been further examined by Zuckschwerdt (*ibid.* clxiv. 308), who finds that it is more abundantly obtained by treating the product of the action of sulphurous acid on zinc-ethyl directly with nitric acid. The product, which is viscid and ropy, after being freed by a little water from ethyl oxide (formed in its preparation), is gently heated in separate small portions with a large excess of nitric acid of sp. gr. 1·4, whereupon a violent reaction soon sets in, accompanied by evolution of nitrous fumes and separation of an oily liquid, which soon solidifies to a crystalline mass. This mass is separated from the liquid (available for a further operation), pulverised, purified by washing and fusion under water, and

finally twice crystallised from boiling alcohol of 96 per cent. Its formation is represented by the equation:

Trisulphonethyl-nitrosyl, when slowly separated from a moderately concentrated alcoholic solution, forms large colourless tabular crystals, easily soluble in boiling alcohol, less soluble in cold alcohol and in ether, very sparingly in cold water, somewhat more freely in hot water. It melts at $81\cdot5^\circ$, volatilises without residue when cautiously heated, and at a higher temperature carbonises and burns, emitting sulphurous vapours. When burnt in a current of air, it gives off large quantities of red vapours. It is not altered by strong sulphuric or hydrochloric acid, even when heated, but by prolonged boiling with nitric acid it yields ethylsulphonic and sulphuric acids. Its alcoholic solution is not precipitated by mercuric chloride, platinic chloride, or silver nitrate. By alcoholic potash at ordinary temperatures, or by aqueous potash at the boiling heat, and more slowly in the cold, or by boiling with baryta-water, it yields ammonia equivalent to one-fourth of the total nitrogen, sulphuric acid, and as chief product (more than 2 mol. to 1 mol. of the substance), ethylsulphonic acid:

and

The oxygen of the NO-group is, however, partly employed in oxidising the ethylsulphonic acid to sulphuric acid. Trisulphonethyl-nitrosyl, heated at 180° with *fuming hydrochloric acid*, is resolved into ammonia, containing the whole of the nitrogen, and ethylsulphonic acid, while sulphuric acid is formed in relatively small quantity only. The same decomposition takes place, though much more slowly, on heating the compound at 180° with *water*, the quantity of sulphuric acid thereby produced being relatively greater, and that of ammonia smaller, than in the former case. Heated at 160° with twice its weight of *phosphorus pentachloride*, the nitrosyl-compound is converted into chlorisethionic chloride:

TRITHIACETALDEHYDE, $\text{C}^6\text{H}^{12}\text{S}^3$. See THIALDEHYDE (p. 1950).

TRITHIACETANILIDE, $\text{C}^6\text{H}^4(\text{NH})\text{C}^2\text{H}^3\text{O}^2\text{S}^3\text{.C}^2\text{H}^4(\text{NH})\text{C}^2\text{H}^3\text{O}^2$, is formed, together with dithiacetanilide, by the action of sulphur chloride on acetanilide at 100° . The two compounds may be separated by means of glacial acetic acid, in which the dithio-compound is easily, the trithio-compound only sparingly soluble. The latter crystallises from solution in glacial acetic acid in nacreous laminae melting at 213° – $214\cdot5^\circ$. It dissolves readily in warm alcohol, and separates therefrom in stellate groups of small crystals (E. B. Schmidt, *Ber.* xi. 1168).

TRITHIOCARBONATE, BUTYLIC, $(\text{C}^4\text{H}^9\text{S})^2\text{CS}$. This thio-ether, formed by heating butyl iodide with a strong aqueous solution of potassium trithiocarbonate at 100° – 180° , is an orange-yellow oily liquid having a faint odour and boiling at 285° – 289° . By alcoholic potassium hydrosulphide at the boiling heat, it is resolved into butyl hydrosulphide, potassium sulphide, and potassium carbonate; by ammonia into butyl hydrosulphide and ammonium thiocyanate (Myllius, *Ber.* vi. 312).

TRITHIONIC ACID, $\text{S}^3\text{O}^6\text{H}^2$. See SULPHUR, OXYGEN-ACIDS OF (p. 1882).

TRITICIN, $\text{C}^{12}\text{H}^{22}\text{O}^{11}$. A gummy substance, isomeric with cane sugar, occurring in the root of couch-grass (*Triticum repens*). See COUCH-GRASS (p. 574).

TRITICUM. The pericarp and embryo of common wheat (*Tr. sativum*) have been analysed by A. H. Church (*Arch. Pharm.* [3], x. 60) with the following results:

	Pericarp	Embryo
Water.	15·17	12·53 p. c.
Fat	1·31	4·18
Albuminous matter	10·37	35·70
Cellulose and lignose	70·51 }	3·12
Starch, dextrin, &c.		38·71
Ash	2·64	5·76

TRITOLYL-ARSINE, $\text{As}(\text{C}^7\text{H}^7)^3$. See TOLYLARSENIC COMPOUNDS (p. 2031).

TRITOLYL-GUANIDINE (α), $\text{C}^{22}\text{H}^{23}\text{N}^3 = (\text{C}^7\text{H}^7)\text{N}=\text{C}[\text{NH}(\text{C}^7\text{H}^7)]^2$. *Tri-p-tolyl-guanidine* is formed by heating mono-*p*-tolylcarbamide with *p*-toluidine and PCl^3 (p. 909).

Tri-o-tolyl-guanidine, or *Tri pseudotolyl-guanidine*, is obtained by heating diorthotolylcarbamide with PCl_3 and orthotoluidine, or from the corresponding thiocarbamide by heating with *o*-toluidine alone, or in alcoholic solution with *o*-toluidine and lead oxide. It forms cauliflower-like groups of white needles, melts at a little above 100° , is insoluble in water, but soluble in alcohol and ligroin. Heated with carbon bisulphide at 180° , it is resolved into diorthotolylthiocarbamide and orthotolylthiocarbimide:

(E. Girard, *Ber.* vi. 444).

TRITOLYLOXETHYLENE-BIURET,

See GLYCOLLAMIDES (p. 883).

TRIURET, $\text{C}^8\text{H}^6\text{N}^4\text{O}^3$, appears to be formed, together with biuret and phosphamido-compounds, by the action of phosphorus trichloride on urea (Weith, *Ber.* x. 1743).

TRIVALERYLENE, $\text{C}^{30}\text{H}^{20}$. See VALERYLENE.

TRÖGERITE, $3\text{UO}^3, \text{As}^2\text{O}^5 + 12\text{H}^2\text{O}$. See URANIC ARSENATES (vii. 1190).

TROPEOLINES. This name is given in commerce to certain yellow and orange colouring matters produced by the action of diazosulphonic acids on phenols. See SULPHONIC ACIDS (p. 1857); further O. N. Witt (*Chem. Soc. J.* xxxv. 179).

W. v. Miller (*Ber.* xi. 460) recommends these dye-stuffs as indicators in alkalimetry. The one best adapted for the purpose is known in commerce as tropeoline 00; its aqueous solution, when treated with acids, acquires a yellow colour changing to crimson, whereas the same coloration is not produced either by acid carbonates or free carbonic acid or solutions of metallic salts.

TROPIC ACID, $\text{C}^9\text{H}^{10}\text{O}^3 = \text{CH}_2(\text{OH}).\text{CH}(\text{C}^6\text{H}^5).\text{CO}^2\text{H}$. This acid, one of the proximate constituents of atropine (vi. 249), has lately been prepared synthetically from atropic acid by Ladenburg a. Rügheimer (*Ber.* xiii. 373). Atropic acid, $\text{C}^9\text{H}^8\text{O}^2$, treated with hypochlorous acid, is converted into chlorotropic acid, $\text{C}^9\text{H}^8\text{ClO}^3$ (m. p. 129°):

and this chlorinated acid, which is very soluble in water, is reduced in alkaline solution by zinc-dust and iron filings to atropic acid:

TROPINE, $\text{C}^8\text{H}^{15}\text{NO}$. This base, which Kraut obtained, together with atropic acid, by the action of baryta-water on atropine, may also be extracted in considerable quantity from the residues of the preparation of atropine. It is likewise produced, together with a brown resinous body called *belladonic acid*, by boiling belladonine with alcoholic potash. Tropine, mixed with benzoyl chloride, yields benzoyl-tropine as an oily mass, which after a while solidifies in the crystalline state, and unites with acids, forming salts very much like those of atropine. The action of tropine on the pupil and on the contractile apparatus of the heart is much weaker than that of benzoyl-tropine or of belladonine (R. Buchheim, *N. Rep. Pharm.* xxv. 344).

TSCHERMAKITE. This triclinic felspar from Bamle in Norway, analysed with somewhat different results by v. Kobell and by G. W. Hawes (p. 774), has been further examined by Pisani (*Compt. rend.* lxxx. 370), whose analysis agrees nearly with that of Hawes, especially in assigning to the mineral only a small amount of magnesia:

SiO^2	Al^2O^3	CaO	MgO	Na^2O	H^2O	Sp. gr.
66.37	22.70	1.40	0.95	9.70	0.70 = 101.82	2.60

These numbers show that the mineral is an albite, and this result is confirmed by the optical investigations of Des Cloizeaux (*Compt. rend.* lxxx. 364).

TSCHUKING, or **ZERECHTITE**, an Abyssinian drug, consisting of the leaves, flowers, and fruit of *Ubyæa Schimperii*, contains, according to Dragendorff (*Arch. Pharm.* [3], xii. 116):

Moisture	6.11 p. c.
Ash	9.23
Sand	2.81
Ammonia	0.93
Albumin	0.93
Other Proteids	11.74
Cellulose	35.19
Vasculose, Cuticular Substance, &c.	2.57
Pararabin	2.27
Pectin-substance	2.32
Mucus soluble in Water	1.98
Carbohydrate (not Glucose)	11.26
Essential oil	1.72
Fat and a small quantity of Chlorophyll	1.50
Resin and Chlorophyll	2.05
Tannic acid	2.82
Tartaric, Citric, and Oxalic acids	3.61
Oxalic acid combined with lime	0.96

100.00

TUFA. The tufas of the island of Ischia have been analysed by C. W. C. Fuchs (*Jahrb. f. Min.* 1873, 429): 1. *Green Epomeo tufa*; sp. gr. = 2.17. 2. *Pumice tufa* from Monte di Vico. 3. *Trachytic tufa*: Punta S. Angelo. 4. So-called *Marl*: Epomeo. 5. Mass resembling lithomarge from the so-called *Marl*: Casamicciola di sopra. 6. Clay (so-called): *Oreta*; *a*. Entire mass; *b*. Soluble in acetic acid; the acetic acid dissolves out 18.44 per cent. CaCO_3 :

	SiO_2	Al_2O_3	Fe_2O_3	FeO	MnO	CaO	MgO	K_2O	Na_2O	P_2O_5	X (%)
1.	54.69	20.00	3.13	2.26	0.02	2.17	0.70	4.77	0.28	0.021	11.61 = 99.65
2.	54.02	18.18	3.64	2.23	0.11	2.01	0.79	3.86	1.71	0.004	14.30 = 100.85
3.	53.71	16.35	2.82	2.19	0.03	1.38	0.55	6.73	2.53	—	14.43 = 100.72
4.	59.88	17.28	5.06	2.30	trace	1.69	0.80	6.43	2.97	0.043	3.69 = 100.14
5.	58.31	19.79	2.86	2.11	—	0.70	0.81	6.29	2.88	—	7.24 = 100.99
6a.	46.28	12.71	4.46	2.14	—	11.27	2.17	2.58	0.82	—	8.67 = 91.10
6b.	57.20	15.71	5.51	2.64	—	1.16	2.68	3.19	1.01	—	10.71 = 99.81

(1) Loss by ignition.

Tufa accompanying the diorite of the gold-field of Gympie in Queensland (p. 654) has been analysed by R. Daintree (*Geol. Soc. Qu. J.* xxviii. 271). It contains little or no gold, whereas the diorite is rich in that metal: *a*. Entire composition; *b*. Soluble in hydrochloric acid (54.9 p. c.); *c*. Insoluble (45.1 p. c.):

	SiO_2	Al_2O_3	Fe_2O_3	FeO	CaO	MgO	K_2O	Na_2O	CO_2	H_2O
a.	43.150	21.570	3.610	8.520	12.450	1.785	1.310	1.710	3.560	1.600 = 99.265
b.	28.234	23.442	6.575	11.666	16.074	2.022	—	—	6.484	2.913 = 97.410
c.	60.753	19.395	—	4.800	7.206	1.873	2.904	3.791	—	— = 100.722

The following analyses of tufa-formations in South Tyrol are given by C. Doelter (*Jahrb. f. Min.* 1873, 569):

1. *Augitic Porphyry* from the Sasso di Mezzodi on the Padoa-peak, designated by v. Richtenhofen as *Eruptive Tufa*; analysed by Epp. 2 and 3. *Pietra verde* from Monte Frisolet near the village of Andraz in the Buchenstein Thal. The name 'Pietra verde' is given to various tufa-formations; in the present case the chemical composition indicates a quartz porphyry tufa: analysed by P. Schridde:

	SiO_2	Al_2O_3	Fe_2O_3	FeO	CaO	MgO	K_2O	Na_2O	H_2O	P_2O_5	CO_2
1.	53.17	15.57	8.12	2.42	4.88	4.18	3.58	3.22	3.31	1.21	— = 99.66
2.	68.95	10.44	1.30	1.82	5.07	1.47	3.96	2.14	0.60	—	3.74 = 99.49
3.	69.10	10.50	—	3.97	4.62	1.04	7.15	—	—	3.23	—

TUNGSTEN. Atomic Weight, 184.—F. Jean (*Compt. rend.* lxxxi. 95) prepares metallic tungsten by mixing finely pounded wolfram with 3 per cent. potassium carbonate and 20–30 per cent. common salt, heating the mixture to redness for half an hour, boiling the cooled and pulverised mass with hydrochloric acid—whereby pure tungsten trioxide is obtained—and reducing this oxide in a stream of hydrogen. F. Filsinger (*Chem. Ind.* 1878, 229) prepares the metal from commercial sodium tungstate by adding 1 pt. of the salt to 2 pts. by weight of common hydrochloric acid of sp. gr. 1.18 to 1.19, passing steam into the liquid till it boils; then adds nitric acid

of sp. gr. 1.35 in quantity equal to 4 or 5 per cent. of the sodium salt; and continues the boiling till the separated tungstic oxide assumes a dark yellow colour. This oxide, after being thoroughly washed and dried, is ultimately mixed with 10 per cent. finely pounded charcoal, and 2 or 3 per cent. powdered rosin, and heated to whiteness for several hours in a well-closed crucible. The product, when pulverised and freed from charcoal by levigation, yields 80–90 per cent. metallic tungsten.

On the Estimation of Tungsten in Iron and Steel, see S. Kern (*Chem. News*, xxxv. 67, 247, 270).

On the Technical Applications of Tungsten and its Compounds, see J. Philipp (*Hofmann's Entwicklung der Chemischen Industrie*, 745).

Chlorides and Oxychlorides. Persoz a. Bloch (*Compt. rend.* xxviii. 86, 289), by heating tungsten trioxide with phosphorus pentachloride at 200°, obtained a product to which they assigned the formula $WO^3 \cdot 2PCl^5$, and H. Schiff (*Liebigs Annalen*, cii. 211) obtained by the same reaction a product which he regarded as a compound of $POCl^3$ with WO^3Cl^2 . According to N. Teclu, on the other hand (*ibid.* clxxxvii. 255), the sole products of this reaction are phosphorus oxychloride and tungsten hexchloride, WCl^6 , which is thus obtained in metallically lustrous steel-blue crystals, melting at 189°, easily soluble in phosphorus oxychloride, retaining their metallic lustre undiminished when immersed in water of ordinary temperature even for thirty-six hours, and exhibiting in other respects the properties assigned to the compound by Roscoe (vii. 1184).

Further experiments on the action of PCl^5 on WO^3 have been made by Schiff a. Piutti (*Gazz. chim. ital.* ix. 277), who find that, under the conditions described by Teclu, the hexchloride is the only product obtained, but that under other conditions oxychlorides are likewise produced. When the trioxide (prepared from ammonium tungstate) is heated in a retort with 1 or 2 mol. PCl^5 , phosphorus oxychloride distils over, together with a small quantity of the higher chlorides of tungsten, chiefly the hexchloride. The red-brown residue is washed with cold carbon sulphide to remove small quantities of hexchloride, and then treated with a larger quantity of warm carbon sulphide, which dissolves up the tungsten oxychlorides, leaving a residue of unattacked tungsten trioxide and lower chlorides of tungsten. A portion of the oxychlorides separates in red crystals on cooling, but the greater part remains dissolved, and is obtained as a crystalline cake on evaporating the carbon sulphide. By careful sublimation in a stream of carbon dioxide, the more volatile oxytetrachloride, $WOCl^4$, may be separated from the less volatile yellow dioxydichloride, WO^2Cl^2 . When 1–2 mol. PCl^5 is employed to 1 mol. WO^3 , the chief product of the reaction is the oxytetrachloride, which, when purified by sublimation, is sometimes obtained in splendid red needles melting at 208°–210°. By heating with PCl^5 to about 170°, it is converted into the hexchloride, a small portion of which is resolved into chlorine and the pentachloride.

A mixture of tungsten oxychlorides is obtained by heating the trioxide to redness in a stream of the vapour of carbon tetrachloride, or in a stream of chloride and carbon dioxide previously passed over red-hot charcoal (C. W. Watts a. C. A. Bell, (*Chem. Soc. J.* xxxiii. 360).

Trioxide or Tungstic Oxide, WO^3 , and Tungstates. On the preparation of the pure trioxide from commercial sodium tungstate, see p. 2063.

The following reactions of soluble tungstates are described by J. W. Mallet (*Chem. Soc. J.* xxviii. 1228): 1. Contrary to the statements in many manuals, the precipitate formed by hydrochloric acid in an alkaline tungstate is redissolved by an excess of strong hydrochloric acid. 2. Such a solution gradually brought in contact with small pieces of zinc exhibits various colours, the most striking of which is a brilliant magenta-red. 3. On treating the hydrochloric acid solution with potassium thiocyanate, and then introducing a piece of zinc, a deep green colour is produced. 4. When, on the other hand, the solution of an alkaline tungstate is treated first with potassium thiocyanate, then with hydrochloric acid and zinc, a fine amethyst colour is produced. 5. The blue colour characteristic of the lower oxides of tungsten is best obtained by reduction with hyposulphurous acid, SO^2H^2 .

According to O. Maschke (*Zeitschr. anal. Chem.* 1877, 427), a strongly alkaline solution of sodium tungstate is reduced and turned blue by organic bodies.

On the reaction of sodium tungstate with *sal-ammoniac*, see F. Jean (*Compt. rend.* lxxviii. 1436; *Jahresb. f. Chem.* 1874, 283).

Tungsto-sodic Tungstate (gold-bronze) is best prepared by adding tungstic oxide to a mixture of tin and acid sodium tungstate, in such quantity that the mixture when fused in a crucible at a rather strong heat, then pulverised and introduced into a porcelain tube, merely sinters together over a weak charcoal fire. Reduction by means of coal-gas then takes place in a few hours. After repeated purification with

hot nitric acid to oxidise the excess of tungsten dioxide, and with soda-ley, the preparation forms a powder having in sunlight a splendid gold-yellow colour. The corresponding potassium-salt (violet-bronze) requires a higher temperature (H. Schnitzler, *Dingl. pol. J.* cxxi. 484).

Acid Tungstates (J. Lefort, *Compt. rend.* lxxxvii. 748; lxxxviii. 798; *Ann. Chim. Phys.* [5]. xvii. 470).—The following acid tungstates of potassium and sodium are obtained by the action of organic acids on the corresponding normal tungstates. *Sodium ditungstate*, $\text{Na}^4\text{W}^2\text{O}^{17}, 6\text{H}^2\text{O}$, is obtained in fine long prismatic crystals on adding acetic acid to a solution of the normal tungstate till the liquid exhibits an acid reaction. The *tritungstate*, $\text{Na}^4\text{W}^3\text{O}^{10}, 4\text{H}^2\text{O}$, is easily prepared by pouring a boiling-hot solution of the ditungstate into boiling acetic acid. The liquid, if left in a cold place, separates into two layers, the lower of which—heavy, semi-transparent, syrupy, and difficult to crystallise—contains the tritungstate, while the upper consists chiefly of sodium acetate and excess of acetic acid. The *tritungstate* crystallises in elongated prisms. A salt, $\text{Na}^4\text{W}^3\text{O}^{17}, 11\text{H}^2\text{O}$, intermediate between the two preceding, is obtained in oblique prisms on adding a solution of the normal tungstate to acetic acid. Corresponding *potassium salts* are obtained in like manner: $\text{K}^2\text{W}^2\text{O}^7, 3\text{H}^2\text{O}$ crystallises in nacreous laminae; $\text{K}^2\text{W}^3\text{O}^{10}, 2\text{H}^2\text{O}$, in small very slender needles; $\text{K}^4\text{W}^3\text{O}^{17}, 2\text{H}^2\text{O}$ in prismatic tablets, easily resolved by boiling water into the di- and tri-tungstate. The tritungstate of potassium is especially distinguished by its property of being transformed into the metatungstate by prolonged boiling with acetic acid, a character not exhibited by the corresponding sodium salt.

Oxalic acid converts the normal tungstates of potassium and sodium into ditungstate and oxalate, which, in the case of the sodium salts, crystallise together and cannot be separated, whereas the potassium salts are easily separated in consequence of the relatively sparing solubility of the ditungstate. The action of *tartaric acid* on normal alkali-tungstates appears to give rise to uncrystallisable double salts; *citric acid* also produces double salts, one of which crystallises in tufts of oblique prisms.

The following tritungstates are obtained by mixing the solution of sodium tritungstate with an equivalent quantity of a metallic acetate, and leaving the mixture at rest for some time. Excepting in the case of the barium, strontium, and lead salts, which are but slightly soluble in water, no precipitation takes place at first, but on addition of alcohol the salts separate in the form of bulky precipitates which aggregate into semi-transparent and semi-solid viscid masses. The tritungstates are for the most part unstable, and easily decompose, especially in aqueous solution, into insoluble ditungstates and soluble tetratungstates. They are also decomposed by mineral acids, and in the first instance without separation of tungstic acid, the formation of the hydrate of that acid taking place only after some hours.

Barium Tritungstate, $\text{BaW}^3\text{O}^{10}, 4\text{H}^2\text{O}$, or $\text{BaO}, 3\text{WO}^3, 4\text{H}^2\text{O}$, is a white bulky amorphous precipitate, soluble in about 300 pts. water at 15° ; it is not decomposed by cold water, but is resolved on boiling into insoluble di- and soluble tetratungstate. The *strontium salt*, $\text{SrW}^3\text{O}^{10}, 5\text{H}^2\text{O}$, separates as a white bulky precipitate, which coagulates to a colourless viscid mass. The *calcium salt*, $\text{CaW}^3\text{O}^{10}, 6\text{H}^2\text{O}$, is a white semi-solid glutinous precipitate, soluble in cold water. The *magnesium salt*, $\text{MgW}^3\text{O}^{10}, 4\text{H}^2\text{O}$, is a white glutinous mass very soluble in water. The *manganous salt*, $\text{MnW}^3\text{O}^{10}$, is a wax-yellow translucent pasty mass. The *ferrous salt*, $\text{FeW}^3\text{O}^{10}, 4\text{H}^2\text{O}$, is a reddish precipitate which coagulates to a brown pasty mass, and quickly oxidises in moist air. The *nickel salt*, $\text{NiW}^3\text{O}^{10}, 4\text{H}^2\text{O}$, is a greenish-white mass of the consistence of honey. The *cobalt salt*, $\text{CoW}^3\text{O}^{10}, 4\text{H}^2\text{O}$, is a reddish viscid mass. The *cadmium salt*, $\text{CdW}^3\text{O}^{10}, 4\text{H}^2\text{O}$, is a white semi-transparent gummy mass. The *lead salt*, $\text{PbW}^3\text{O}^{10}, 2\text{H}^2\text{O}$, is a white pulverulent precipitate which does not become viscid. Neither a cupric nor a mercurous tritungstate appears to exist.

The following tungstates have also been prepared by Lefort (*loc. cit.* 748; lxxxviii. 798). *Aluminium Salts*.—The *normal salt*, $\text{Al}^2\text{O}^3, 3\text{WO}^3, 8\text{H}^2\text{O}$, is obtained by precipitating alum-solution with normal sodium tungstate, as a white bulky precipitate soluble in 1500 pts. water at 15° . An *acid salt*, $\text{Al}^2\text{O}^3, 4\text{WO}^3, 9\text{H}^2\text{O}$, formed on mixing the concentrated aqueous solutions of alum and acid sodium tungstate, is a white, much denser precipitate, soluble in 400 pts. water at 15° . Another acid salt, $\text{Al}^2\text{O}^3, 5\text{WO}^3, 6\text{H}^2\text{O}$, is obtained on mixing aluminium acetate and sodium tritungstate in equivalent proportions, as a white precipitate which thickens to the consistence of honey. *Ferric salts*.— $2\text{Fe}^2\text{O}^3, 3\text{WO}^3, 6\text{H}^2\text{O}$ is obtained by precipitating ferric acetate with normal sodium tungstate, as a yellow precipitate, soluble in about 300 pts. water at 15° . $\text{Fe}^2\text{O}^3, 2\text{WO}^3, 4\text{H}^2\text{O}$, obtained in like manner with sodium ditungstate, is a brown-yellow precipitate soluble in about 50 pts. of water. $\text{Fe}^2\text{O}^3, 4\text{WO}^3, 4\text{H}^2\text{O}$ is obtained by precipitation with sodium tritungstate as a deep-red pasty mass. *Chromic salts*.—The *basic salt*, $\text{Cr}^2\text{O}^3, 2\text{WO}^3, 5\text{H}^2\text{O}$, is obtained with chromic acetate and normal

sodium tungstate, as a blue-green powder soluble in 400 pts. water at 15° the *normal salt*, $\text{Cr}^2\text{O}^3 \cdot 3\text{WO}^3 \cdot 3\text{H}^2\text{O}$, by precipitating chrome-alum with sodium ditungstate, as a dingy green powder; an *acid salt*, $\text{Cr}^2\text{O}^3 \cdot 4\text{WO}^3 \cdot 6\text{H}^2\text{O}$, by mixing the solutions of chromic acetate and sodium ditungstate, and pouring the mixture into strong alcohol; and another acid salt, $\text{Cr}^2\text{O}^3 \cdot 5\text{WO}^3 \cdot 5\text{H}^2\text{O}$, with chromic acetate and sodium tritungstate, as a bluish translucent viscid mass. *Antimony salts*.—The *normal salt* appears to be formed on mixing a solution of tartar-emetic with normal sodium tungstate, as a white precipitate slowly decomposed by washing with water. An *acid salt*, $\text{Sb}^2\text{O}^3 \cdot 5\text{WO}^3 \cdot 4\text{H}^2\text{O}$, is formed on mixing the solutions of tartar-emetic and sodium ditungstate, as a heavy yellowish precipitate which dissolves in water with moderate facility and without decomposition. Another acid salt, $\text{Sb}^2\text{O}^3 \cdot 6\text{WO}^3 \cdot 8\text{H}^2\text{O}$, is obtained as a white precipitate on mixing the solutions of tartar-emetic and sodium tritungstate. The *bismuth salt*, $\text{Bi}^2\text{O}^3 \cdot 6\text{WO}^3 \cdot 8\text{H}^2\text{O}$, obtained in like manner with bismuth acetate, is also a white precipitate. *Uranic salts*.—The *basic salt*, $\text{UO}^3 \cdot \text{WO}^3 \cdot 2\text{H}^2\text{O}$, is a yellow amorphous sparingly soluble precipitate; the *normal salt*, $\text{UO}^3 \cdot 3\text{WO}^3 \cdot 5\text{H}^2\text{O}$, is a yellow amorphous precipitate (Lefort).

Lanthanum Tungstate, $\text{La}^2\text{O}^3 \cdot 3\text{WO}^3$, obtained on mixing sodium tungstate with a lanthanum salt, is a colourless gelatinous precipitate which dries up at the heat of a water-bath to a thick white crust, soluble in acids. The *didymium salt*, $\text{Di}^2\text{O}^3 \cdot 3\text{WO}^3$, is obtained in like manner as a gelatinous precipitate, which dries up to a transparent rose-coloured mass (Frerichs a. Smith, *Liebig's Annalen*, xcxi. 331).

Native Tungstates.—Wolfram and Scheelite, occurring at Meymac, Département Correze, France, have been analysed by A. Carnot (*Compt. rend.* lxxix. 637). 1-3. *Wolfram*. Sp. gr. = 6.54. 1 and 2. Black shining fragments with brown streak. 3. Laminar black, with greyish veins; streak grey. 4 and 5. *Scheelite*:

	WO^3	FeO	MnO	CaO	MgO	Ta^2O^5	Gangue	H^2O
1.	74.75	16.17	6.40	0.40	0.17	0.95 ⁽¹⁾	1.12	= 99.96
2.	74.25	15.85	6.51	0.80	0.04	1.10 ⁽¹⁾	—	0.70 = 99.25
3.	72.67	14.70	3.38	0.70	trace	0.90 ⁽¹⁾	4.00	1.55 = 97.90
4.	74.50	1.05	0.30	18.70	—	—	5.20	= 99.75
5.	74.20	1.51	0.35	18.84	—	0.40	4.24	= 99.54

(¹) In other specimens the proportion of Ta^2O^5 rose to 5 per cent. (²) Fe^2O^3 . (³) Mn^2O^3 .

On the Crystalline Form of Wolfram, see Jeremejew (*Jahrb. f. Min.* 1873, 421); Groth a. Arzruni (*Pogg. Ann.* cxlix. 235); Krenner (*Jahrb. f. Min.* 1875, 648); also *Jahresb. f. Chem.* 1873, 1184; 1875, 1232.

On *Platinotungstates*, see PLATINUM (p. 1656).

TURMERIC. This substance may be detected in rhubarb and mustard by exhausting these latter with absolute alcohol and mixing the yellow filtrate with borax. If turmeric is present, the solution acquires a deep red-brown colour, the intensity of which is scarcely diminished by addition of hydrochloric acid (Maisch, *Dingl. pol. J.* cxxviii. 80). L. Howie (*Arch. Pharm.* [3], v. 251) places the pulverised mustard or rhubarb on white paper, and moistens it with a few drops of chloroform. This liquid on evaporating leaves the powder surrounded with a yellow ring of various depths of colour; and on placing thereon a drop of concentrated borax solution and a drop of hydrochloric acid, the presence of turmeric will be detected by the production in a few seconds of a decided red colour, changing on addition of potash-ley to a black or greenish-black.

TURNERITE. The native cerous phosphate called by this name has been shown to be identical with monazite. See PHOSPHATES (p. 1599).

TURNBULL'S BLUE, $\text{Fe}^3(\text{CN})^{12}$. On the occurrence of this pigment in commercial Prussian blues, see FERROCYANIDES (p. 614).

TURPENTINE. See TERPENES (p. 1901).

TURQUOISE. H. Bucking (*Jahrb. f. Min.* 1878, 655) has examined turquoises from the Megara Valley, Sinai, Nicabar in Persia, Moses Well in Arabia, Steine in Silesia, Oelsnitz in Saxony, and Silver Peak, Columbus District, Nevada. The nature of the colouring matter in these turquoises has not been determined with certainty. The mass is for the most part homogeneous, made up of very small double-refracting particles, and when examined by ordinary light, exhibits darker-coloured annular portions in some specimens only (especially those from the Megara Valley); in polarised light, on the other hand, especially in specimens exhibiting incipient decomposition, chalcedony-like particles having a concentrically scaly structure may be detected most abundantly in the German specimens. The so-called 'Persian turquoise' lately introduced into commerce, and often regarded as an artificial product,

approaches most nearly to the American, and may be recognised as genuine by the brown hematite which adheres to it and penetrates the mass; it is perhaps a particularly fresh variety from Nicabur. Sections of turquoise when heated turn first green, then black, and finally brown, a reaction which indicates copper phosphate as the admixed pigment. According to J. J. Pohl (*Jahrb. f. Min.* 1878, 364; *Chem. Soc. J.* xxxvi. 209), genuine turquoises may be distinguished with certainty from imitations by the decrepitation which they exhibit when heated.

TYROLEUCINE. See PROTEIDS (p. 1682).

TYROSINE, $C^9H^{10}NO^3$, probably $C^9H^4(OH).C^2H^3(NH^2).COOH$. This compound occurs, together with aspartic acid, glutamic acid, and leucine, in pumpkin-sprouts (Schulze a. Barbieri, *Ber.* xi. 710); also in yeast (Schützenberger, *Compt. rend.* lxxviii. 943). It is formed, together with leucine and volatile fatty acids, by the action of melting potash on albumin, but is decomposed if the action be prolonged, with formation of phenol (Nencki, *J. pr. Chem.* [2], xvii. 97). It is also produced in the decomposition of albumin and gelatinous substances by pancreatic ferments in closed vessels (Jeanneret, *ibid.* xv. 353). On its formation from proteids by heating with baryta-water, see p. 1682. By fusion with sodium hydroxide it is converted into para-hydroxybenzoic acid (Ost, *J. pr. Chem.* [2], xii. 159). By oxidation with potassium permanganate in ammoniacal solution, it is converted into ammonium carbamate (Drechsel, *ibid.* xii. 417).

Copper-tyrosine, $(C^9H^{10}NO^3)_2Ca$, obtained by adding cupric hydrate to a saturated solution of tyrosine, crystallises in shining needles soluble in 1230 pts. cold and 240 pts. boiling water (F. Hofmeister, *Liebig's Annalen*, clxxxix. 6).

U.

ULMIC SUBSTANCES. On the relation of these bodies to the Azo-compounds, see DIAZOXYBENZOIC ACID (p. 278).

On the formation of Ulmic substances from Sugar by the action of Acids, see Sestini (*Gazz. chim. ital.* 1880, 121; *Chem. Soc. J.* xxxviii. 538).

On the formation of a black liquid resembling the ulmic compounds by the electrolysis of a 5 per cent. solution of ammonia with a cathode of platinum and an anode of gas-carbon, see Millot (*Compt. rend.* xc. 611; *Chem. Soc. J.* xxxviii. 482).

ULMUS. The flowers of the common elm (*U. campestris*) have been analysed by A. H. Church (*Journal of Botany*, March 1876; *Arch. Pharm.* [3], x. 60). The female flowers gathered in May gave, after drying, 8.15 per cent. ash and 3.31 nitrogen. 100 pts. of the ash contained:

	CaO	K ² O	P ² O ⁵	SO ³	SiO ²	
	13.95	29.27	11.95	16.39	5.57	
100 pts. of the dry flowers yielded:

ULTRAMARINE. *Manufacture and Constitution.*—From an examination of the influence of the relative proportions of silica and alumina on the formation of ultramarine, C. Böttger (*Liebig's Annalen*, clxxxii. 305) infers that these proportions may vary within somewhat wide limits without making any essential difference in the quality of the product, provided that a certain proportion between the silica and sulphur be not exceeded.

A series of experiments on the influence of varying proportions of soda to sulphur led to the conclusion that ultramarine may be regarded as the last term of a series of molecular compounds of an aluminium silicate with a sodium silicate in which the oxygen is more or less replaced by sulphur. The same view is taken by Fürstenau (*Dingl. pol. J.* cccix. 269), who also finds that only two aluminium silicates are adapted for the preparation of ultramarine, viz. $4Al^2O^3.9SiO^2$ and $Al^2O^3.3SiO^2$. These, when treated with di- or pentasulphide of sodium, give pigments having the following properties: (a) $4Al^2O^3.9SiO^2$ with Na^2S^2 : pure clear blue, but with little colouring power; (b) $4Al^2O^3.9SiO^2$ with Na^2S^3 : pure dark blue, with great colouring power; both these products are free from alum. (c) $Al^2O^3.3SiO^2$ with Na^2S^2 forms a light reddish somewhat dingy-coloured product; and (d) with Na^2S^3 , a product having a dark violet-blue colour and great tinctorial power; both these ultramarines contain alum.

In selecting a kaolin for the preparation of ultramarine, care must be taken that it does not contain any untempered clay or finely divided stony matter, as such clays always yield muddy colours. The proportion of silica may be adjusted by addition of very finely ground and levigated quartz and ignited siliceous earth (*Kieselguhr*). The following proportions have been found to give good results: (1) for blue wares: $4\text{Al}^2\text{O}_3, 9\text{SiO}_2 + 8\text{Na}^2\text{CO}_3 + 8\text{C} + 14\text{S}$, and (2) for reddish aluminiferous strongly colouring sorts: $\text{Al}^2\text{O}_3, 3\text{SiO}_2 + 4\text{Na}^2\text{CO}_3 + 8\text{C} + 16\text{S}$. If in the first of these mixtures the sodium carbonate be replaced by sulphate and charcoal (so that the oxygen is given off as carbon oxide), light colours with little tinctorial power will be produced.

Whether the calcination is performed in reverberatory furnaces or in pots, a single burning is not sufficient to produce a perfectly blue ultramarine. For this reason, three-staged furnaces have come into use, the lowest stage being used for the ignition, the other two for the blue-burning and drying. A charge of 30 to 35 cwt. requires eighty-six hours' heating before raking out, and ten days for cooling. A reverberatory furnace yields about 15 cwt. of blue ultramarine in fourteen days. To obtain a purer product in shorter time, Fürstenau proposes to conduct the process in a pot-furnace capable of holding from 64 to 80 kg. of the mixture. This furnace may be raked out after eight hours at the latest, requires two days for cooling, and yields 25 cwt. green ultramarine convertible into 18.57 cwt. blue, the rate of production being 47 cwt. blue in fourteen days. The green product is converted into the blue by roasting with sulphur in the usual way.

The relation between blue and green ultramarine has been investigated by J. Philipp (*Ber.* ix. 1109). When green ultramarine is heated with water at 100° in sealed tubes, it assumes a fine bright blue colour; its weight, however, remains nearly the same—the water taking up only a small quantity of sodium compounds—and its composition is unaltered. Moreover, the sulphur exists in the same state in blue ultramarine prepared in the wet way as in the green ultramarine from which it has been produced. The formation of blue ultramarine is therefore in no way dependent upon the oxidation of sulphur, but the difference between the two ultramarines is due to the presence in the green substance of a small quantity of sodium sulphide, either mechanically mixed or chemically combined, on the removal of which the blue colour appears. Green ultramarine may indeed be actually formed by fusing blue ultramarine with sodium sulphate and charcoal.

Comparative analyses of Blue, Green, and Violet Ultramarine have been published by E. Dollfus and F. Goppelsröder (*Bull. de Mulhouse*, 1875, Mai; *Dingl. pol. J.* cxxx. 337, 431).

	Green	Blue	Violet
Silicon	17.963 p. c.	19.160 p. c.	20.440 p. c.
Aluminium	17.702	13.925	12.735
Sodium as Na_2O	10.487	10.088	11.110
Potassium	0.420	—	—
Sulphur as SO_3	0.292	0.500	0.877
Sulphur as SO_2	0.213	0.441	0.834
Sulphur as S^2O_3	—	0.469	2.536
Sulphur as Na_2S	3.718	3.057	1.165
Free sulphur	3.491	8.977	6.964
Sodium as Na^2	5.345	4.395	1.676
Oxygen	40.363	38.984	41.748
	99.994	99.996	100.085

The behaviour of these three ultramarines to various reagents is given in the following table (p. 2070) in which the numbers placed after each colour denote the more or less rapid progress of the action. 0 denotes no reaction; 1, slow; 2, moderately quick; 3, quick; 4, very quick.

A violet ultramarine from the Vienna exhibition has been examined by Lussy (*Ber.* viii. 979). It appeared homogeneous under the microscope, was acted upon by acids and by alum solution, but resisted the action of ammonia and sodium carbonate. Caustic soda extracted sulphur and silica from it, and changed its colour to blue. Previous to quantitative analysis it was exhausted with water, which dissolved out 12.85 per cent. sodium sulphate without altering the colour. Thus purified, it gave:

SiO_2	SO_3	Al^2O_3	Na_2O	CaO	$\text{S}^{(1)}$	$\text{S}^{(2)}$
47.23	1.88	20.93	19.28	1.97	0.82	9.25 = 100.36

(¹) Expelled as H_2S . (²) Determined as BaSO_4 in the residue.

100 pts. of this violet ultramarine lost by boiling with soda-ley 12·44 per cent. silica and 0·62 sulphur, and the residual mass exhibited exactly the composition and reactions of blue ultramarine.

According to R. Hoffmann (*Chem. Industrie*, 1878, 304), blue and green (so-called white) ultramarine are converted, by the action of acids at high temperatures, or of salts which give up their acid at high temperatures, into purple-red or violet colouring matters, which when further heated with acids, with or without access of air, are converted into a red.

G. Scheffer (*Ber.* vi. 1450) observes that in the preparation of ultramarine a yellow body is sometimes produced, which, as the operation proceeds, is converted into red, violet, and then suddenly into blue ultramarine. The final product having been freed by water from sodium sulphate was found to contain 28·83 pts. yellow to 24·50 red, and 17·95–19·32 ultramarine. The undissolved masses contained :

	Yellow	Red	Blue
SiO ²	49·55	46·35	49·38–50·64
Na	8·97	9·33	11·90–12·00
Al ² O ³	22·13	23·20	20·95–26·95
Sa	13·22	13·96	14·02–13·46
Sb	12·27	12·15	12·00–11

Sa is the total quantity of sulphur; Sb the amount remaining after decomposition of the substance by hydrochloric acid. Free sulphur, removable by extraction with carbon sulphide or by roasting, is found only in the blue. E. Büchner (*Ber.* vii. 989) regards these yellow and red bodies as products of the decomposition of blue ultramarine at high temperatures.

According to Unger (*Ber.* v. 989), ultramarine contains nitrogen, and has the composition Al²Si²O³N², the sodium used in its manufacture being eliminated in the course of the reaction as sulphide and sulphate. The nitrogen is supposed to be derived partly from the air, partly from the sal-ammoniac with which the green ultramarine is sometimes heated to convert it into the blue. On the other hand, W. Morgan (*Ber.* vi. 24; *Chem. News*, xxvii. 39) and E. Büchner (*Ber.* vii. 989) were unable to separate nitrogen from ultramarine in weighable quantities, either by heating with acid sodium sulphate in a stream of carbon dioxide, or by fusion with ignited phosphorus-salt, or by ignition with soda-lime.

Büchner finds, by experiments in which sodium aluminate was ignited with sulphur and charcoal, with or without silica, that silica is essential to the production of ultramarine. The greater the proportion of silica in the mixture, the smaller is the quantity of sodium sulphate that can be extracted from the product. Büchner is therefore of opinion that the sulphur in ultramarine stands to the silica in closer relation than to the alumina or the soda. Mixtures of clay and sodium carbonate, heated in a stream of hydrogen sulphide or vapour of carbon sulphide, became green and afterwards blue when heated in a current of air. Finely pulverised natrolite, ignited in vapour of carbon sulphide, became black, but on subsequent heating in sulphurous oxide gas it became blue.

On the theory of the formation of Ultramarine, see R. Hoffmann (*Liebig's Annalen*, xciv. 1–22; *Chem. Soc. J.* xxxvi. 108–113).

Crystalline Structure of Ultramarine.—R. Hoffmann first observed that ultramarine possesses a crystalline structure (*Notizen für die Jury der Weltausstellung in Wien*, 1873). This was attributed by Büchner to the presence of crystalline quartz-sand. Grünzweig a. Hoffmann, however (*Ber.* ix. 864), have confirmed the existence of a crystalline structure in the ultramarine itself, and H. Vogelsang found a preparation received from those chemists to consist for the most part of single-refracting crystals belonging to the regular system. Hoffmann (*Ber.* ix. 868) further observes that these crystals, which have a green colour, are converted by calcination with sulphur into blue ultramarine without alteration of form.

Silver-ultramarine.—K. Heumann (*Ber.* x. 991; *Liebig's Annalen*, cci. 262–291), by acting on ultramarine with solution of silver nitrate, has obtained a yellow amorphous body consisting of a silver-ultramarine, in which one-third of the silver is present as sulphide, and two-thirds as aluminium-silver silicate. According to J. Philipp (*ibid.* 1227), silver nitrate acts both on the ultramarine itself and on the silicates with which it is mixed, producing a mixture of silver ultramarine with several argentiferous silicates. A dilute solution of zinc sulphate acts only on the admixed-silicates, but a concentrated solution having a higher boiling temperature acts both on these and on a small portion of the ultramarine itself.

Heumann has obtained *potassium, sodium, and lithium ultramarines* by fusing silver ultramarine with the iodides of the corresponding metals. The lithium-

compound has a fine blue colour, changing to green and afterwards to pink, when the compound is heated with sulphur in a current of air. By heating the blue lithium ultramarine in a current of hydrochloric acid and air, a red compound is formed, which becomes blue on exposure to sulphur vapour or hydrogen.

By long-continued digestion with an ammoniacal solution of silver chloride, blue sodium ultramarine is converted into a yellow compound, in which two-thirds of the sodium in the ultramarine have been replaced by silver. On exposure to hydrochloric acid gas, this product turns blue.

By the action of silver nitrate on green ultramarine at 120° , a yellow compound is obtained, which bears a strong resemblance to the silver ultramarine above described, but differs from it in yielding a green product on fusion with potassium iodide.

Ultramarines containing *alcohol-radicles* are formed by heating silver-ultramarine with alkyl iodides. The *ethyl-compound* is obtained—though not pure—by heating silver-ultramarine with excess of ethyl iodide in a sealed tube at 180° for fifty to sixty hours. It is a light grey or greyish-yellow powder, which when heated gives off ethyl sulphide, together with other products of decomposition, including sulphur dioxide. When, on the other hand, the ethyl-ultramarine is intimately mixed with sodium chloride and very cautiously heated, scarcely any ethyl sulphide is given off, but the mixture, previously grey, turns blue, reproducing ordinary ultramarine. Under these circumstances, ethyl chloride is also given off, the reaction being exactly analogous to the formation of silver chloride when silver-ultramarine is heated with sodium chloride. Similar ultramarines are formed by the action of amyl, allyl, and benzyl iodides; but the two former have not been obtained free from silver (De Forcrand, *Bull. Soc. Chim.* [2], xxxi. 161).

UMBELLIFERONE, or *Hydroxycoumarin*, $C^9H^6O^3 = C^6H^3(OH) \begin{array}{l} \diagup CH=CH \\ \diagdown O-CH \end{array}$.

This compound is found amongst the products of the dry distillation of the resin of larch-fungus (p. 1165). Its acetyl-derivative, $C^9H^5(C^2H^3O)O^3$, or an isomeric thereof, is formed by heating resorcylic aldehyde with sodium acetate and acetic anhydride (p. 1752).

UNDECANE, $C^{11}H^{24}$. This paraffin is formed, together with several of its homologues, lower and higher, by the action of strong sulphuric acid on the products of distillation of the fatty acids (Cahours a. Demarçay). See HYDROCARBONS (p. 1064); also by fractional distillation of the product obtained by the action of fuming sulphuric acid on that portion of the spongy mass remaining after the preparation of *enanthal* from castor-oil, which boils below 200° . Undecane obtained by this latter process boils between 180° and 185° (D. Amato, *Gazz. chim. ital.* 1872, 6).

UNDECOLIC ACID, $C^{11}H^{22}O^2 = C^{10}H^{21}.CO^2H$. *Undecylic acid*.—This acid, the eleventh member of the fatty series, is produced by heating undecylenic acid at 200° – 220° with hydriodic acid and amorphous phosphorus, and may be purified by treating the crude product with sulphurous acid, then with sodium in alkaline solution; distilling the separated acid under reduced pressure; dissolving the portion which distils at 227° – 230° (about 70 per cent.), in alcoholic ammonia; adding an alcoholic solution of lead acetate (which precipitates from 70–80 per cent. of the entire quantity), then adding water, and decomposing the precipitate with nitric acid.

Undecolic acid thus prepared is a colourless scaly mass, transparent immediately after solidification, but quickly exfoliating. It melts at 28.5° , and boils under 160 mm. pressure at 228° . It is insoluble in water, but dissolves very easily in alcohol and in ether. It does not exhibit the indifferent properties of palmitic acid, but on the contrary is somewhat strongly corrosive, and has at ordinary temperatures a not unpleasant odour, recalling that of caproic acid. Bromine acts very slowly on it, and only with the aid of heat.

UNDECOLIC ACID, $C^{11}H^{18}O^2$ (F. Krafft, *Ber.* xi. 1414). The potassium salt of this acid is obtained by heating dibromundecylenic acid (*infra*) with 2 mol. alcoholic potash in sealed tubes at 180° for three hours; and on decomposing this salt with a mineral acid, undecolic acid separates as a white crystalline precipitate. It melts at 59.5° , may be distilled without change under reduced pressure, dissolves readily in ether, alcohol, and carbon sulphide, very sparingly in water, from which, as well as from dilute alcohol, it crystallises on cooling in thin shining plates. It forms well-defined salts, mostly crystallisable and sparingly soluble. The *barium salt*, $(C^{11}H^{17}O^2)^2Ba$, forms warty crusts, soluble in 212 pts. water at 15.5° . By fusion with *potash*, undecolic acid is converted into a liquid fatty acid (probably *enanthylic acid*) boiling at 220° – 222° ; by *fuming nitric acid* into azelaic acid, $C^9H^{16}O^4$, which may in this way be most conveniently prepared.

The whole of the nitroamido-acids obtained by Griess from the uramidobenzoic acids may be represented by the following formulæ:

URAMIDOCAPROIC ACID, $C^7H^{14}N^2O^8 = NH^2.CO.NH.C^5H^{10}.COOH$. This acid appears to be identical in composition with a compound, crystallising in needles, which is obtained by fusing leucine with urea (F. Hofmeister, *Ber.* vi. 1278).

URAMIDOISETHIONIC ACID, $C^8H^8N^2SO^4 = NH^2.CO.NH.C^2H^4.SO^3H$. Syn. with TAUCROCARBAMIC ACID (p. 1892).

URAMIDOISOBUTYRIC or **ACETONYLURAMIC ACID**, $NH^2.CO.NH.C(CH^3)^2.COOH$. See ACETONYL-UREA (vii. 18).

URANIUM. *Atomic Weight*.—J. Donath (*Wien. Acad. Ber.* [2 Abth.], lxxix. April-heft) has determined the specific heat of uranoso-uranic oxide by means of Bunsen's ice-calorimeter (vii. 595), and finds it to be equal to 0.07979. Hence, assuming the specific heat of oxygen in solid compounds to be 0.25, that of metallic uranium must be 0.0421, a value which, when multiplied by the old atomic weight of uranium, 120, gives for the atomic heat the value 5.04, agreeing with the average atomic heat of the metals (6) much more nearly than the number 10.08 obtained with Mendelejeff's value (240) of the atomic weight of uranium. As, however, the matter cannot be regarded as quite decided, and there are many considerations which favour the adoption of the higher atomic weight, the uranium compounds about to be described will be represented by formulæ in accordance with it (compare vii. 1189).

The presence of Uranium in the sun has been demonstrated by Lockyer (*Proc. Roy. Soc.* xxvii. 279).

On the Fluorescence, Phosphorescence, and Absorption-spectra of Uranium-compounds, see LIEHT (p. 1195).

A process for the preparation of pure uranium-compounds, with especial attention to the separation of Vanadium, is described by C. Bolton (*Amer. Chem.* v. 363).

A method of separating uranium from the residues obtained in the titration of phosphoric acid (p. 1584) depending on the solubility of uranic phosphate in ammonium carbonate, and the complete precipitation of the phosphoric acid from the resulting solution by magnesia-mixture, is described by A. Gawalowski (*Zeitschr. anal. Chem.* 1876, 292; *Chem. Soc. J.* 31, 345). Another method is given by H. Strohmeyer (*Dingl. pol. J.* ccxxv. 56; *Chem. Soc. J.* xxxiv. 115).

Separation of Uranium from Iron and Chromium.—A. Ditte (*Compt. rend.* lxxxv. 281) effects this separation for quantitative analysis by precipitating the oxides with ammonia; igniting the dried precipitate in a stream of hydrogen; weighing the residue and igniting it in a stream of hydrogen chloride to distil off the iron as ferrous chloride; extracting the uranous oxide (UO²) from the weighed residue by nitric acid; and finally igniting the undissolved portion, and weighing it as chromic oxide.

The method of igniting the precipitated oxides in hydrogen, and distilling off the iron as chloride in a stream of hydrogen chloride, may of course be employed also for the separation of uranium from iron alone.

On the separation of Uranium from Chromium, see also CHROMIUM (p. 457).

A Chemico-technological report on Uranium-compounds is given by A. Paterna in Hofmann's *Entwicklung der chemischen Industrie*, p. 986.

OXIDES AND SALTS OF URANIUM.—1. **Dioxide** or **Uranous oxide**, UO². A hydrate of this oxide is obtained by the action of hydrogen dioxide on uranium nitrate, as a yellowish-white precipitate, which, when dried at 100°, has the composition UO².H²O (T. Fairley, *Chem. Soc. J.* xxxii. 319). When uranous oxide is added to a solution of *silver nitrate*, a precipitate of metallic silver is formed, the reaction, according to Isambert (*Compt. rend.* lxxx. 1087), taking place by two stages, an argentous and a uranous salt being formed in the first instance, and the argentous oxide being afterwards reduced, with formation of a uranyl salt, the green colour of the liquid changing at the same time to yellow:

The oxide Ur²O³ also throws down metallic silver from a solution of the *nitrate*, though very slowly.

Uranic Oxide and Uranyl-compounds (R. Sendtner, *Liebig's Annalen*, cxcv. 325).

Uranyl Selenates are obtained by dissolving uranoso-uranic oxide in dilute selenic acid, and evaporating the solution on the water-bath. The strongly acid concentrated liquid deposits, after some time, light yellow, tough, very deliquescent masses, having a wavelitic structure, and agreeing approximately in composition with the formula $(\text{UO}^2)\text{SeO}^4 \cdot \text{H}^2\text{SeO}^4 + 18\text{H}^2\text{O}$. At the same time there is formed another salt, $2(\text{UO}^2)\text{SeO}^4 \cdot \text{H}^2\text{SO}^4 + 12\text{H}^2\text{O}$, which is more permanent in the air, and crystallises more readily in greenish-yellow needles, which are difficult to dry, and easily effloresce. A saturated solution of uranic hydroxide in selenic acid dries up in the exsiccator to a varnish-like mass.

Uranyl-potassium Selenate, $(\text{UO}^2)\text{SeO}^4 \cdot \text{K}^2\text{SeO}^4 + 2\text{H}^2\text{O}$, is obtained by mixing a solution of uranic oxide in selenic acid containing the smallest possible quantity of free acid, with potassium selenate, and evaporating to the crystallising point, or better by adding potassium uranate to warm selenic acid as long as it continues to dissolve. The double salt crystallises from aqueous solution in granular crusts. *Uranyl-ammonium Selenate*, $(\text{UO}^2)\text{SeO}^4 \cdot (\text{NH}^4)^2\text{SeO}^4 + 2\text{H}^2\text{O}$, prepared in like manner, is very soluble in water.

Selenites.—*Uranyl-hydrogen Selenite*, $(\text{UO}^2)\text{SeO}^3 \cdot \text{H}^2\text{SeO}^3$, noticed by Berzelius (v. 229), may be prepared by adding uranic hydroxide to boiling selenious acid, whereupon a violent reaction takes place, and the hydroxide is converted into a lemon-yellow crystalline powder. The same compound is more abundantly produced by mixing uranyl chloride with selenious acid, and heating the mixture to boiling, whereupon it deposits a large quantity of the acid salt in yellow microscopic crystals.

Uranyl-potassium Selenite, $(\text{UO}^2)\text{SeO}^3 \cdot \text{K}^2\text{SeO}^3$, is obtained in greyish-yellow crystalline crusts insoluble in water, on saturating warm selenious acid with potassium uranate. The *ammonium salt*, $(\text{UO}^2)\text{SeO}^3 \cdot (\text{NH}^4)^2\text{SeO}^3$, prepared in like manner, forms microscopic crystals of a deeper yellow colour and likewise insoluble in water.

Uranyl Bromide, $\text{UO}^2\text{Br}^2 + 7\text{H}^2\text{O}$, is obtained, as already described (v. 942), by dissolving uranic hydroxide in strong hydrobromic acid, as a yellowish-brown mass which deliquesces on exposure to the air, and unites very readily with other metallic bromides, forming double salts which are most easily obtained by dissolving the corresponding uranates in hydrobromic acid. The *potassium salt*, $\text{UO}^2\text{Br}^2 \cdot 2\text{KBr} + 7\text{H}^2\text{O}$, crystallises in yellow-brown rhombic plates, which dissolve very readily in water but are decomposed thereby. The *ammonium salt*, $\text{UO}^2\text{Br}^2 \cdot 2\text{NH}^4\text{Br} + \text{H}^2\text{O}$, forms large rhombic plates, somewhat less stable than the potassium salt, but very much like it in other respects (Sendtner).

Uranic hydroxide dissolves in *hydriodic acid*, forming a dark-brown liquid, solidifying in the exsiccator to a brown-black mass which gives up free iodine, and after the removal of this body, yields nothing but the uranium iodide described by Rammelsberg (v. 945).

Tetroxide, UO^4 (T. Fairley, *Chem. Soc. J.* 1877, xxxi. 127). When hydrogen dioxide is added to a solution of uranyl nitrate or acetate, a yellowish-white precipitate is formed, which in presence of an excess of the uranyl salt is very stable, and may be dried without deposition even at 100° . The precipitation is prevented by the presence of salts of the alkali-metals, or of barium or calcium salts, as well as by a moderate excess of a strong mineral acid, especially sulphuric acid. The dried precipitate is a yellowish-white powder, dissolving in strong hydrochloric acid, with evolution of chlorine. When heated to a temperature somewhat below redness, it burns away with a glimmering light, giving off oxygen and leaving green uranic oxide. On treating it with alkalis, part of it is precipitated as uranic oxide, while another portion dissolves in combination with the alkali, forming a salt of peruranic acid, an acid analogous in composition to perchromic acid (i. 953). The composition of the air-dried compound is $\text{UO}^4 \cdot 6\text{H}^2\text{O}$; that of the compound dried at 100° is $\text{UO}^4 \cdot 2\text{H}^2\text{O}$. The mode of decomposition of this compound by alkalis, however, tends to show that its molecular weight is three times as great as that which is denoted by the latter formula, and that it must be regarded as a uranic salt of peruranic acid, $\text{UO}^6 \cdot 2\text{UO}^3 + 6\text{H}^2\text{O}$. The anhydrous tetroxide appears to be formed when the hydrogen dioxide is added to a large excess of uranic nitrate solution. In this case no precipitate is formed at first, and it is only after some weeks that a heavy white crystalline precipitate is deposited, having the empirical composition UO^4 . Higher oxides have not been obtained in the free state, but free peruranic acid, $\text{UO}^6 \cdot 2\text{H}^2\text{O}$, appears to exist in the precipitates which are formed by the slow decomposition of its salts.

Ammonium Peruranate, $\text{UO}^6 \cdot \text{UO}^3 \cdot (\text{NH}^4)^2\text{O} + 8\text{H}^2\text{O}$ or $2\text{UO}^4 \cdot (\text{NH}^4)^2\text{O}^2 + 8\text{H}^2\text{O}$, is thrown down on addition of alcohol to a solution of uranic nitrate mixed with hydrogen dioxide and excess of ammonia, as an orange-yellow precipitate easily soluble in

water and less alterable in contact with the air than the corresponding sodium or potassium salt. When alkaline hydroxides are added to a solution of this ammonium salt, uranic hydroxide is precipitated and peruranates are dissolved. Its solution gives precipitates with most metallic salts. The salt when heated smoulders away like tinder, and leaves a residue consisting of lower oxides of uranium.

Sodium Peruranate, $\text{UO}^6, 2\text{Na}^2\text{O} + 8\text{H}^2\text{O}$ or $\text{UO}^4, \text{Na}^4\text{O}^4 + 8\text{H}^2\text{O}$, is readily obtained by dissolving ordinary uranic hydroxide or the hydrate of the above-mentioned tetroxide in soda-ley, with addition of hydrogen dioxide. If the solutions are sufficiently concentrated, the sodium salt separates after a few seconds in yellow needles often united in stellate groups; if they are dilute, the separation may be effected by addition of a little alcohol. The crystals have a golden lustre when freshly prepared, but effloresce on exposure to the air, taking up carbon dioxide, and giving off oxygen. The salt forms precipitates with most metallic salts. When heated alone it gives off three-fourths of its water and 3 at. oxygen; when heated in a stream of carbon dioxide it gives off all its water. *Red sodium peruranate*, $\text{UO}^6, \text{UO}^3, \text{Na}^2\text{O} + 6\text{H}^2\text{O}$ or $2\text{UO}^4, \text{Na}^2\text{O}^2 + 6\text{H}^2\text{O}$, is formed when the minimum quantity of caustic soda is used, and separates on addition of alcohol, before the former salt, in the form of a deep-red oil, which slowly becomes crystalline.

Potassium Peruranate, $\text{UO}^6, 2\text{K}^2\text{O} + 10\text{H}^2\text{O}$ or $\text{UO}^4, \text{K}^4\text{O}^4 + 10\text{H}^2\text{O}$, prepared like the corresponding sodium salt, is a yellow-red or orange-red precipitate; it is even more unstable than the sodium salt, and rapidly absorbs carbonic acid from the air (Fairley).

URANOSPHÆRITE, $\text{Bi}^2\text{O}^3, \text{UO}^3 + \text{H}^2\text{O}$, and **URANOSPINITE** $\text{CaO}, 2\text{UO}^3, \text{As}^2\text{O}^5 + 8\text{H}^2\text{O}$. See URANIC ARSENATES (vii. 1190).

UREAS. See CARBAMIDES (pp. 388–401).

URECHITIS. The leaves of *Urechitis suberecta*, a poisonous plant growing in Jamaica, sometimes in clumps, but more frequently as a creeper, yield three active principles, which have been examined by J. Bowrey (*Chem. Soc. J.* xxxiii. 252), and are named by him *Urechitin*, *Crystallised Urechitoxin*, and *Amorphous Urechitoxin*; neither of them contains nitrogen.

Urechitin, $\text{C}^{28}\text{H}^{42}\text{O}^8$, obtained from the air-dried leaves by extraction with alcohol, crystallises in colourless hydrated needles, nearly insoluble in water and dilute alcohol, more readily soluble in ether, hot alcohol, amyl alcohol, chloroform, and glacial acetic acid. By strong acids it is decomposed like a glucoside. Strong sulphuric acid dissolves it, forming a yellow liquid, which gradually turns red and finally purple, the change of colour being accelerated by the addition of a trace of any oxidising substance. *Urechitin* is intensely bitter (even to the 40,000th degree of dilution) and very poisonous.

Crystalline urechitoxin, $\text{C}^{18}\text{H}^{20}\text{O}^5$, extracted from the leaves after drying at 100° , is more readily soluble than urechitin. It is bitter, poisonous, easily alterable, and is resolved by acids into urechitoxetin, and a substance which reduces cupric oxide. *Amorphous urechitoxin* resembles the crystallised modification, but has not yet been obtained pure.

The leaves of *Urechitis* are intensely bitter and very acid, and produce on the lips and tongue a sensation of being swollen and blistered; their powder applied to the nostrils produces violent sneezing. These active properties are possessed by all the green parts of the plant, and by the flowers, but exist very slightly, if at all, in the woody portions. The poisonous action is due to the presence of urechitin, the decomposition of which gives rise to urechitoxin.

URETHANES. See CARBAMATES, ALCOHOLIC (p. 384).

URIC ACID, $\text{C}^5\text{H}^4\text{N}^4\text{O}^8$. *Formation from Ammonia in the Animal Organism*. From experiments by W. Schröder (*Zeitschr. physiol. Chem.* ii. 228) it appears that ammonia, when introduced by the mouth into the bodies of poultry, in combination with carbonic acid, or with any organic acid that is easily oxidised in the circulation to carbonic acid and water, is for the most part converted into uric acid.

Oxidation.—1. When *iodine* is added to uric acid suspended in water, the uric acid disappears gradually, or more quickly on application of heat, and alloxan is found amongst the products, together with hydriodic acid and apparently also urea (F. Wurtz, *Compt. rend.* lxxvii. 1548). 2. When *bromine* is dropped into water in which uric acid is suspended, the latter is oxidised to isalloxanic acid, $\text{C}^4\text{H}^4\text{N}^2\text{O}^5$ (Magnier de la Source, p. 1127). 3. Uric acid, exposed in alkaline solution to the action of *atmospheric oxygen*, is converted into oxonic acid, $\text{C}^4\text{H}^2\text{N}^2\text{O}^4$ (Strecker, p. 1458). 4. Uric acid, treated in alkaline solution with the exact quantity of *potassium permanganate* required for its oxidation, yields allantoin in nearly

theoretical quantity. When the action takes place in the cold, 1 mol. permanganate oxidises 3 mol. uric acid, or 1 mol. uric acid takes up 3 at. oxygen. To ensure the quantitative fulfilment of the reaction, all rise of temperature must be avoided, and as soon as the colour of the permanganate has disappeared, the liquid must be filtered from the deposited manganese dioxide and supersaturated with acetic acid. The colourless liquid free from manganese, if left to itself in the cold for twenty-four hours, deposits the allantoin produced by the reaction (A. Claus, *Ber.* vii. 226). 5. By the action of *ammonium cuprate* in presence of potash, uric acid is resolved into urea and oxalic acid (O. Loew, *J. pr. Chem.* [2], xviii. 298).

The relation between uric acid and certain of its oxidation-products, which by their decomposition yield glyoxalyl-urea, may be represented according to L. Medicus (*Ber.* x. 544) by the following formulae

Estimation.—To estimate uric acid in urine, E. Salkowsky (*Zeitschr. anal. Chem.* 1877, 371) mixes 200 c.c. of the urine with an alkaline carbonate to strong alkaline reaction; adds after an hour 20 c.c. of strong sal ammoniac solution; and leaves the liquid to itself for forty-eight hours in a cool place. The precipitate having been washed two or three times on a weighed filter, this filter is filled with dilute hydrochloric acid; the liquid which runs through is collected, this treatment being repeated till the ammonium urate is completely converted into uric acid; and the filtrate is left to itself for six hours. The uric acid thus separated is added to the portion first precipitated, and the whole is twice washed with water, then with alcohol till the filtrate appears neutral, and dried at 110°. To the weight thus obtained it is necessary to add 0.030 (the weight of uric acid dissolved in 200 c.c. water). Thin urines must be evaporated down till they exhibit a specific gravity of 1.017–1.020.

On the Estimation of Uric acid in Urine, see also R. Maly (*Liebigs Annalen*, clxv. 315; *Jahresb. f. Chem.* 1873, 980; and Magnier de la Source, *Bull. Soc. Chim.* [2], xxi. 290; *Jahresb.* 1874, 1052).

Methyluric Acid, $\text{C}^5\text{H}^2(\text{CH}^3)\text{N}^4\text{O}^3$, is obtained by heating dry lead urate to 150°–160° with methyl iodide diluted with ether, and treating the product with hydrogen sulphide to remove lead. The hot filtrate, on cooling, deposits crystals of methyluric acid, which are purified by dissolving them in hot soda-ley, precipitating with hydrochloric acid, and recrystallising from boiling water. It forms thin prisms, fusible with decomposition at a high temperature, soluble in 250 pts. of boiling water, nearly insoluble in alcohol and ether. The aqueous solution reddens litmus. The ether dissolves in cold strong sulphuric acid, and is deposited in crystals when the solution is diluted. It dissolves easily in alkalis: alcohol throws down from the solutions dense precipitates of the alkali-salts, aqueous solutions of which precipitate many salts of the metals.

Alcohol added to a solution of the acid in potash throws down the salt $\text{K}^2\text{C}^5\text{H}(\text{CH}^3)\text{N}^4\text{O}^3 + 3\text{H}^2\text{O}$, and the corresponding sodium salt is obtained in like manner. A solution of the acid in hot baryta-water deposits on cooling tufts of delicate needles of the barium salt, $\text{BaC}^5\text{H}(\text{CH}^3)\text{N}^4\text{O}^3 + 3\frac{1}{2}\text{H}^2\text{O}$, and a similar salt is formed with calcium hydrate. The following salts are formed by boiling the acid with the respective carbonates and precipitating the resulting solutions with alcohol:—

A solution of the mono-barium salt mixed with sodium sulphate gives, on addition of alcohol, a precipitate of the salt, $\text{NaC}^5\text{H}^2(\text{CH}^3)\text{N}^4\text{O}^3, \text{H}^2\text{O}$. Moderately strong solutions of the alkali salts gelatinise on cooling.

Methyluric acid in alkaline solution, when oxidised with a dilute solution of potassium permanganate, yields methylallantoin, $\text{C}^4\text{H}^2(\text{CH}^3)\text{N}^4\text{O}^3$, which substance crystallises in monoclinic prisms resembling allantoin, and melts with decomposition at 225°. A silver compound, $\text{AgC}^4\text{H}^4(\text{CH}^3)\text{N}^4\text{O}^3$, is formed on adding silver nitrate and excess of ammonia to a hot solution of methylallantoin: it crystallises in short prisms soluble in hot water. Methylallantoin, heated with strong hydriodic acid, yields urea and methylhydantoin—

URIC ACID (DIMETHYL-)-UROSUCCINAMIDE. 2077

Methyluric acid is oxidised by potassium chlorate and hydrochloric acid in the manner indicated by the following equation, the products being urea and methylalloxan:—

Methylalloxan, boiled with strong nitric acid, yields methyl-parabanic acid, $\text{C}^6\text{H}(\text{CH}^3)^2\text{N}^2\text{O}^3$ (H. Hill, *Ber.* ix. 370, 1090; *Sill. Am. J.* [3], xii. 428).

Dimethyluric Acid, $\text{C}^6\text{H}^2(\text{CH}^3)^2\text{N}^4\text{O}^3$ (Mabery a. Hill. *Ber.* xi. 1329). This acid is best prepared by heating lead urate with a slight excess of methyl iodide diluted with an equal quantity of ether. The decomposition proceeds rapidly at 165° , and is completed in fifteen to twenty hours. The product of the reaction is boiled with water, the dissolved lead removed by sulphuretted hydrogen, and the crystals which separate out on cooling are recrystallised from hot water.

Dimethyluric acid forms small monoclinic prisms containing 1 mol. of water. From saturated solutions it sometimes separates at temperatures near 100° in thick prisms, pointed at both ends and anhydrous. It melts only at a high temperature, with partial decomposition and sublimation; dissolves in 200 pts. of boiling and 800 pts. of cold water, scarcely at all in alcohol, ether, and glacial acetic acid, easily in concentrated sulphuric and hydrochloric acids, and crystallises out on dilution.

Dimethyluric acid is bibasic. The *dipotassic salt*, $\text{K}^2\text{C}^6(\text{CH}^3)^2\text{N}^4\text{O}^3 + 4\text{H}^2\text{O}$, is formed on dissolving the acid in a small quantity of hot potash-ley, and separates, on addition of alcohol, in silky needles very soluble in water, very slightly soluble in alcohol. The *disodic salt*, $\text{Na}^2\text{C}^6(\text{CH}^3)^2\text{N}^4\text{O}^3 + 4\frac{1}{2}\text{H}^2\text{O}$, obtained in like manner, is still less soluble in alcohol. The *acid salts*, $\text{KC}^6\text{H}(\text{CH}^3)^2\text{N}^4\text{O}^3 + 1\frac{1}{2}\text{H}^2\text{O}$, and $\text{NaC}^6\text{H}(\text{CH}^3)^2\text{N}^4\text{O}^3 + 2\text{H}^2\text{O}$, are obtained by boiling the acid with aqueous potassium or sodium carbonate, and precipitating with alcohol. The *normal barium salt*, $\text{BaC}^6(\text{CH}^3)^2\text{N}^4\text{O}^3 + 3\text{H}^2\text{O}$, obtained by dissolving the acid in baryta-water, separates on cooling in flat transparent prisms, soluble with difficulty in cold water, more easily in hot. The *acid salt*, $\text{Ba}[\text{C}^6\text{H}(\text{CH}^3)^2\text{N}^4\text{O}^3]^2 + 3\text{H}^2\text{O}$, is obtained by boiling an aqueous solution of the acid with barium carbonate, and precipitating with alcohol.

Dimethyluric acid heated to 170° with strong hydrochloric acid is resolved into carbon dioxide, ammonia, methylamine, and glycocine, according to the equation

The preceding facts show that the two hydrogen-atoms in uric acid which are replaceable by metals are directly combined with two distinct nitrogen-atoms. If these two hydrogen-atoms be replaced by methyl, the two remaining hydrogen-atoms may then be exchanged for metals. This relationship finds a simple explanation only on the assumption that uric acid contains the group NH four times; and this requirement is fulfilled by two only of the various structural formulæ proposed

for uric acid, viz., by that of Medicus, $\begin{array}{c} \text{NH.CO.C.NH} \\ | \\ \text{CO.NH.C.NH} \end{array} \text{CO}$ (p. 2076), and by that of Fittig, $\text{CO} \begin{array}{c} \text{NH.C} \diagup \text{NH} \\ | \quad | \\ \text{N.HC} \diagdown \text{NH} \end{array} \text{CO}.$

Isouric Acid, $\text{C}^6\text{H}^4\text{N}^4\text{O}^3$ (perhaps = $\text{CO} \begin{array}{c} \text{NH} \text{---} \text{CO} \\ | \quad | \\ \text{NH} \text{---} \text{CO} \end{array} \text{CH} \text{---} \text{N} = \text{C} = \text{NH}$), is formed by mixing a concentrated boiling solution of alloxantin with a solution of cyanamide, and separates on boiling the mixture briskly as a heavy powder. Its solution in dilute potash-ley gives with excess of hydrochloric acid a gelatinous precipitate which, unlike that of uric acid, does not become crystalline when heated with hydrochloric acid. The same solution, like that of uric acid, gives with silver nitrate an immediate black precipitate. Isouric acid further resembles uric acid in being nearly insoluble in water and in exhibiting a faint acid reaction after boiling therewith (E. Mulder, *Ber.* vi. 1233).

URIMIDOSUCCINAMIDE, $\text{C}^8\text{H}^7\text{N}^3\text{O}^3 = \text{NH} \begin{array}{c} \text{CO.NH} \\ | \\ \text{CO.CH.CH}^2\text{CO.NH}^2 \end{array}$ (Guareschi, *Gazz. chim. ital.* 1876, 370). This substance, identical with Grimaux' *Malyuramide* (*Compt. rend.* lxxxi. 325), is formed by the action of urea on asparagine. It crystallises with great facility, melts with decomposition at 230° – 235° is insoluble in cold water, also in alcohol and in ether.

according to Guareschi, $\begin{array}{c} \text{CO.CH}^2\text{CH.CO.OH} \\ | \\ \text{NH.CO.NH} \end{array}$ *Malybureidic acid* (according to Grimaux)

is formed by heating the amide just described with acids (Guareschi), also by heating aspartic acid (2 pts.) with urea (1 pt.) at 125°–130° for eight hours (Grimaux). The solution of its ammonium salt gives with ferric chloride and a little ammonia a brown precipitate slightly soluble in acetic acid. The silver salt remains unaltered at 100°–110°. The barium salt, $(\text{C}^8\text{H}^5\text{N}^2\text{O}^4)^2\text{Ba} + 4\text{H}_2\text{O}$, gives off its water at 100°–120° (Guareschi); according to Grimaux, the air-dried salt contains 1 mol. H_2O . The acid treated with fuming nitric acid is converted into a crystalline body which is coloured yellow by alkalis, and decomposes with explosive violence when heated to 188° (Guareschi).

URINE. *Constituents.*—1. Thiocyanates. J. Munk (*Ber.* ix. 1799) observes that when the urine of men or dogs is distilled with hydrochloric or sulphuric acid, hydrogen sulphide and hydrogen cyanide may be detected in the distillate, and he attributes these products to the decomposition of a thiocyanate contained in the urine. By a quantitative estimation in the form of silver thiocyanate, he finds that 100 c.c. urine contains on the average 0.008 g. thiocyanic acid. The existence of thiocyanates in the urine of men, horses, oxen, rabbits, dogs, and cats has also been demonstrated by Gscheidlen (*Chem. Centr.* 1877, 88; *Jahresb. f. Chem.* 1877, 1001; *Chem. Soc. J.* xxxii. 205).

2. Acid Sulphuric Ethers are found in the urine of various animals. The amount of these ethers is considerable in the urine of herbivora, and in that of the horse it exceeds the quantity of sulphuric acid present as sulphates. The same ethers are normal constituents of man's and dog's urine, in which, however, they exist in much smaller quantities. The three principal sulphuric ethers of urine are the so-called 'phenol-forming,' 'indigo-forming,' and 'catechol-forming' substances, the last of which is found only in horse's urine.

The phenol-forming substance may be obtained in the crystalline state by simply evaporating horse's urine to a syrup, treating this with alcohol, and evaporating the alcoholic liquid to a thin syrup, which is left for some days in the cold. A brown crystalline mass is thus obtained, which, after recrystallisation from water, forms dazzling-white pearly plates, solutions of which exhibit a fine blue fluorescence. The crystals may be boiled with acetic acid without decomposition; when heated with strong hydrochloric acid they break up into phenol and acid potassium sulphate. They yield on analysis numbers agreeing with the formula of potassium phenylsulphate.

The urine of patients under treatment with phenol contains no trace of that substance in the free state, but after being warmed with hydrochloric acid, it yields considerable quantities of phenol. Such urine always contains a large proportion of acid sulphuric ethers, amounting to ten to fifteen times the quantity present in normal human urine.

Direct experiments with dogs showed that, after the introduction of phenol in sufficient quantity into the system, sulphates almost entirely disappeared from the urine, their place being taken by phenylsulphates. The urine contained only a trace of phenol, but much phenylsulphuric acid. Analogous results were produced by the administration of catechol. (E. Baumann, *Ber.* ix. 54; *Pföger's Archiv. f. Physiologie*, xii. 691; xiii. 285).

Cresols (*o*-, *m*-, and *p*-) are found in horse-urine as cresyl-sulphuric acids (Preisse, *Zeitschr. Physiol. Chem.* ii. 355).

3. Inosite. From experiments made by E. Külz on six persons, it appears that inosite occurs in the urine of healthy individuals after drinking large quantities of water. The occurrence of inosite in diabetes insipidus is not constant.

4. Allantoïn has been found in the urine of a dog fed on meat and fat. Hippuric acid also is found in small quantity in the urine of dogs fed on meat, the maximum amount being 1 pt. hippuric acid to 129 pts. urea (E. Salkowski, *Ber.* xi. 500).

5. Oxalates. From examination of forty-four specimens of urine, A. B. Prescott (*Chem. News*, xxxvii. 76) finds that urine which in the fresh state is free from calcium oxalate, frequently deposits oxalates after standing for five days.

Relative Weight of different Constituents of Urine.—The urine of a dog fed on meat alone was found to contain 14 pts. by weight of phosphoric acid to 100 nitrogen; that of a dog fed on potatoes and bread contained 20 to 30 phosphoric acid to 100

nitrogen. In healthy men from twenty to twenty-five years old, living on a sufficiency of mixed diet, the urine contains from 17 to 19 pts. phosphoric acid to 100 nitrogen; with pure meat diet the phosphoric acid decreases; with pure vegetable diet it increases. The proportion of the two constituents varies greatly also with the time of day and the state of health. The urine of healthy men contains to 100 pts. nitrogen, 12 to 14 sulphuric acid, 0.3 to 0.7 lime, and 0.6 to 1.0 magnesia (W. Zuelzer, *Ber.* viii. 1670).

Influence of various Substances on the Composition and Properties of the Urine.—

1. Benzoic acid. The urine of a dog whose food was mixed with benzoic acid was found by Baumstark (*Ber.* vi. 883) to contain a substance having the composition $C^8H^5N^2O$. This substance unites with acids, forming easily soluble salts; is precipitated by mercuric nitrate; yields sarcosolactic acid when treated with nitrous acid; and gives off half its nitrogen as ammonia when boiled with baryta-water, the other half probably as ethylamine, with separation of barium carbonate.

2. Orthonitrotoluene. This substance given to dogs in their food appears in the urine, partly as orthonitrobenzoic acid, but the chief product of its transformation is a crystalline substance having the composition $C^{14}H^{10}N^3O^{10} + 2\frac{1}{2}H^2O$, which may be regarded as a compound of urea with *uronitrotoluenic acid*, $C^{12}H^9NO^8$ (Jaffe; see p. 1994).

3. Salicylic acid. Sodium salicylate, introduced into the stomach of a dog, appears in the urine after forty-five minutes. In man it is quickly eliminated by the kidneys, appearing in the urine after twenty minutes (Blanchier a. Bochefontaine, *Compt. rend.* lxxxvii. 657).

4. Salicin, taken by the mouth, passes into the urine partly unaltered, partly decomposed, with formation of salicylic acid (Weith, *Ber.* x. 979).

5. Proteids. Many of these bodies, when introduced into the animal body by intravenous injection, remain there; others are eliminated in the urine, either unaltered or after undergoing various transformations. The urine after such injections is mostly alkaline (Béchamp a. Batus, *Ann. Chim. Phys.* [5], xiv. 512).

6. When urine voided after eating asparagus is distilled, an alkaline distillate is obtained having the characteristic odour of asparagus. Such urine contains a proportion of ammonia much above the normal amount; considerable quantities of succinic acid; also hippuric and benzoic acids, but no asparagine. This last substance must therefore have been decomposed, in passing through the organism, into succinic acid and ammonia, which appear in the urine (A. Hilger, *Liebig's Annalen*, clxxi. 308).

7. On the influence of Chloral Hydrate on the composition of the Urine, see UROCHLORALIC ACID (p. 2080).

Pathological Urine.—Markownikoff (*Ber.* ix. 1441, 1603) has found acetone and ethyl alcohol in *diabetic urine*, and is of opinion that these bodies are formed in the organism by a peculiar fermentation of glucose induced by an *acetone-ferment*. E. Reichardt found dextrin in the urine of diabetic patients who had been drinking the Carlsbad waters (*Arch. Pharm.* [3], v. 502). The urine of a *typhus patient* was found by A. Strumpell (*Zeitschr. anal. Chem.* xvi. 134) to contain thiosulphuric acid. Selmi (*Ber.* vii. 1463) finds that fresh urine voided after poisoning with phosphorus does not give off phosphine when treated with zinc and sulphuric acid, but that, after standing for twenty-four hours, it acquires an alliaceous odour, and then gives off phosphine when treated as above.

On the colouring matters obtained from the urine of a leprous patient, see UROSCOELEMATIN (p. 2080).

Detection and Estimation of various Substances in Urine.—1. Albumin. See PROTEINS (p. 389). 2. Blood (p. 337). 3. Indigo. To estimate this substance, E. Salkowski (*Zeitschr. anal. Chem.* 1877, 366), after oxidising the urine, renders it alkaline with caustic soda, whereby the indigo is precipitated together with phosphates, and extracts the indigo from the dried precipitate with chloroform. 4. Iodine may be estimated by acidulating the urine with hydrochloric acid, and titrating with a solution of palladious chloride, 10 c.c. of which are equivalent to 0.0119 g. iodine. The titration is best performed by measuring out 10 to 20 c.c. of the palladium solution, heating the liquid in a stoppered flask placed in the water-bath, and adding the urine-solution, previously brought to a definite volume, till all the palladium is thrown down as PdI^2 (A. Hilger, *Zeitschr.* 1873, 342; *Liebig's Annalen*, clxxi. 212). 5. Peptone. See PROTEINS (p. 1639). 6. Phenol may be detected by agitating the urine with petroleum-ether, which dissolves the phenol; and testing the solution with ferric chloride, bromine-water, chloride of lime with ammonia, mercuric nitrate with a small quantity of nitrous acid (Dragendorff, *Arch. Pharm.* [3], xii. 298).

7. Quinine may be detected by rendering the urine alkaline with ammonia, agitating with ether, which takes up the quinine, evaporating after addition of hydrochloric acid, and testing with chlorine-water, which, if quinine is present, brings out the well-known green coloration (Vitali, *Zeitschr. anal. Chem.* 1874, 476). 8. Urea. See CARBAMIDES (p. 389). 9. Uric acid (p. 2076).

URN-RESIN. This resin, which is of frequent occurrence in ancient tombs, has been examined by Hostman a. Flückiger (*Arch. Pharm.* [3], vii. 1). It consists of a dark-coloured amorphous mass, which softens at 100° without melting, and gives off an odour like that of storax. It burns with a smoky flame, leaving 1.58–1.65 per cent. ash, which does not effervesce with hydrochloric acid, has an alkaline reaction, and contains manganese. Petroleum-ether and alcohol dissolve but little of the resin, carbon sulphide rather more; ether takes up about 60 per cent. of it. The resin extracted by ether gave by combustion 72.77 per cent. carbon and 9.26 hydrogen. By dry distillation the resin yields a brown oil in which catechol can be detected. When fused with potash, it yields a quinone-like body. These results do not lead to any definite conclusion as to the origin of the resin, but they show that it is not identical with any of the resins in common use.

UROBILIN, syn. with HYDROBILIRUBIN (pp. 921, 1063). See further L. Disqué (*Zeitschr. physiol. Chem.* ii. 360; *Jahresb. f. Chem.* 1878, 1002).

UROCANINIC ACID. This name is given by Jaffe (*Ber.* viii. 811) to a substance having the composition $C^{12}H^{12}N^4O^4$, which he has obtained from dogs' urine. It reacts both as acid and as base, and melts at 212° – 213° , giving off water and carbon dioxide, and leaving a strong base, $C^{11}H^{10}N^4O$, called urocanine. This base dissolves readily in alcohol, sparingly in water, and forms a red pulverulent platinum salt which melts in hot water.

UROCHLORALIC ACID, $C^7H^{12}Cl^2O^6$. This acid was found in the urine of persons who had for some time taken 5 or 6 grams of chloral hydrate in the evening. It is extracted from the urine, after concentration and acidulation with sulphuric acid, by a mixture of alcohol and ether. It crystallises in colourless silky needles, dissolves in water, alcohol, and a mixture of alcohol and ether, but is insoluble in pure ether; forms well-crystallised salts with potassium, sodium, barium, and copper (v. Mering a. Musculus, *Ber.* viii. 662).

UROFUSCO- and URORUERO-HÆMATIN. Two peculiar colouring matters obtained by F. Baumstark (*Ber.* vii. 1170) from the urine of a patient suffering from Lepa. *Urorubrohematin*, $C^{28}H^{24}N^8Fe^2O^{22}$, is a blue-black light mass, insoluble in water, alcohol, ether, chloroform, and solution of common salt; soluble in the fixed alkalis and in ammonia, in alkaline phosphates and carbonates, and in acidulated alcohol; sparingly soluble in dilute sulphuric acid, and in solution of common salt acidulated with hydrochloric acid. The acid solution exhibits a characteristic absorption-spectrum. *Urofuscohematin*, $C^{28}H^{108}N^8O^{28}$, is black, pitchy, insoluble in water, alcohol, ether, chloroform, acids, and in solution of common salt, either neutral or mixed with hydrochloric acid; soluble in the fixed alkalis, ammonia, alkaline phosphates and carbonates, and acidulated alcohol.

URONITROTOLUENIC ACID, $C^{13}H^{15}NO^9$. An acid occurring, in combination with urea, in the urine of dogs to which orthonitrotoluene has been administered. See TOLUENES (NITRO-), (p. 1994).

UROXANIC ACID, $C^8H^8N^4O^6$. The potassium salt of this acid is formed when a solution of uric acid in potash-ley is left in contact with the air, but protected from access of carbonic acid. It decomposed when heated with ammonia at 60° , and the lead salt prepared from the viscid mass remaining in the retort has the composition of lead allantate (E. Mulder, *Ber.* viii. 1291).

USNIC ACID, $C^{18}H^{18}O^8$ (Paternò, *Ber.* ix. 345; *Gazz. chim. ital.* 1878, 225). This acid was discovered in 1840 by Knop in several lichens of the genera *Usnea*, *Parmelia*, *Evernia*, *Cladonia* and *Lecanora*; and nearly at the same time Rochleder a. Heldt observed its presence in *Cladonia rangiferina* and *Usnea barbata* (Fries). Stenhouse, in 1846, found usnic acid in *Evernia prunastri*, and obtained, by dry distillation of the crude acid, a new substance which he named *betaorcin*. Hesse, in 1861 (*ibid.* cxvii. 343), observed that the acid extracted from *Cladonia rangiferina* melted at 175° , and therefore regarded it as isomeric with Knop's usnic acid, distinguishing it as *beta-usnic acid* (v. 970; vii. 353, 1194); and in 1866 the same chemist, in examining *Usnea barbata* (Hoffm.), extracted from it a new yellow crystalline substance, deceptively like usnic acid in most of its properties, but differing from it slightly in composition, and melting at 195.4° (usnic acid at about 200°). This substance he designated as *carbusnic acid*, assigning to it the formula $C^{16}H^{16}O^8$, usnic acid being at that time generally regarded as $C^{18}H^{18}O^7$ (vi. 413).

The existence of beta-usnic acid was corroborated in 1870 by Stenhouse, who

moreover showed (correcting a former statement) that beta-orcin was a derivative, not of usnic acid, but of the acid extracted from *Cladonia rangiferina*, for which he proposed the name *cladonic* instead of beta-usnic acid.

The existence of the second acid (carbusnic) was supposed to be confirmed by the difference of the results obtained by Paternò and by Salkowski with the acids prepared from *Zeora sordida* and from *Usnea barbata*, Fr. (*Florida*, Hoffm.), notwithstanding that the supposition of Salkowski's acid being carbusnic acid was to a certain extent in contradiction to his own analyses of the salts of this acid, which gave for it an equivalent number (molecular weight) between 329.7 and 347.1, whereas the formula $C^{10}H^{16}O^8$ requires 372.

Finally, Hesse in his last memoir has re-examined the acid prepared from *Usnea barbata*, Hoffm., with results which he regards as confirmatory of those previously obtained. He is still of opinion that the lichen just mentioned contains an acid having the composition $C^{10}H^{16}O^8$, mixed perhaps with a small quantity of usnic acid. This conclusion is based on the result of two combustions of the acid, which gave, as a mean, 61.72 p. c. C and 4.42 H (the formula $C^{10}H^{16}O^8$ requiring 61.29 and 4.30), and on analyses of the potassium salt. This salt crystallises from alcohol of 93 p. c. in yellow flattened prisms containing 4.09 p. c. water and 9.46 potassium, and from dilute alcohol in beautiful pale-yellow leaflets containing 11.18 water and 8.97 potassium. These results agree tolerably well with the formulæ $C^{10}H^{15}KO^8 + H^2O(4.20H^2O \text{ and } 9.15K)$, and $C^{10}H^{15}KO^8 + 3H^2O(11.63H^2O \text{ and } 8.47K)$, and are regarded by Hesse as affording decided confirmation of the existence of carbusnic acid, $C^{10}H^{16}O^8$.

On the other hand, Paternò finds that usnic acid from *Zeora sordida*, from which he has prepared decarbusnein $C^{15}H^{16}O^5$, pyrousnic acid $C^{12}H^{12}O^5$, and other well-defined compounds, yields, when boiled with potassium bicarbonate in such quantity as to leave a little of the acid undissolved, a potassium salt which crystallises from water in a mass of yellow leaflets giving off 12.23 p. c. water at 110°; from alcohol of 93 p. c. in yellow prisms containing 4.82 p. c. water and 9.48 p. c. potassium (or 9.91 calculated on the dry salt); and from alcohol of 51 p. c. in pale yellow leaflets containing 12.19 p. c. water and 8.64 potassium (9.84 for the dry salt).

These results agree very nearly with those which Hesse obtained with the potassium salt of the acid prepared from *Usnea barbata* (Hoffm.), but they are more in accordance with the formula $C^{18}H^{17}KO^8$ for the dry salt, than with $C^{15}H^{15}KO^7$, which would correspond with $C^{18}H^{16}O^7$, the formula originally assigned by Paternò to usnic acid.

	$C^{18}H^{17}KO^8 + 3H^2O$			$C^{18}H^{17}KO^8 + H^2O$			
	Calc.	Paternò.	Hesse.	Calc.	Paternò.	Exp.	Hesse.
Water . . .	11.89	12.19	11.49	4.30	4.32	4.07	4.11
Potassium . . .	8.59	8.64	8.97	9.33	9.48	—	9.46
Anhydrous salt, $C^{18}H^{17}KO^8$.							
Potassium . . .		Calc.			Paternò.		
		9.75			9.91 and 9.84		

Knop also, in 1843, found in dried potassium usnate 9.16 p. c. potassium, which agrees better with $C^{18}H^{17}KO^8$ than with $C^{18}H^{15}KO^7$, the latter requiring 10.20 p. c. potassium.

On the other hand, the experiments of Paternò on the derivatives of the compound hitherto called usnic acid (extracted from *Usnea barbata* and *Zeora sordida*) have clearly shown that it has the composition $C^{18}H^{16}O^7$; and since this compound, when treated with alkalis, yields salts having the composition $C^{18}H^{15}M''O^7$, it must be inferred to be, not an acid, but an anhydride, a view which is confirmed by other facts and considerations. Thus the formation of carbusneide, $C^{15}H^{16}O^5$, and pyrousnic acid, $C^{12}H^{12}O^5$, from the compound $C^{18}H^{16}O^7$ (*infra*), may be represented by the equations—

Here the elimination of CO^2 from the compound $C^{18}H^{16}O^7$ is accompanied by assumption of the elements of water, which would not be necessary if this compound were really an acid containing the group CO^2 in the form of $CO.OH$, as in the transformation of benzoic, salicylic, and orsellinic acids into benzene, phenol, orcin, &c.

The experiments above detailed are sufficient to establish the identity of Hesse's carbusnic acid from *Usnea barbata*, Hoffm., with usnic acid. The carbusnic acid which Salkowski obtained from *Usnea florida*, Hoffm., is also identical therewith, inasmuch as Paternò has found that when boiled with aniline, it yields two compounds identical with those obtained from usnic acid, one melting at 142°, the other at 170°.

The acid regenerated from these compounds by hydrochloric acid is converted by heating with alcohol in a sealed tube into decarbusnein, $C^{15}H^{16}O^3$.

The so-called *usnetic acid*, $C^9H^{10}O^3$, recently found by Hesse in the mother-liquors of usnic acid from *Usnea barbata*, is regarded by Paternò as identical with decarbusnein.

Decarbusnein, $C^{15}H^{16}O^3$, obtained by heating usnic acid at 150° with three or four times its weight of alcohol, crystallises in yellow silky needles, which turn reddish in the air, melt at 175° , and decompose at a higher temperature. It dissolves in hot alcohol, sparingly also in water and in ether; does not colour ferric chloride, but when heated to 200° with alcohol and water, it yields an amorphous substance which colours ferric salts; acetyl chloride does not act upon it; nitric acid acts violently, forming oxalic acid. It reduces warm ammoniacal silver nitrate, with formation of an amorphous reddish-yellow substance.

Pyrousnic Acid, $C^{12}H^{12}O^5$, is prepared by gradually heating usnic acid to boiling with $2\frac{1}{2}$ pts. potash-solution in an atmosphere of hydrogen, and remains, on acidifying the brown solution with hydrochloric acid, then shaking it with ether, and leaving the ether to evaporate, in shining scales which melt with partial decomposition at 195° , and dissolve freely in alcohol and in boiling water. Its alkaline solutions rapidly absorb oxygen, turning green and ultimately brown. The ammoniacal solution quickly reduces silver nitrate.

UVIC ACID, CHO. Syn. with PYROTARTARIC ACID (p. 1724).

UVITIC ACID, $C^9H^8O^4 = C^9H^2(CO^2H)(CH^3)^3CO^2H$. *Symmetrical Methyl-isophthalic acid*. *Mesidic acid* (v. 970; vi. 821).—This acid, intermediate in composition between mesitylenic acid, $C^9H^8(CH^3)^3CO^2H$, and trimelic acid, $C^6H^2(CO^2H)^3$, is formed: α . By oxidation of mesitylenic acid (vi. 821); β . Together with uvitonic acid and other products, by heating pyroracemic acid with excess of barium hydrate, or by the action of heat on normal barium pyroracemate (p. 1717); probably also, together with oxalic acid and urea, by boiling pyruvil with baryta-water (p. 1718). β . By oxidation of methyl-diethyl-benzene and of ethyl-dimethyl-benzene (p. 1285).

Nitro- and Amido-uvitic Acids (Böttger, *Ber.* ix. 804). Uvitic acid heated for several days with a mixture of strong sulphuric and fuming nitric acids, yields two mononitro-derivatives, separable by their different degrees of solubility in water, together with dinitro-derivatives and several products of oxidation.

α -*Mononitrouvitic acid*, $C^9H^7(NO^2)O^4 + 2H^2O$, the chief product of the reaction, dissolves but very sparingly in cold water, a little more freely in boiling water, and crystallises in groups of needles or long prisms, melting at 226° – 227° , and containing 2 mols. water. Its potassium-salt is very soluble and forms microscopic needles containing 1 mol. of water. The barium salt dissolves but sparingly in hot water, and forms slender needles which lose 1 mol. water at 150° . The calcium salt, which is more soluble, crystallises in needles with 3 mols. of water.

β -*Mononitrouvitic acid* is much more freely soluble in water than the α -acid, and forms acute rhombohedrons, melting at 249° – 250° , and containing half a molecule of water. The two nitro-acids treated with tin and hydrochloric acid, yield the corresponding amido-acids.

α -*Amidouvitic acid* is insoluble in water and sparingly soluble in hot alcohol, from which it crystallises in small yellow needles, melting and decomposing at 240° . Its impure alcoholic solution shows a splendid greenish-blue fluorescence, but that of the pure acid is less beautiful and of a reddish-blue. When this acid is stirred up with water to a thick paste, and nitrous gas is passed into the mixture, it liquefies, and on addition of alcohol and ether, deposits the corresponding diazo-compound as a hygroscopic mass which quickly turns red on exposure to the air, and when heated with water yields a hydroxyuvitic acid (*infra*).

β -*Amidouvitic acid* forms a yellow crystalline powder or light-yellow needles; it is nearly insoluble in water, and melts, with decomposition, at 250° – 255° . The alcoholic solution of the impure acid exhibits a greenish-blue, the alcoholic-aqueous solution of the pure acid a fine reddish-blue fluorescence. The tin-salt of this acid is very sparingly soluble and is not decomposed by water. The β -amido-acid yields a moderately stable diazo-compound, which when heated with water is converted into β -hydroxyuvitic acid.

Hydroxyuvitic Acids, $C^6H^2(OH)(CH^3)(CO^2H)^2$. Two of these acids, α and β , are obtained, as already observed, by the action of boiling water on the corresponding

diazo-acids. As uritic acid has the symmetrical constitution 1 : 3 : 5, these two hydroxy-acids must be represented by the formulæ:

but it has not yet been ascertained which of these formulæ must be assigned to the α -acid (m.p. 285°), and which to the β -acid (m.p. 220°).

Another hydroxyuvitic acid (or more properly *hydroxyxylicidic acid*) is formed (as ethylic ether) by the action of chloroform on a mixture of ethylic acetosodacetate and sodium ethylate, or on the crude product of the action of sodium on acetic ether, which contains both these bodies. Its constitution, as already shown (p. 17), is represented by the formula:

By dry distillation of its calcium or barium salt it is converted into *meta*-cresol (Oppenheim a. Pfaff, pp. 17 and 1477).

UVITONIC ACID, $\text{C}^6\text{H}^{10}\text{O}^7$ (?). This acid is one of the products obtained by boiling pyroracemic acid with excess of barium hydrate, and probably also by the action of heat on barium pyroracemate (p. 1717). It is partly converted into uvitic acid when left in contact with the air, and completely by prolonged treatment with barium hydrate (Böttinger, *Ber.* ix. 336).

UVITONINIC ACID, $\text{C}^6\text{H}^8\text{NO}^4$. The acid ammonium salt of this acid is obtained as a precipitate, together with carbonic and acetic acids, by the action of alcoholic ammonia on pyroracemic acid. Its *barium salt* contains $\text{C}^6\text{H}^8\text{NO}^4\text{Ba} + 3\text{H}^2\text{O}$; the *silver salt*, $\text{C}^6\text{H}^8\text{NO}^4\text{Ag}^2 + \text{H}^2\text{O}$. The acid is not acted on by nitric acid. Chromic acid oxidises it to carbon dioxide, ammonia and acetic acid (Böttinger, *Ber.* x. 362).

V

VALERAL or VALERALDEHYDE, $\text{C}^5\text{H}^8\text{O} = \text{C}^4\text{H}^7\text{CHO}$. This compound is formed, together with methylisopropyl ketone, by the action of zinc chloride or phosphorus pentoxide on isopropylethylglycol (Flawitzky, *Ber.* x. 2240).

Valeral and *acetyl chloride* heated together at 100° in a sealed tube unite and form the compound $\text{C}^5\text{H}^{10}\text{O} \cdot \text{C}^2\text{H}^3\text{OCl}$, which is a liquid having a density of 0.987 at -17°, boiling at 118-128°, and gradually decomposed by water into acetic acid, hydrochloric acid, and valeral (Maxwell Simpson, *Proc. Roy. Soc.*, xxvii. 120).

Valeral and *chloral-ammonia* unite, with elimination of H^2O , forming the compound $\text{C}^4\text{H}^{12}\text{Cl}^3\text{NO} = \text{CCl}^3\text{CH} \begin{smallmatrix} \text{N}=\text{CH.C}^4\text{H}^9 \\ \text{OH} \end{smallmatrix}$

$\text{C}^4\text{H}^8\text{CHO} + \text{CCl}^3\text{CH} \begin{smallmatrix} \text{NH}^2 \\ \text{OH} \end{smallmatrix} = \text{H}^2\text{O} + \text{CCl}^3\text{CH} \begin{smallmatrix} \text{N}=\text{CH.C}^4\text{H}^9 \\ \text{H} \end{smallmatrix}$
(R. Schiff, *Ber.* xi. 1694).

Valeral and *benzidine* unite in the proportion of 2 mol. $\text{C}^5\text{H}^{10}\text{O}$ to 1 mol $\text{C}^{12}\text{H}^{12}\text{N}^2$, forming a sparingly soluble compound (H. Schiff, *Ber.* xi. 830).

Polymerides. The polymeric valeral $n\text{C}^5\text{H}^{10}\text{O}$, homologous with aldol, which Borodin obtained by the action of sodium, or of potassium hydroxide at 0°, on valeral (vii. 1196) has been further examined by the same chemist (*Ber.* vi. 982), also by Gäss a. Hell (*ibid.* viii. 369), and by Bruylants (*ibid.* 414). It is a colourless viscid liquid, which, when heated, is converted, with elimination of water, into a condensation-product, viz. an aldehyde $\text{C}^{10}\text{H}^{18}\text{O}$, and a neutral body $\text{C}^{20}\text{H}^{38}\text{O}^2$, together with valeral, the decomposition being exactly analogous to that of aldol under similar circumstances. The polymeric valeral further resembles aldol in depositing crystals when left for some time in contact with dilute soda-ley. This, however, does not always take place, and the amount formed and the rate of formation vary greatly in different experiments conducted apparently under precisely similar conditions; in fact, the conditions under which these crystals are produced have not yet been ascertained. The composition of the air-dry crystals is represented by the formula $(\text{C}^{10}\text{H}^{20}\text{O}^2)^n\text{H}^2\text{O}$. When heated, they melt slowly to a colourless liquid, which, if not heated too long, solidifies to a crystalline mass on cooling. If it be heated above the melting point, decomposition takes place, valeral passing over first, then the aldehyde $\text{C}^{10}\text{H}^{18}\text{O}$, and finally the compound $\text{C}^{20}\text{H}^{38}\text{O}^3$; these products are obtained quite colourless, and no residue

remains in the retort. The crystals are similarly decomposed when heated with water or very dilute sulphuric acid; they are also decomposed, with loss of water, when exposed over sulphuric acid.

Gäss a. Hell obtain a polymeric valeral by prolonged contact of valeral with recently ignited potassium carbonate, the valeral thickening, and acquiring in a few days at ordinary temperatures, more quickly at 50° – 60° , the consistence of honey. This polymeride is permanent in sunshine, and does not unite either with ammonia or with alkaline bisulphites; by distillation or by heating in a sealed tube it is reconverted into ordinary valeral. Its consistence varies with the temperature; at 60° – 70° it is comparatively mobile, but at -45° it is so viscid as to be no longer capable of running; it does not however solidify completely. Bruylants, on the other hand, by pressing the thickened mass between paper, after washing it with water, obtained a solid body, which, after recrystallisation from ether, formed slender silky needles, having the percentage composition of valeral, and yielding a vapour having the density of that substance, showing that the polymeride undergoes dissociation when heated. The crystals are insoluble in water, but dissolve readily in alcohol, still more readily in chloroform and carbon bisulphide. They melt at 83° – 84° , and decompose at a higher temperature, yielding a liquid which unites like an aldehyde with bisulphites and silver-solution, and does not easily resolidify on cooling.

Condensation-products of Valeral (Gäss a. Hell, *Ber.* viii. 369). These are obtained by boiling valeral with solution of potassium carbonate. The liquid, which at first is turbid, becomes clear after about two hours' boiling, the reaction being then complete. The change affects, however, only about half the quantity of valeral present, which is thereby converted into products of higher boiling point, the other and somewhat larger portion remaining unaltered. The residue left after distilling off this unaltered valeral is resolved by fractionation into three portions, the largest, which boils at 187° – 191° (189.9° – 194° corr.) under a pressure of 742 mm., having the composition $C^{10}H^{18}O = 2C^5H^{10}O - H^2O$; the second, which is much smaller in quantity and boils at 235° – 240° , being represented by the somewhat doubtful formula $C^{18}H^{38}O^2 = 3C^5H^{10}O - H^2O$; while a third, which boils apparently at 265° – 270° , has the composition $C^{30}H^{58}O^3 = 4C^5H^{10}O - H^2O$, and is resolved by prolonged distillation into water, the compounds above mentioned, and others of higher boiling point.

A condensation-product having the formula $C^{20}H^{40}O^3$ was obtained by Borodin, who, however, describes it as boiling without decomposition (vii. 1196). The body $C^{10}H^{18}O$ was previously obtained by Riban and by Kekulé (*loc. cit.*) Gäss a. Hell describe it as a yellowish oil, which gradually becomes colourless on exposure to light and assumes a viscid consistence at low temperatures, but does not solidify completely even at -45° . Sp. gr. = 0.861 at 0° , 0.851 at 14° , referred to water at 0° . The compound has a strong odour like that of amyl valerate, and is insoluble in water, but dissolves readily in alcohol and ether. It does not unite with ammonia, nor (contrary to Borodin's statement) with bisulphites; but it reduces silver oxide on boiling, also an ammoniacal solution of silver. It acts violently on phosphoric anhydride, forming hydrocarbons of the formula nC^5H^8 ; with bromine it yields an oily product. It is not attacked by water even at 250° . By boiling with alcoholic potash it is converted partly into valeric acid, but for the greater part into a brown viscid condensation-product, apparently $C^{30}H^{52}O^2$, which cannot be distilled either alone or with vapour of water.

Valeral-ammonia, $C^5H^{10}O.NH^3 = C^4H^9.CH(NH^2)OH$ (Ljubavin, *Ber.* vi. 1460). This compound is formed immediately by the action of ammonia on pure valeral, slowly, on the other hand, when impure valeral is used. In the fused state it may be dehydrated by solid caustic alkalis without decomposition. It is decomposed by alcohol of 95 per cent. The dry compound, when distilled, first gives off a large quantity of ammonia, then at 250° a mixture of valeral-ammonia and Erdmann's trioxamylidene or trioxamylamine, $(C^5H^{10}O)^3.NH^3$ (v. 886); the same products, together with valeral, are formed on distilling valeral-ammonia with aqueous vapour at 100° , also on boiling valeral-ammonia with potash. The alcoholic solution of valeral-ammonia, when left to itself for some time, likewise yields trioxamylamine. This base, treated with hydrochloric acid, forms white flocks, melting at 112° – 113° and consisting of a mixture of $C^{15}H^{33}NO^3.HCl$ and $C^{15}H^{31}NO^2.HCl$.

Valeral-xanthamide,

On adding hydrochloric acid to a mixture of xanthamide and valeral, a glutinous mass is formed, which on addition of a small quantity of alcohol breaks up without dissolving, and yields with water a yellowish white or pure white crystalline powder made up of small indistinct cohering laminæ. This is the compound above formu-

lated. It has a faint, peculiar odour, dissolves but sparingly in ether, more readily in alcohol, and melts at 108° . When heated in the dry state it emits an odour of mercaptan, and at the same time gives off ammonia and cyanic acid, and finally strongly alkaline vapours having an intensely repulsive odour (C. Bishoff, *Ber.* vii. 1078).

VALERIC ACID. $C^5H^{10}O^2 = (CH^3)^4CH.CH^2.COOH$. *Isopentioic, Isopropylacetic, Isobutylformic Acid.*—See PENTOID ACIDS (p. 1500). The properties of this acid and of several of its salts and derivatives have lately been fully investigated by E. Schmidt and R. Sachtleben (*Liebig's Annalen*, xciii. 87). The acid was prepared by a slight modification of Erlenmeyer and Hell's process, in which isobutyl cyanide is decomposed by alcoholic potash (vii. 1197). The free acid boils at 175° under a pressure of 754.8 mm. Sp. gr. 0.93087 at 17.4° . It is optically inactive.* Its salts are partially converted into basic compounds on keeping; their aqueous solutions have a slightly acid reaction. The alkaline and alkaline-earth salts are easily soluble in water, but those of the heavy metals are difficultly soluble, and generally moresoluble in cold than in hot water. The *calcium salt*, $(C^5H^9O^2)^2Ca + 3H^2O$, is more soluble than that of active valeric acid, and is not so prone to form basic salts. The *manganese salt*, $(C^5H^9O^2)^2Mn + 2H^2O$, the *zinc salt*, $(C^5H^9O^2)^2Zn + 2H^2O$, and the *copper salt*, $(C^5H^9O^2)^2Cu$, are more soluble in cold than in hot water. *Quinine isobutylformate*, $C^{20}H^{34}N^2O^2.C^5H^{10}O^2$, closely resembles the active valerate. *Methyl isobutylformate*, $C^5H^9O^2.CH^3$, is a colourless liquid with a pleasant fruity odour (b. p. 117° at 763.8 mm.) Sp. gr. at $17^{\circ} = 0.885465$.

Isobutylformamide, $C^5H^9O.NH^2$, is prepared by heating the methylic ether with a mixture of aqueous and alcoholic ammonia for five hours at 120° in sealed tubes, and evaporating the product over sulphuric acid. It crystallises in silky plates (m. p. 135°), which are easily soluble in water and alcohol, and can be sublimed.

Isobutylformanilide, $C^5H^9O.NH(C^6H^5)$, is obtained by boiling the acid and aniline together in molecular proportions for two days. It is sparingly soluble in hot water, but dissolves easily in alcohol or ether. It sublimes when heated, and volatilises in a current of steam (m. p. 100°).

Bromisobutylformic acid seems to be formed when isobutylformic acid is heated with bromine at 140° , but it has not been obtained pure.

Amido-isobutylformic acid (Isopropylglycocine), $NH^2.C^5H^8.COOH$, is prepared by heating bromisobutylformic acid with 4 vols. of concentrated ammonia in sealed tubes for six hours at 130° , removing the ammonia by evaporation, digesting the residue with lead hydroxide until it ceases to smell of ammonia, collecting the precipitated lead bromide on a filter, and removing the lead in solution by sulphuretted hydrogen; the filtrate, on evaporation over sulphuric acid, solidifies to a yellow crystalline mass, which may be purified by washing with a mixture of alcohol and ether and crystallisation from alcohol.

Amido-isobutylformic acid crystallises in colourless plates, which are easily soluble in water, but difficultly soluble in alcohol and ether. When heated, it volatilises without melting. In these properties it agrees entirely with Clark and Fittig's amido-valeric acid (v. 278).

Hydroxyisobutylformic acid, $C^5H^8(OH).COOH$, is obtained by boiling bromisobutylformic acid with a slight excess of concentrated potash for a short time. After separating the potassium bromide and acidifying with strong hydrochloric acid, a yellow oil separates, which consists essentially of isobutylformic acid; this is removed, and the hydroxyisobutylformic acid extracted from the acid liquid by agitation with ether; on distilling off the latter, a yellow syrup remains, from which colourless crystals separate after some time. The acid may be purified by crystallisation from ether. Hydroxyisobutylformic acid (m. p. 82°) and its salts do not differ in any of their properties from those of the hydroxy-acid and salts obtained by Clark and Fittig (vi. 894) from ordinary valeric acid.

Ethylidene hydroxyisobutylformate, $C^5H^8O^3.C^2H^5$, is obtained by the action of ethyl iodide on the silver salt. It is a colourless liquid of pleasant odour, and is lighter than water, in which it is but slightly soluble. It boils at 175° with slight decomposition. Treated with phosphorus trichloride, it does not give an acid identical or isomeric with angelic acid, but amorphous phosphides and a highly chlorinated oil.

Valerolactide, $C^5H^8O^2$, is obtained when hydroxyisobutylformic acid is heated in sealed tubes at 200° for six hours, thus:— $C^5H^{11}O^3 = C^5H^8O^2 + H^2O$. It crystallises in white needles melting at 126° , boiling at 220° – 240° , insoluble in cold water, and melting in hot water to a colourless oil. It is easily soluble in alcohol and ether, and may be sublimed in silky needles. It is not attacked by dilute alkaline solutions.

* Active valeric or pentoic acid is methylethylacetic acid, $(OH^3)(C^2H^5)CH.COOH$ (p. 1501),

Trichlor-hydroxyvaleric or *Trichlorovalerolactic acid*, $C^3H^2Cl^3O^3$, formerly described by Pinner and Bischoff, forms the following salts:—The *sodium salt*, $C^3H^2NaCl^3O^3 + H^2O$, loses its water of crystallisation at 100° . The *ammonium salt* forms small granular crystals, and the *lead salt* is an amorphous precipitate. The *acetyl-compound*, $C^3H^2(C^2H^3O)Cl^3O^3 + H^2O$, which crystallises in white needles (m. p. 84°), is prepared by digesting the acid with acetic anhydride and pouring the product into cold water. It is insoluble in cold water, and is slowly decomposed by boiling with water. The anhydrous compound forms a thick uncrystallisable syrup.

Ethylric trichlorhydroxyvalerate, $C^3H^2Cl^3O^3.C^2H^3$, forms long prismatic crystals, which melt at 40° and boil at 255° . If this ether is dissolved in alcoholic ammonia, and the solution left at rest for several weeks, a white crystalline crust is formed, which consists of a mixture of ammonium chloride and the amide of *monochlorimidoangelic acid*, $C^3H^2ClN^2O$. This amide is soluble in hot benzene, and is reprecipitated by the addition of light petroleum to this solution; melts with decomposition at 118° . Platinum chloride and silver nitrate produce precipitates in the aqueous solution (Pinner & Klein, *Ber.* xi. 1488).

VALERITRINE, $C^{15}H^{27}N$. This base, obtained by heating 1 volume valeral with 2 volumes alcoholic ammonia at 150° (vii. 1200), has been further examined by Ljubavin (*Ber.* vi. 565). To purify it, the hydrochloride, which forms an uncrystallisable syrup, is mixed with caustic potash, and the base thereby set free is distilled off with steam, precipitated from alcoholic solution by picric acid, and again set free by an alkali.

Valeritrine is a colourless, very mobile liquid, having great dispersive power, boiling at 250° – 260° , easily soluble in alcohol, ether, and weak acids, nearly insoluble in water and aqueous alkalis. Its salts are mostly uncrystallisable, dissolve easily in water, and are decomposed by boiling therewith. The base is on the whole very stable, and is not decomposed by sodium even at 250° . The *platinochloride*, $(C^{15}H^{27}N.HCl)^2PtCl^4$, crystallises in transparent, brittle, orange-coloured granules, easily soluble in alcohol, sparingly in water and in ether; in boiling water it melts to an oil, which floats on the surface and gradually dissolves. The *mercuriochloride*, $C^{15}H^{27}N.HCl.HgCl^2$, forms rhombohedral crystals, which dissolve in boiling dilute alcohol and melt at 86° – 88° . The *picrate*, $C^{15}H^{27}N.C^6H^3(NO^2)^3O$, purified by crystallisation from warm alcohol, forms needles melting at 129° – 130° , sparingly soluble in cold, freely in warm alcohol.

VALEROLACTIDE, $C^8H^8O^3$. On the modification of this compound, formed by the action of heat on hydroxyisobutylformic acid, see p. 2085.

VALERYLENES, or **PENTINES**, C^5H^8 (see p. 1500). According to Boucharlat (*Compt. rend.* lxxxvii. 654), valerylene (which modification?), heated for about six hours at 250° – 260° in a sealed tube filled with carbon dioxide, is converted into a terpinene, $C^{10}H^{16}$, which, after several rectifications, has a density of 0.848 at 0° , and 0.836 at 15° , and distils at about 180° . The condensation of the same valerylene also gives rise to a trivalerylene, $C^{15}H^{24}$, which is found in the portion of the crude product distilling between 240° and 250° , and yields a monohydrochloride, which is completely decomposed by heat.

Methyl-ethylacetylene, $C^2H^3.C\equiv C.CH^3$, is obtained by the action of alkalis on methylethyl-ethylene bromide, $C^2H^3.CHBr.CHBr.CH^3$, and forms the portion of commercial valerylene which is insoluble in sulphuric acid. It boils at 51° (Eltékoff, *Bull. Soc. Chim.* [2] xxix. 210), and is converted by oxidation with chromic acid mixture into propionic and acetic acids.

Isopropylacetylene, $(CH^3)^2CH.C\equiv CH$. Flavitzky & Kriloff (*Ber.* x. 110; *Bull. Soc. Chim.* [2] xxix. 214) have prepared this modification of valerylene from the mixture of pentylenes obtained from amyl iodide, by heating the bromides of these pentylenes with alcoholic potash on a water-bath in a flask with reversed condenser. According to their observations it boils at 28° – 30° , not at 35° , as found by Bruylants and Eltekoff (p. 1500). By oxidation with potassium dichromate and sulphuric acid it yields acetone and lactic acid, and when treated with sulphuric acid it yields methylisopropyl ketone, $(CH^3)^2CH.CO.CH^3$, together with products of higher boiling point.

VALERYL-TRIMETHYLAMMONIUM CHLORIDE, $(C^5H^9)(CH^3)^3NCl$, is prepared by digesting trimethylamine with commercial amylene chloride for several days at 50° – 60° . It is very hygroscopic, and forms a *platinum salt*, $(C^5H^9NCl)^2PtCl^4 + H^2O$, which crystallises in hemispherical groups of irregular laminae. The *gold salt*, which is anhydrous, melts when heated, without loss of weight, and solidifies in the crystalline state on cooling (Harnack, *Chem. Centr.* 1876, 560).

VANADIUM. Atomic weight 51. Lockyer has detected this element in the sun by the coincidence of nine lines in the solar spectrum and in that of incandescent

vanadium (*Proc. Roy. Soc.* xxvii. 279). The presence of vanadium in a meteorite from Adare, County Limerick, has been demonstrated by R. Apjohn (*Chem. Soc. J.* xxvii. 104).

J. Walz (*Amer. Chemist*, vi. 453) has demonstrated the widely diffused occurrence of vanadium, especially in primary iron ores, having found it in all the American magnetic iron ores which he examined. He has also observed an intimate connection between the occurrence of vanadic and titanitic acid, all the ores which contain the latter in relatively large quantity being also proportionately rich in the former.

On the preparation of Vanadium from the uranium ore of Joachimsthal, see Paterna (*Dingl. pol. J.* cccxxxi. 556).

On the physiological action of Vanadium, see J. Priestley (*Proc. Roy. Soc.* xxiv. 40; *Jahresb. f. Chem.* 1877, 887).

On the industrial uses of Vanadium compounds, see J. Philipp (*Hofmann's Ent wicklung der Chemischen Industrie*, p. 836) and R. v. Wagner (*Dingl. pol. J.* cccxxiii. 631).

Estimation.—To estimate small quantities of vanadium in *silicates*, V. Roussel (*Compt. rend.* lxxvii. 1102) fuses the substance with sodium carbonate; oxidises it with a small quantity of nitre; exhausts the cooled and pulverised melt with boiling water; washes it completely; evaporates; precipitates with ammonium carbonate; filters; adds ammonium sulphide; leaves the liquid at rest for several days; again filters; adds hydrochloric acid, which throws down vanadium sulphide mixed with sulphur; and weighs the precipitate after expelling the free sulphur by ignition.

For the volumetric analysis of *vanadium sulphates* and double sulphates with alkali-metals, Gerland (*Ber.* x. 1216) reduces the vanadic acid by means of sulphurous acid to vanadium tetroxide, which is stable in acid solution, but is completely oxidised to vanadic acid by permanganate. On the other hand, vanadium tetroxide may be advantageously used for the titration of permanganate solutions.

To separate vanadium from *thallium*, Carnelley (*Chem. Soc. J.* xxvi. 323) mixes the solution of the two metals in sulphuric acid with a small quantity of sulphurous acid; precipitates the thallium with potassium iodide; evaporates the filtrate; fuses the residue with sodium carbonate; and saturates the aqueous solution of the melt with sal-ammoniac. The ammonium metavanadate which separates after twelve hours is washed, first with a saturated solution of sal-ammoniac, then with alcohol, and converted by ignition into vanadium pentoxide.

Vanadic acid may be separated from *alumina* by dissolving the compound (ardennite, for example) in a small quantity of hydrochloric acid, and digesting the solution for a short time on the water-bath with a few drops of phosphoric acid, whereby the aluminium vanadate is completely converted into aluminium phosphate, which may be completely precipitated by ammonia, while the whole of the vanadium remains in solution (Bettendorff, *Ann. Phys. Chem.* clx. 126).

Compounds of Vanadium.

Ethylchloride, $V(OC^2H^5)_2Cl^3$. This compound is formed by the action of ethyl oxide on vanadium oxychloride. Equal parts of ether and the oxychloride are digested for two or three hours in a closed vessel at 60° – 70° , and the lighter of the liquids thereby formed is distilled under a pressure of 160–200 mm., whereby the ethylchloride is obtained in shining needle-shaped crystals melting at a temperature below 20° . It is slowly decomposed by water into ethyl oxide, vanadium pentoxide, and hydrochloric acid, and changes spontaneously into a brown liquid even in a sealed tube (P. P. Bedson, *Chem. Soc. J.* xxix. 309).

Ferrocyanides. See CYANIDES (p. 618).

Fluoride. According to A. Guyard (*Bull. Soc. Chim.* [2] xxv. 350) an anhydrous vanadic acid is given off in yellow vapours, when the oxyfluoride obtained by treating vanadic acid with hydrofluoric acid and a little alcohol is heated to redness.

Oxyhaloid Compounds. The tetroxychloride or vanadic oxychloride, $V^2O^4Cl^2 + 5H^2O$, is obtained by dissolving vanadic acid in strong hydrochloric acid, and reducing the solution with hydrogen sulphide. On evaporating to dryness on the water-bath, the oxychloride remains as a brown amorphous substance which forms a blue solution with water and a brown solution with alcohol and strong hydrochloric acid (J. K. Crow, *Chem. Soc. J.* xxx. 453). The same compound is described by A. Guyard (*Bull. Soc. Chim.* [2], xxv. 350; *Chem. Soc. J.* xxx. 173), who, however, calls it *chlorure vanadoux*.

The corresponding oxybromide (*bromure vanadoux*), easily obtained by treating vanadic acid with bromine-water and alcohol, or with hydrobromic acid, resembles the oxychloride, but decomposes more readily, with formation of vanadium tetroxide.

To obtain it in the dry state the solution must be evaporated at a temperature below 80° (Guyard, *loc. cit.*)

The oxyiodide, obtained by the action of hydriodic acid on the tetroxide, resembles the preceding compounds, and forms in the dry state a blackish-green, uncrystallisable mass.

The oxyfluoride, obtained by treating vanadic acid with hydrofluoric acid and a little alcohol, is less easily decomposable than the preceding compounds. At a red heat it is at first resolved into hydrogen fluoride and vanadium tetroxide, but afterwards gives off thick yellow vapours of anhydrous vanadium fluoride (Guyard).

A *silicofluoride* of vanadium is obtained by treating vanadic acid with silicofluoric acid and a small quantity of alcohol. The solution, which is blue at first, becomes green when concentrated, and ultimately yields a greyish uncrystallisable mass (Guyard).

Oxides and Oxy-salts of Vanadium. TETROXIDE or HYPOVANADIC OXIDE, V^2O^4 . This oxide, obtained either by slow oxidation of the trioxide in contact with the air, or by heating the tetroxychloride, $V^2O^4Cl^2$, in a stream of carbon dioxide, is a dark green, amorphous powder, insoluble in water, easily soluble in alkalis and in acids. When exposed to the air it gradually absorbs oxygen and is converted into the pentoxide.

The *hydrate*, $V^2O^4 \cdot 7H^2O$, prepared by careful precipitation of the sulphate or chloride, and filtered and dried out of contact with the air, forms a black amorphous mass having a vitreous fracture. It unites with bases, forming salts called Hypovanadates, and with acids, forming the Vanadyl Salts.

Hypovanadates. The *potassium salt*, $(V^2O^4)^2K^2O + 7H^2O$, forms dark brown, shining crystals, easily soluble in water, nearly insoluble in potash-ley, quite insoluble in alcohol. The *sodium salt*, $(V^2O^4)^2Na^2O + 7H^2O$, exhibits precisely similar characters. The *ammonium salt*, $(V^2O^4)^2(NH^4)^2O + 3H^2O$, is a brown crystalline mass. The *barium salt*, $(V^2O^4)^2BaO$, is obtained as a yellow-brown precipitate on adding barium chloride to a solution of $V^2O^4Cl^2$. The *lead salt*, $V^2O^4 \cdot PbO$, is a brown precipitate; the *silver salt*, $V^2O^4 \cdot Ag^2O$, a black crystalline powder (J. K. Crow, *Chem. Soc. J.* xxx. 453).

Vanadyl Salts (Crow, *loc. cit.*; Gerland, *Ber.* ix. 869, x. 2109). *Trisulphate*, $V^2O^4 \cdot 3SO^3$.—This salt forms two hydrates, one soluble, the other insoluble. (a) The *insoluble hydrate*, $V^2O^4 \cdot 3SO^3 + 4H^2O$, is prepared by treating a solution of the pentoxide in sulphuric acid with reducing agents, such as sulphurous acid, oxalic acid, hydrochloric acid, or alcohol, and evaporating, whereby a blue syrup is obtained, which on further heating, or better on addition of strong sulphuric acid, deposits the sparingly soluble hydrate in light blue, very slender needles, which may be purified by pouring off the mother-liquor, mixing them with water, avoiding all rise of temperature, and washing them on a filter with cold water, or better with dilute alcohol. These crystals dissolve but very slowly in cold water, and even more slowly in dilute alcohol, but are quickly dissolved by hot water. On exposure to the air they deliquesce to a blue mass having the consistence of honey. (b) *More soluble hydrate*, $V^2O^4 \cdot 3SO^3 + 15H^2O$. This hydrate is obtained by treating the concentrated solution of the above-described crystals with strong alcohol and repeatedly kneading the precipitate with fresh quantities of alcohol; it then forms a transparent waxy mass, which is not altered even by prolonged sojourn over strong sulphuric acid. The aqueous solution of either of these hydrates mixed with ammonium vanadate assumes a dark green colour, and remains clear at ordinary temperatures, but on boiling deposits a black precipitate, which adheres closely to the sides of the vessel, forming a hard specular crust, the solution at the same time becoming lighter in colour. Sodium phosphate produces in the same solution a greenish-blue precipitate, easily soluble in excess of the reagent and in acetic acid. Normal potassium chromate forms a yellow-brown precipitate. Vanadyl trisulphate unites with potassium sulphate, forming an easily soluble double salt, $V^2O^4 \cdot 3SO^3 + K^2SO^4$, which dries up over sulphuric acid to a clear syrup, and separates after some time in the form of a light blue powder (Gerland). A *heptyhydrate*, $V^2O^4 \cdot 3SO^3 + 6H^2O$, is formed on evaporating the blue solution obtained by reduction of vanadium pentoxide dissolved in strong sulphuric acid (Crow).

Bisulphate, $V^2O^4 \cdot 2SO^3$.—This salt is known in two modifications—one soluble, the other insoluble, in cold water. The insoluble modification is formed on heating a solution of vanadium tetroxide in excess of sulphuric acid for several hours to the boiling point of sulphuric acid, and separates as a heavy microcrystalline powder, having a light grey-green colour. It is quite insoluble in cold water, and acquires a faint blue colour on prolonged boiling with water, more quickly in presence of hydrochloric or sulphuric acid. By prolonged heating at 400° it acquires a pure greenish-

blue colour, and is converted, without change of composition, into the soluble modification. In this state the salt dissolves completely when heated with water in sealed tubes at 130° , forming a deep blue solution, which, when evaporated over sulphuric acid, leaves a hard, resinous, transparent mass; and this, when moistened with dilute alcohol, changes in the course of a few weeks into a conglomerate of fine blue radiate crystals, having the composition $V^2O^4, 2SO^3 + 7H^2O$, and identical with the salt which Crow obtained by the action of alcohol on the trisulphate (*Chem. Soc. J.* xxx. 453). The crystals, when exposed to moist air, swell up considerably, absorbing 6 mol. H^2O more, and even deliquesce in a very damp atmosphere, but effloresce and turn white in dry air. A *decahydrate*, $V^2O^4, 2SO^3 + 10H^2O$, separates in groups of deep blue crystals an inch long from the solution of the preceding hydrate, when left to itself for a month; it is also formed on moistening the amorphous sulphate with water. Of the 10 mol. water of crystallisation five are given off very quickly at 100° , two more slowly, while the last three cannot be driven off even at 130° (Gerland, *Ber. x.* 2109).

Acid Vanadyl Sulphates.—Crow (*Chem. Soc. J.* xxx. 455), by dissolving vanadic oxide in strong sulphuric acid, and reducing the solution with sulphurous acid, obtained an acid vanadyl sulphate as a light blue crystalline powder, having the composition $V^2O^4, 3SO^3 + 6H^2O$ or $V^2O^4, 2SO^3, H^2SO^4 + 5H^2O$. Gerland (*loc. cit.*) has prepared two more of these salts. A solution of vanadium tetroxide in excess of sulphuric acid deposits an abundance of small blue transparent crystals, grouped in crusts; they are very deliquescent, and in contact with water, alcohol, or ether are thrown into rapid movement, and either dissolve or are converted into small silvery scales, which, when strongly magnified, appear as square plates or groups of cubes. The composition of the crusts appears to be represented by the formula $V^2O^4, 2SO^3, H^2SO^4 + 3H^2O$; that of the scales by $V^2O^4, 2SO^3, H^2SO^4 + 2H^2O$. This last compound is formed in larger quantity when a solution of the tetroxide in a large excess of sulphuric acid is heated at 140° – 160° , and it may be safely assumed to exist ready-formed in the crusts above-mentioned. This acid vanadyl sulphate, like many other vanadium compounds, possesses in a high degree the property of carrying down other soluble salts with it (Gerland).

Vanadic Sulphates, or Sulphates of Vanadium Pentoxide (Gerland, *Ber. xi.* 98; *Chem. News*, xxxvii. 127, 138). The pentoxide dissolves in sulphuric acid more or less readily, according to the manner in which it has been prepared, the fused oxide dissolving more slowly than that prepared by the ignition of ammonium vanadate. The trisulphate, $V^2O^5, 3SO^3$, is prepared by dissolving vanadic oxide in excess of sulphuric acid at a low temperature, the excess of sulphuric acid being afterwards removed by heating in an air-bath at 200° . The dry residue thus obtained is covered on the surface with a green compound, $V^2O^5, 2SO^3$, which is insoluble in water; and under this is the red crystalline compound, $V^2O^5, 3SO^3$. This latter salt absorbs water from the air, forming a red syrup, which, on addition of water, is decomposed, vanadic acid separating out. The separation of the two above-named sulphates is effected by heating the mixture with dilute nitric acid, $V^2O^5, 2SO^3$ remaining undissolved.

$V^2O^5, 3SO^3$ is also formed by boiling the pentoxide in sulphuric acid, and separates in ruby-red transparent octohedrons; but if the boiling be continued for some time, it crystallises in golden-yellow needles. The simultaneous formation of $V^2O^5, 2SO^3$, and the rapidity with which the trisulphate absorbs moisture, render its preparation and analysis difficult.

Solutions of V^2O^5 in excess of sulphuric acid, heated for some time at 130° – 150° , yield an opaque red crystalline crust, which Fritzsche regarded as $V^2O^5, H^2O, 2SO^3$ (*Jahresb.* 1851, 35), but which, according to Gerland, is an impure anhydrous bisulphate, $V^2O^5, 2SO^3$. This *basic sulphate* is, however, more readily obtained by heating the normal salt ($V^2O^5, 3SO^3$) at the temperature of melting lead, until sulphuric anhydride ceases to be expelled. Thus prepared, the basic sulphate is a red crystalline mass, deliquescent in moist air to a brown solution, which, on dilution with water, yields a precipitate of vanadic oxide.

Dialysis of a Solution of Vanadic Acid in Sulphuric Acid.—1. When a solution of V^2O^5 in hot sulphuric acid is diluted with water, and dialysed into water, sulphuric acid at first diffuses out rapidly, and a solution is left in the dialyser, containing vanadic acid and sulphuric acid in the proportion of 3 molecules of the former to 1 molecule of the latter. If the diffusion be continued for some time, the dialysed product contains vanadic acid and sulphuric acid in the proportion of 2 molecules to 1 molecule.

2. When a solution of V^2O^5 in cold sulphuric acid is dialysed into water, the sulphuric acid diffuses out, and vanadic acid separates in the dialyser, whilst the liquid

contains sulphuric and vanadic acids in the proportion of 1 molecule to 1.32 molecule. This difference in the two cases appears to be due to the fact that the cold solution contains only a molecular compound of V^2O^5 and H^2SO^4 , whilst the solution prepared by the aid of heat contains the atomic compound $V^2O^5(SO^4)^3$.

Double Sulphates.—Calculated quantities of $V^2O^5(SO^4)^3$ and K^2SO^4 dissolved in water and mixed, yield, on heating to a blood heat, amber-coloured crystals, grouped in transparent or turbid nodules. The crystals have the composition $K^2O, V^2O^5, 2SO^3 + 6H^2O$, and are decomposed by water, with liberation of vanadic acid as a brown mud containing some potassium.

Ammonium sulphate forms a double salt similar to the potassium double salt, having the composition $(NH^4)^2O, V^2O^5, 2SO^3 + 4H^2O$. It crystallises in nodular masses formed of needles grouped together, and dissolves in water without separation of vanadic acid. The sulphates of sodium and magnesium do not form double salts with vanadic sulphate.

Metavanadic Acid, VO^3H .—Gerland (*Chem. News*, xxxiv. 2) prepares this acid by mixing a cold saturated solution of copper sulphate with a strong solution of ammonium chloride in large excess, then adding ammonium vanadate in saturated solution till a permanent precipitate appears, and slowly heating the mixture to 75° , when gold-like scales of vanadic acid form and continue to do so for some hours. The precipitate is collected, treated with dilute sulphuric and sulphurous acids, then washed with water and dried, but it still retains traces of ammonia. Metavanadic acid may also be obtained by precipitating ammonium vanadate with a copper salt, separating the precipitated cupric vanadate, and warming the remaining solution. The acid thereupon separates and may be purified from copper by hydrochloric acid.

Metavanadic acid is highly hygroscopic, suffers no change at 150° , but loses its water at higher temperatures. The filtrate from the copper vanadate, if kept for ten days, remains clear on boiling. The original liquor evaporated in a thin layer at low temperature, leaves a crystalline residue, forming with cold water a clear solution which, when heated to 75° , deposits metavanadic acid in scales.

Vanadates. The following vanadates have been examined by J. A. Norblad (*Ber.* viii. 126).

K^2O, V^2O^5 . . . lenticular crystals.	$K^2O, 3V^2O^5 + 6H^2O$. . insoluble.
$K^2O, V^2O^5 + 2HO$. capillary needles.	Na^2O, V^2O^5 .
$2K^2O, V^2O^5 + 3H^2O$. monoclinic.	$Na^2O, V^2O^5 + 4H^2O$.
$K^2O, 2V^2O^5 + 4H^2O$ orange red.	$2Na^2O, 3V^2O^5 + 9H^2O$.
$2(K^2O, 2V^2O^5) + 7H^2O$ laminae having a golden lustre.	$Na^2O, 3V^2O^5 + 9H^2O$.
$K^2O, 3V^2O^5$.	$Li^2O, 2V^2O^5 + 9H^2O$.
	$(NH^4)^2O, 3V^2O^5$. v. Hauer's salt with $6H^2O$ (v. 990) was not obtained.

Ammonium Vanadate.—This salt, when precipitated by ammonium chloride from a solution of sodium vanadate, is obtained pure and free from fixed alkali, whereas when a potassium salt is used, a certain portion of potassium vanadate always goes down with the precipitate (Gerland, *Chem. News*, xxxvi. 29).

The reactions of ammonium vanadate with various organic substances of technical importance have been examined by R. v. Wagner (*Dingl. pol. J.* ccxxxiii. 631).

With *tannin-solution* this salt forms a blue-black precipitate, which remains suspended in the liquid for several days, making it like ink. A similar precipitate is formed with *gallic acid*, but it settles down more quickly. *Pyrogallol* forms no precipitate, but a deep black-blue liquid excellently adapted for use with steel pens. *Maclurin* in aqueous solution also forms a deep black liquid with a greenish tinge; *catechol* reacts in like manner. *Hæmatoxylin* yields a deep black-blue liquid, which may be used as ink. With solution of *logwood-extract* and ammonium vanadate, a fine black colour may be produced on wool or silk, by the usual dyeing process for wood- or chrome-black, the chromate being replaced by vanadate. Extract-solutions of *Brazil-wood* produce with the vanadate at boiling heat a black-brown dyeing liquid; pure *brazilin* acquires only a dark violet colour. A decoction of *fustic* forms with the vanadate a blackish-green ink. The vanadate solution produces no coloration with phenol, salicylic acid, resorcinol, quinol, caffeine, eosin, or fluorescein. Lastly, Wagner recommends ammonium vanadate for detecting the addition of tannin to red wines, which when thus adulterated produce inky liquids, whereas with pure wines only red-brown colorations are obtained.

Silver Vanadates.—An *octovanadate*, $Ag^{12}V^8O^{26}$, is obtained as a dark yellow precipitate on adding silver nitrate to a solution of the corresponding sodium salt.

Sp. gr. = 5.67 at 18°. One part of it dissolves in 21,414 pts. water at 14°, in 13,617 pts. at 160°. The *pyrovanadate*, $\text{Ag}^{\text{I}}\text{V}^2\text{O}^7$, is obtained, likewise by precipitation, from the corresponding sodium salt.

Sodium Vanadates.—The *octovanadate*, $\text{Ag}^{\text{I}2}\text{V}^8\text{O}^{28}$, with 4 or 12 mol. H^2O , is formed by fusing 6 mol. sodium carbonate with 4 mol. vanadium pentoxide. On dissolving the melt in water, evaporating the solution to a syrup, and leaving it at rest for some time, the salt is obtained as a crystalline mass slightly soluble in cold water (Carnelley).

Thallium Vanadates. (Carnelley, *Chem. Soc. J.* xxvi. 323).—These salts for the most part differ greatly in character from the phosphates of the alkali-metals and of thallium, and are more nearly allied to the vanadates of silver and lead. *Thallium orthovanadate*, $\text{TI}^{\text{I}}\text{VO}^4$, is formed by fusing together at a moderate heat 3 mol. thallium carbonate and 1 mol. vanadium pentoxide, a red mass being thereby produced, which yields a light brown powder. The salt has a sp. gr. of 8.6 at 17°; it is but slightly soluble in water, although it is the most soluble of all the thallium vanadates. It dissolves in 999 pts. water at 15°, and in 574 pts. at 100°. The *pyrovanadate*, $\text{TI}^{\text{I}}\text{V}^2\text{O}^7$, is obtained as a light yellow precipitate on mixing the cold solutions of thallium sulphate and sodium orthovanadate, the liquid at the same time becoming strongly alkaline:

The same salt is formed by fusing 2 mol. thallium carbonate with 1 mol. V^2O^5 , or 2 mol. thallium carbonate with 1 mol. thallium octovanadate:

Thallium pyrovanadate is a light yellow or cream-coloured powder; the sp. gr. of the precipitated salt at 18.5° is 8.21; that of the salt obtained by fusion is 8.812 at the same temperature. 1 pt. of the salt dissolves in 4,996 pts. water at 14°, and in 3,840 pts. at 100°. *Thallium octovanadate*, $\text{TI}^{\text{I}2}\text{V}^8\text{O}^{28}$ or $6\text{TI}^{\text{I}}\text{O}^4\text{V}^2\text{O}^5$, analogous to Fleitmann a. Henneberg's sodium octophosphate (v. 537), is prepared by boiling a solution of sodium pyrovanadate, leaving it to cool, and then adding a cold solution of thallium sulphate as long as a precipitate is formed. It has a great resemblance to silver chloride, but changes on standing, especially if the precipitate be stirred, into a fine dense yellow powder. The filtrate contains caustic soda, so that the reaction may be represented by the equation:

Sp. gr. 8.59 at 17.5°. 1 pt. of the salt dissolves in 3,406 pts. water at 8.59°, and in 3,533 pts. at 100°. *Thallium decavanadate*, $\text{TI}^{\text{I}2}\text{V}^{10}\text{O}^{31}$, is formed on adding thallium sulphate to a boiled and cooled solution of sodium pyrovanadate containing an excess of vanadium pentoxide, and separates as a white precipitate, becoming light yellow on addition of a larger quantity of thallium sulphate. The filtrate contains free soda. The salt forms a light yellow powder, having a sp. gr. of 7.86 at 17°. One part of it dissolves in 9,372 pts. water at 11° and in 3,366 pts. at 100°. *Thallium metavanadate*, TIVO^3 , obtained by fusing 1 mol. thallium carbonate with 1 mol. V^2O^5 , is a dark-coloured, scaly, crystalline mass, yielding a slate-grey powder. Sp. gr. 6.019 at 17°. One part dissolves in 11,534 pts. water at 11°, and in 4,756 pts. at 100°. *Tetradecavanadate*, $\text{TI}^{\text{I}2}\text{V}^{14}\text{O}^{41}$. When thallium sulphate is added to a solution of ammonium metavanadate, a yellowish precipitate is formed, which gradually becomes darker, and changes on standing into a dirty white crystalline powder, which on addition of more thallium sulphate, or spontaneously after some time, acquires a reddish colour. This product is the tetradecavanadate. The same salt is obtained on adding an excess of thallium sulphate to a solution of the decavanadate.

NATIVE VANADATES. *Mottramite*, a basic vanadate of copper and lead, occurring in crystalline or amorphous incrustations on the keuper sandstone of Alderley Edge and Mottram St. Andrews, Cheshire, has been analysed by H. E. Roscoe (*Proc. Roy. Soc.* xxv. 111). The layers, which are for the most part only 3–4 mm. thick, and the more rarely occurring lumps of the size of a walnut, are either red-brown, opaque, and massive, or are made up of very small needles, black by reflected, yellow by transmitted light. The direct results of analysis are given under Nos. 1 and 2, the mean under No. 3; No. 4 gives the corrected values, after deduction of adventitious constituents, and No. 5 the values calculated from the formula

	V ² O ⁵	PbO	CaO	FeO,ZnO,MnO	CaO	MgO	H ² O	H ² O ⁽¹⁾	SiO ²	
1 (found)	16.78	50.49	16.72	2.52	2.61	0.37	3.63	0.22	0.87	= 97.21

(¹) Hygroscopic.

Another vanadate of copper and lead, called *Psittacinite*, occurs in fine-green, occasionally botryoidal crusts on quartz, accompanying gold, cerussite, copper-pyrites, and brown hematite, in several mines of the Silver Star District, Montana, especially the Iron Road and New Career mines. Its analysis by F. A. Genth (*Sill. Am. J.* [3], xii. 35) leads to the formula $3(3\text{PbO}, \text{V}^2\text{O}^5) + 3\text{CuO}, \text{V}^2\text{O}^5 + 6(\text{CuO}, \text{H}^2\text{O}) + 12\text{H}^2\text{O}$, the values calculated from which are given below (No. 6):—

	PbO	CuO	V ² O ⁵	H ² O	SiO ²	Al ² O ³	Fe ² O ³	MgO	CuO
1 (found)	41.36	14.34	14.64	7.42	15.13	1.29	2.72	undet.	undet.

Volborthite, a vanadate occurring at Woskresowskoi, in the government of Perm, Russia, as a crystalline coating on the granules and in the cavities of an argillaceous quartz-conglomerate, has been analysed by Genth (*Zeitschr. f. Kryst.* ii. 12), who refers the analyses (1 and 2), after deduction of impurities, to the formula $(\frac{1}{3}\text{Ba}, \frac{2}{3}\text{Ca}, \frac{1}{3}\text{Cu})\text{V}^2\text{O}^5 + 3\text{CuH}^2\text{O} + 12\text{H}^2\text{O}$ (No. 3), closely related to that of psittacinite.

	SiO ²	Al ² O ³	Fe ² O ³	MgO	CuO	CaO	BaO	V ² O ⁵	H ² O ⁽¹⁾
(1)	1.38	4.45	1.77	3.01	34.04	4.29	4.29	13.62	33.15

(3)	—	—	—	—	38.41	6.77	6.17	19.63	29.02

(¹) Determined by difference.

Roscoelite.—This name has been given by J. Blake (*Sill. Am. J.* [3], xii. 31) to a mineral found in a gold-mine at San Francisco, where it serves as a matrix for gold. It occurs in radiating and foliated tale-like masses, filling cavities in a schistose porphyry. It is of a greenish-grey colour, opaque when seen in mass, but translucent in thin splinters. Lustre subvitreous to fatty; hardness about equal to that of tale; specific gravity = 2.902.

Two analyses gave the following results:—

	SiO ²	V ² O ⁵	Al ² O ³	Fe ² O ³	Mn ² O ³	MgO	CaO	K ² O	Na ² O	H ² O
(1)	41.25	28.85	14.34	1.04	1.45	1.96	.61	8.25	0.72	0.94
(2)	—	28.36	13.94	1.23	0.85	2.06	.62	8.87	0.92	1.22
Mean	41.25	28.60	14.14	1.13	1.15	2.01	.61	8.56	0.82	1.08

These numbers lead to the formula $2(\text{Al}^2\text{O}^3, \text{V}^2\text{O}^5) + 2\text{K}^2\text{O}, 9\text{SiO}^2 + \text{H}^2\text{O}$ or $4\text{AlVO}^4 + \text{K}_2\text{Si}_2\text{O}_7 + \text{H}^2\text{O}$, a portion of the alumina being replaced by the sesquioxides of iron and manganese, and a portion of the potash by lime, magnesia, and soda (Roscoe, *Proc. Roy. Soc.* xxv. 109). See also Genth, *Chem. News*, xxxiv. 78; *Chem. Soc. J.* xxxi. 175.

FLUOROXYVANADATES (H. Baker, *Chem. Soc. J.* xxxiii. 388). *Laminar Potassium Fluoroxovanadate*, $6\text{KF}, \text{V}^2\text{O}^5, 2\text{VOF}^3 + 2\text{H}^2\text{O}$, is obtained by dissolving vanadium pentoxide in acid potassium fluoride, the dissolution being attended with rise of temperature, and separates from the liquid on cooling in yellow crystalline spherules made up of groups of small hexagonal tablets. Its aqueous solution has a deep yellow colour.

The *needle-shaped potassium salt*, $3\text{HKF}^2, 2\text{VOF}^3$, is formed on dissolving the preceding salt in warm aqueous hydrofluoric acid, and separates in tufts of long slender needles, which smell of hydrofluoric acid, attack glass quickly, and are decomposed with effervescence by cold sulphuric acid.

Ammonium Fluoroxovanadates are easily formed by dissolving vanadium pentoxide in acid ammonium fluoride. The solution, if rich in vanadium, does not crystallise on standing, but on addition of an excess of hydrogen-ammonium fluoride deposits

faintly yellowish, nacreous, translucent, extremely thin hexagonal laminae of *Laminar Ammonium Fluorovanadate*. Its aqueous solution, mixed with a larger quantity of hydrogen-ammonium fluoride, yields a light yellow crystalline precipitate of *Pyramidal Ammonium Fluorovanadate*. This salt has a yellow colour, very much like that of potassium monochromate, and approximates in crystalline form to the regular octohedron, but its behaviour to polarised light shows that it does not belong to the regular system. By dissolving it in warm hydrofluoric acid, and leaving the solution to cool, *Needle-shaped Ammonium Fluorovanadate*, $3(\text{NH}_4)\text{HF}_2 \cdot 3\text{VOF}_3$, is obtained in light yellow needles or prisms, which smell of hydrofluoric acid when dry, effervesce with cold sulphuric acid, and when laid on glass acquire a reddish colour, with separation of vanadic acid. *Ammonium Fluorohypovanadate*, $2\text{NH}_4\text{F} \cdot \text{VOF}_3$, is obtained by adding hydrogen-ammonium fluoride to vanadium tetroxide prepared by passing hydrogen sulphide into a solution of the pentoxide in hydrofluoric acid. It then separates in clear blue monoclinic crystals, exhibiting the combination $\infty \text{P} \cdot 0\text{P}$. often with an indication of $+\text{P}$. Axial ratio, $a : b = 0.9653 : 1$. Axial angle, $38^\circ 2'$. The aqueous solution is precipitated by alcohol. The salt is not attacked by cold sulphuric acid.

Zinc Fluorovanadate, $\text{ZnF}_2 \cdot \text{ZnO} \cdot 2\text{VOF}_3 + 14\text{H}_2\text{O}$, is formed on dissolving zinc carbonate and vanadium pentoxide in the calculated proportion in hydrofluoric acid, and separates on evaporation in hard yellow monoclinic prisms, $\infty \text{P} \cdot \infty \text{P} \cdot \infty \text{P} \cdot 0\text{P} \cdot + \text{P} \cdot \infty$, and having approximately the axial ratio $a : b : c = 0.93 : 1 : 0.83$, and the axial angle 46° . On exposure to the air it decomposes slowly, becoming covered with a brown to light red film.

VANILLA. Tiemann a. Haarmann (*Ber.* ix. 1287) have found the following proportions of vanillin in different sorts of vanilla: Mexican, 1.32 to 1.86 per cent.; Bourbon, 0.75 to 2.9 per cent.; Java, 1.56 to 2.75 per cent. These vanillas also contain vanillic acid, a small quantity of fat, and a resin having a very faint odour. The benzoic acid, said by former investigators to be present in vanilla, was probably vanillic acid. The aroma of the vanillas above-mentioned is due entirely to vanillin. The West Indian variety called *vanillone* exhibits different characters, its odour strongly resembling that of a dilute solution of piperonal. It contains from 0.4 to 0.7 per cent. vanillin, to which there obstinately adheres an oily substance, probably another aldehyde; the oil absorbed from it by bibulous paper smelt not like piperonal, but like bitter almond oil. The vanillic acid prepared from vanillone was contaminated with another substance, probably benzoic acid. The heliotrope-like odour of vanillone is perhaps due to vanillin mixed with a small quantity of benzaldehyde. The aqueous extract of vanilla pods previously exhausted with ether reduces Fehling's solution, and deposits on boiling a yellow resin: hence it is probable that the water extracts a glucoside which is concerned in the formation of the vanillin.

On the origin of vanilla, its commercial varieties, and their preparation for the market, see *Pharm. J. Trans.*, 1874.

On the estimation of Vanillin in Vanilla, see p. 306.

VANILLIC or **METHYLPROTOCATECHUIC ACID**, $\text{C}^6\text{H}^8\text{O}^4$
 $= \text{C}^6\text{H}^3(\text{CO}^2\text{H})(\text{OCH}^3)(\text{OH})$, and *Isovanillic acid*, $\text{C}^6\text{H}^3(\text{CO}^2\text{H})(\text{OH})(\text{OCH}^3)$. See *BENZOIC ACIDS* (Diox-), p. 289, and *PROTOCATECHUIC ACID*, pp. 1691–1693.

Vanillic acid may be obtained by oxidation of creosol, $\text{C}^8\text{H}^{10}\text{O}^2$ (p. 580). Pure creosol (b. p. 220°) is converted by boiling with acetic anhydride into acetyl-creosol (b. p. 245°); this latter compound suspended in dilute acetic acid is treated with solution of potassium permanganate (1 : 10); and the liquid, filtered from manganese dioxide, is mixed with a slight excess of caustic soda (to decompose aceto-vanillic acid), then concentrated, acidulated, and agitated with ether, which takes up the vanillic acid (Tiemann and Mendelsohn, *Ber.* ix. 417).

Alphahomovanillic Acid, $\text{C}^8\text{H}^{10}\text{O}^4$, and its Derivatives (Tiemann a. Nagai, *Ber.* x. 201).

Acet-alphahomovanillic acid, $\text{C}^8\text{H}^9(\text{OCH}^3)(\text{OC}^2\text{H}^3\text{O}) \cdot \text{CH}^2 \cdot \text{COOH}$, is formed, together with acetovanillic acid, on adding gradually a warm solution of 50 grams of potassium permanganate in 2,000 c.c. of water to a solution of 15 grams of acetugenol (p. 762) in 20 c.c. of glacial acetic acid. It crystallises in transparent prisms, which dissolve easily in boiling water, alcohol, and ether, and melt at 140° . When heated above its melting point for some time, it gives off acetic acid, and yields alphahomovanillic acid. By prolonged fusion with potassium hydrate, it is converted into protocatechuic acid. Its solution in acetic acid is converted by oxidation with potassium permanganate into acetovanillic acid.

Alphahomovanillic acid, $\text{C}^8\text{H}^9(\text{OCH}^3)(\text{OH}) \cdot \text{CH}^2 \cdot \text{COOH}$, is formed, as above

stated, when a solution of acet-alphahomovanillic acid in soda-ley is heated for some time. It crystallises from boiling water or benzene in distinct hexagonal prisms, which melt at 142° – 143° and dissolve easily in alcohol and ether. Its aqueous solution is coloured green by ferric chloride. The acid forms crystallisable and easily soluble ammonium, sodium, calcium, and barium salts, and sparingly soluble lead, silver, and zinc salts, in which the hydrogen of the carboxyl-group of the acid is replaced by the respective metallic radicles. It appears also to form another class of salts, in which the hydrogen of the hydroxyl in the benzene-residue is likewise replaced, but these are obtained with difficulty. Solutions of the alkali-salts do not reduce Fehling's solution.

Creosol (*homoguaiacol*), $C^6H^3(CH^3)(OCH^3)(OH)$, one of the constituents of beech-wood-tar, is formed by elimination of carbon dioxide, when the calcium salt of alphahomovanillic acid is mixed with calcium hydrate and sand, and submitted to dry distillation. It is more easily obtained in the pure state by this process than by treatment of the tar, which yields it only with extreme difficulty.

Alphahomoprotocatechuic acid, $C^6H^3(OH)^2CH^2.COOH$, is formed when alphahomovanillic acid is heated to 170° – 180° with dilute hydrochloric acid in sealed tubes. It crystallises in brilliant transparent needles, which melt at 127° and dissolve easily in water, alcohol, and ether. It yields well-characterised crystallisable salts by substitution of metallic radicles for the hydrogen of the carboxyl-group. Basic salts also are formed by the further replacement of hydrogen in the hydroxyl-group, but they appear to be unstable.

The calcium salt of alphahomoprotocatechuic acid, when distilled with calcium hydrate, yields homocatechol, $C^6H^3(CH^3)(OH)^2$, a thick, colourless, uncrystallisable liquid which dissolves in water, alcohol, ether, and benzene, and in its chemical properties closely resembles catechol.

VANILLIN, $C^8H^8O^3 = C^6.CO^1H.H.OCH^3.OH.H^2$. *Methyl-protocatechuic Aldehyde* (p. 305).—This compound is a constituent of Siamese benzoin. To prepare it therefrom, 2 pts. of the finely pulverised resin are stirred up to a paste with 1 pt. of slaked lime, and 12 pts. of boiling water are added with constant agitation. The acidulated solution, separated from benzoic acid, yields to ether (together with a little more benzoic acid), vanillin, and a compound which dissolves with yellow colour in alkalis. The vanillin is purified by means of sodium bisulphite. It crystallises remarkably well from light petroleum boiling at 90° . It melts at 81° (Jannasch a. Rump, *Ber.* xi. 1634).

VANILLIDIACETONAMINE, $C^{14}H^{19}NO^3$ (Heintz, *Liebig's Annalen*, xciv. 53). This base is obtained by boiling together equal parts of vanillin and acid diacetoneamine oxalate in 10 pts. alcohol, whereupon a fine powder separates, consisting of neutral vanillodiace-tonamine oxalate, which may be separated from admixed ammonium oxalate by boiling with a small quantity of water. The free base separated from the solution of this salt by sodium carbonate is a thickish, yellow-green, uncrystallisable oil, which dissolves with yellow colour in ether and alcohol and has a strong alkaline reaction. The *sulphate* forms small thin rectangular or octagonal anhydrous laminæ, insoluble in absolute alcohol, slightly soluble in dilute alcohol, more freely in boiling water. The *hydrochloride* forms granular masses composed of slender needles; it dissolves easily in alcohol, and is separated from the solution by ether in small spherical granules destitute of crystalline structure. With platinic chloride it forms a brown-red glutinous precipitate of a *platinochloride*, which dissolves in hot alcohol but does not crystallise therefrom. The *nitrate* forms small geodes of prismatic crystals or rectangular plates, moderately soluble in alcohol, not readily in water. When heated it melts, turns brown, froths up, and gives off yellow vapours. By boiling with strong alcohol it becomes anhydrous and then forms a white powder. The crystallised salt contains 1 mol. water, which is easily expelled at 100° . The anhydrous salt is less soluble in alcohol than the hydrated salt. The *normal axalate* (*supra*) forms a white powder or yellowish crystalline crusts, slightly soluble in water, insoluble in alcohol and ether.

VANILLYL ALCOHOL, $C^8H^{10}O^3 = C^6.CH^2OH.H.OCH^3.OH.H^2$ (pp. 305, 1692).

VAPOUR-DENSITY. Numerous methods of determining vapour-densities have recently been proposed, but the only one that need be described in detail is that of V. and C. Meyer (*Ber.* x. 2253). This method consists in dropping a weighed quantity of substance into a heated bulb, and calculating the result from the volume of air displaced. The apparatus used is represented in figs. 50, 51. The bulb is a cylindrical vessel of about 100 c.c. capacity, with a height of 200 mm., to which is

fused a tube 600 mm. long and 6 mm. diameter, and terminating above in a thimble-shaped enlargement. The side exit-tube, which is 1 mm. diam. and 140 mm. long, is bent at an angle downwards, recurved at the end, and joined to the vertical tube at a distance of 100 mm. from the top. For temperatures up to 300° it is heated in a glass tube 40 mm. diam. and 520 mm. long, which terminates below in a bulb of about 80 c.c. capacity (fig. 50). For higher temperatures the glass tube is replaced by a cylindrical iron vessel (fig. 51), 60 mm. diam. and 240 mm. high, containing melted lead. In this case the bulb must be protected by wire gauze. The mode of working is the following:—The instrument, into which a little well-ignited asbestos has been introduced, is fixed in position in the bath, the end of its fine tube dipping below the water in a small trough in which a graduated tube filled with water stands

FIG. 50.

FIG. 51.

FIG. 52.

inverted. A cork is now inserted into the enlargement at the top of the vertical tube, and the extremity of the exit-tube is watched to see that the temperature in the bulb is uniform. The cork is now taken out, the little tube with the substance is dropped in, and the cork is quickly replaced. The first few bubbles of air are not heeded, but immediately afterwards the inverted tube is placed quickly over the point of the delivery-tube. Very soon the substance is vaporised and displaces air, which issues in a rapid stream of bubbles into the graduated tube. As soon as the gas evolution is over the cork is removed, and the air collected is cooled and measured. The formula given is

$$D = \frac{\text{weight of substance}}{\text{weight of air collected}}$$

(It must, however, be observed that no allowance is made for the volume of the substance.) For temperatures above a red heat the following method is employed (*Ber. xii. 1112*):—The substance is contained in a small cup made from the stem of a Dutch pipe. The vessel in which the determination is made is of glazed porcelain; it is first cautiously heated in an ordinary muffle furnace, and then transferred to a muffle heated by a Perrot's gas-furnace (fig. 52). Before introducing the substance the air in the apparatus is displaced by nitrogen.

For the determination of the vapour-density of substances which attack porcelain at a red heat, Meyer a. Züblin (*Ber. xii. 2204*) use the following apparatus:—A porcelain tube (glazed inside and outside), 60 c.m. long, is placed vertically in the Perrot's gas-furnace, so that while the centre is heated the two extremities remain cold. Into this tube is inserted the platinum vapour-density bulb. This consists of a cylinder 225 mm. long by 26 mm. diam., to which is attached a platinum tube 400 mm. long by 7 mm. diam.

L. Meyer (*Ber. xiii. 991*) adds a contrivance for dropping the substance after the cork has been inserted. J. Piccard (*Ber. xiii. 1079*) has proposed another method of inserting the substance, and modified the arrangement for measuring the air. A new

lead bath for high temperatures is described by Watson Smith (*Chem. Soc. J.* 1880, xxxix).

The following are recently proposed modifications of Hofmann's apparatus (vi. 1127):

Grabowski (*Ber.* viii. 1437) uses naphthalene as the heating medium. Engler (*ibid.* ix. 1437) modifies the apparatus in such a manner as to avoid the occasional stoppage of the outlet tube. Hofmann (*ibid.* 1304) also has modified his apparatus, so as to diminish the risk of cracking the tubes and obviate the necessity of having the inner one graduated. Brühl (*ibid.* 1368; *Monit. scient.* Jan. 1878, 14; *Ber.* xii. 197) uses an inner tube 1.5 mm. long, and to eliminate the tension of mercury-vapour heats the column to the required temperature, notes the height, leaves it to cool, then introduces the substance, and heats it again to the same temperature. Muir a. Sugiyra (*Chem. Soc. J.* xxix. 140) insert short glass tubes into the india-rubber disc, to allow free egress to the mercury during the heating. Victor Meyer (*Ber.* ix. 1216; *Monit. scient.* Jan. 1878) uses fusible metal in a bulb with a curved outlet-tube attached to the bottom. His experiments were all made in the vapour of boiling sulphur. Perrenoud (*Liebig's Annalen*, clxxxvii. 77) heats the bulb in an oil-bath, while Knecht (*ibid.* ccii. 31) and Graebe (*Ber.* xi. 1646) use a bath of boiling phosphorus pentasulphide. Frerichs (*Liebig's Annalen*, clxxxv. 199) uses an inverted flask and brings the outlet through the bottom of the bath. Goldschmidt a. Ciamician (*Ber.* x. 641; *Monit. scient.* Jan. 1878) use mercury with the simpler bulb of V. Meyer, but add a small side-tube to the outlet. V. Meyer (*Ber.* x. 2068) modifies the shape of the bulb and heats it in a tube of sufficient length for the upper part to serve as a condenser. Thorpe (*Chem. Soc. J.* 1880, xxxvii. 147) makes the Hofmann apparatus much stronger and more compact, and controls the level of the mercury in the trough by means of a tube passing through the bottom and connected with a movable reservoir. Bell a. Teed (*Chem. Soc. J.* xxxvii. 576) eliminate the atmospheric pressure in Hofmann's apparatus by attaching a side-tube, sealed at the top, which serves as a barometer.

Modifications of Dumas' method (v. 368) have been described by Habermann (*Liebig's Annalen*, clxxxvii. 341) and by Pettersson a. Chatrand (*Ber.* xiii. 1191).

Roscoe (*Proc. Roy. Soc.* xxvii. 426) determines the vapour-densities of high-boiling substances, such as the chlorides of lead and thallium (pp. 1170, 1920), by volatilizing them in a long-necked flask of glazed porcelain heated to bright redness in a muffle, the temperature of the flask being estimated calorimetrically by means of platinum weights, likewise introduced into the muffle, and the result checked by the simultaneous heating of a second flask containing mercury.

Pfaundler (*Ber.* iii. 825; xii. 165) describes a method based on the increased tension of the air in an elongated bulb, consequent on the application of heat after the introduction of the substance under examination. Another method, depending on the same principle, is described by Dulong (*Compt. rend.* lxxviii. 636). Hofmann (*Ber.* xi. 1684) proposes to heat the weighed substance over mercury in the closed limb of a V-tube; he also describes a method based on heating the substance in a partially exhausted tube.

An acoustic method of determining vapour-densities, founded on the tone produced in a tube filled with the vapour, as compared with that produced in the same tube filled with air, has been proposed by H. Goldschmidt (*Ber.* xiii. 770).

Alleged Dissociation of Elements at High Temperatures.—From experiments on the vapour-densities of chlorine, bromine, and iodine at high temperatures made by their method above described, V. and C. Meyer (*Ber.* xii. 609, 1195, 1282) inferred that these elements undergo dissociation at high temperatures, the densities of their vapours being reduced to $\frac{2}{3}$ of their normal values. This result appears to be established in the case of iodine, but in that of chlorine it has been admitted by V. Meyer himself to be due to some unexplained experimental error. See Carnelley (*Ber.* xii. 1836); Seelheim (*ibid.* 2066); Lieben (*ibid.* 2259); Crafts (*Ber.* xiii. 423, 776); V. Meyer (*ibid.* xii. 2202; xiii. 813, 1010, 1103); Meier a. Crafts (*Ber.* xiii. 851); Naumann (*ibid.* 1050); Troost (*Compt. rend.* xci. 54); Berthelot (*ibid.* 77); Crafts (*Ber.* xiii. 1316); Deville a. Troost (*Compt. rend.* xci. 83); further, *Chem. Soc. J.* 1880, xxxviii. 214, 431–434, 606, 646, 788.

J. T. B.

VARISCITE. This aluminic phosphate from Massbach, in Saxony, described by Breithaupt as amorphous (v. 994), is, according to Petersen (*Jahrb. f. Min.* 1871, 353), crystalline, and contains:

P ₂ O ₅	Al ₂ O ₃	Fe ²⁺ O ³ (¹)	CaO	MgO	H ₂ O
44.05	31.25	1.21	0.18	0.41	22.85 = 99.95

(¹) With Cr²⁺O₃.

— These numbers agree with the formula Al₂O₃.P₂O₅ + 5H₂O, which is also that of turquoise.

A mineral from Montgomery County, Arkansas, hitherto regarded as peganite, has been recognised by A. H. Chester (*Sill. Am. J.* [3], xiii. 295; xv. 207) as variscite. It occurs in quartz, so intimately intergrown that it cannot be completely separated. It is emerald-green, bluish-green, or colourless, sometimes apparently amorphous, but occurs also in radio-fibrous spherules, and even in rhombic crystals 3 mm. in size, and exhibiting the combination $\infty P \cdot \infty P \infty \cdot \infty P \infty \cdot OP$. Angle $\infty P : \infty P = 114^{\circ} 6'$.

Analyses.—1. Amorphous variety. 2. Crystalline in both cases after deduction of quartz. 3. Values calculated from the formula $Al_2O^3, P_2O^3 + 4H^2O$:

	P_2O^3	Al_2O^3	H^2O
1.	43.96	32.24	23.80 = 100
2.	44.76	31.46	23.80 = 100
3.	44.80	32.49	22.71 = 100

VATERIA. See PINBY TALLOW (p. 1630).

VEGETABLE TISSUES. The chemical study of vegetable tissues has hitherto received but little attention, and no general method, such as is used in mineral analysis, has been applied to their separation and estimation. Such a method has, however, lately been devised by Frémy (*Compt. rend.* lxxxiii. 1136), and the following bodies have been thereby distinguished in the principal tissues of vegetables: *Cellulose bodies* (cellulose, paracellulose, metacellulose), *Vasculose*, *Cutose*, *Pectose*, *Calcium pectate*, *Nitrogenous substances*, and various mineral compounds.

Cellulose Bodies.—In this class are included those bodies which dissolve without coloration in bihydrated sulphuric acid, ($SO^4H^2 + H^2O$), producing dextrin and sugar, which are not sensibly altered by alkaline solutions, and resist for a long time the action of strong oxidisers.

By means of the ammonio-cupric reagent, three varieties of cellulose may be distinguished:

(1) *Cellulose*, which dissolves immediately in the cupric reagent, and forms a large part of cotton and of the utricular tissue of certain fruits.

(2) *Paracellulose*, which does not dissolve in the cupric reagent until after the action of acids; it forms the utricular tissue of certain roots and the epidermis of leaves.

(3) *Metacellulose* (fungin), insoluble in the cupric reagent even after the action of acids; found chiefly in agarics and lichens.

In the analysis of vegetable tissue, the first variety of cellulose is determined directly by means of the cupric reagent, the second in the same after being submitted to the action of acids, and the third is dissolved in bihydrated sulphuric acid. When it is not required to distinguish these three bodies, the whole may be dissolved in the sulphuric acid.

Vasculose.—This substance constitutes the larger part of the ducts and spiral vessels; it generally accompanies cellulose in plants, but differs completely from it in composition and properties. It contains more carbon and less hydrogen than cellulose; and is the material which cements the fibres and cells together. It may be said to form the heavy part of woody tissue; it abounds in hard wood and in the stony concretions of pears; the shells of nuts and the stones of apricots contain more than half their weight of vasculose.

Vasculose is insoluble in sulphuric acid, and in the ammonio-cupric reagent, also in alkalis under ordinary circumstances, but when heated with alkalis under pressure it dissolves easily; it also dissolves in oxidising agents. Vasculose can be separated from cellulose by sulphuric acid or by the cupric reagent; but if it is intended to weigh the cellulose, the vasculose must be dissolved in dilute nitric acid.

Cutose constitutes the fine transparent membrane which covers the exposed parts of vegetables. It is insoluble in sulphuric acid, but dissolves in dilute solutions of the carbonates of potassium and sodium; with nitric acid it produces suberic acid. It is separated from cellulose by the cupric reagent, and from vasculose by potash under ordinary atmospheric pressure.

Pectose is insoluble in water, but is rendered soluble and transformed into pectin by dilute acids. It occurs in the utricular tissues of fruits and roots, and is estimated by heating with dilute hydrochloric acid, dissolving in water, and precipitating with alcohol.

Calcium pectate forms part of the membrane which binds the cells together. It is estimated by treatment with dilute hydrochloric acid, which liberates pectic acid in the insoluble state; this is dissolved in potash and reprecipitated by an acid.

The *nitrogenous bodies* and the *inorganic constituents* are determined in the usual way.

The following is a summary of the method of analysis :

Cold dilute hydrochloric acid decomposes the calcium pectate, setting free the pectic acid, which is weighed as alkaline pectate. Boiling dilute hydrochloric acid changes the pectose into pectin, which is precipitated with alcohol. The ammonio-cupric reagent dissolves the cellulose. Hot hydrochloric acid renders paracellulose soluble in the cupric reagent. Sulphuric acid (bihydrated) dissolves the cellulose bodies. Hot dilute potash dissolves the cutose. Potash under pressure dissolves vasculose. Dilute nitric acid renders vasculose soluble in alkaline solutions.

VELELLA. The blue colouring matter of *Velevilla limbosa* has been examined by A. and G. de Negri (*Gazz. chim. ital.* 1877, 219). It changes rapidly after the death of the animal; is insoluble in ether, chloroform, light petroleum, and carbon sulphide; dissolves sparingly in water, forming a liquid which is turned yellow by heating, red by acids, amethyst-coloured by alkalis. Neutralisation of the alkali by an acid does not restore the blue colour. This colouring matter is totally distinct from that of murex and that of the aplypsia, and is spectroscopically distinguished therefrom by the complete absence of absorption-bands.

VENERITE. A copper ore, resembling chlorite in appearance, from the Jones mine, near Springfield, Berks County, Pennsylvania. It is usually very impure, but selected portions showed under the microscope thin transparent laminae mixed with quartz and magnetic iron ore. When separated as completely as possible from these substances it gave by analysis (after deduction of 6.22 per cent. sand) :

SiO ²	Al ² O ³	Fe ² O ³	FeO	MgO	CuO	H ² O
30.73	14.67	5.35	0.29	18.55	17.58	12.83 = 100

These numbers lead to the oxygen-ratio RO : R²O³ : SiO² : H²O = 3 : 4 : 6 : 4; but the homogeneity of the substance is open to some doubt (T. Sterry Hunt, *Jahrb. f. Min.* 1877, 837).

VERATRIC ACID, C⁹H¹⁰O⁴ = C⁶H⁵(CO²H)(OCH³).¹(OCH³).²—*Dimethylproto-catechuic acid.* See pp. 991 and 1691-1693.

VERATRUM ALKALOIDS. A. From the seeds of *Veratrum Sabadilla*.—The following bases from *sabadilla* seeds have been examined by Wright a. Luff. (*Chem. Soc. J.* xxxiii. 338):—1. Cevadine, C²²H⁴⁹NO³, identical with the base called veratrine by Merck (v. 996), and by Schmidt a. Köppen (*Ber.* ix. 1115). 2. Veratrine, identical with the base so named by Couerbe (*Ann. Chim. Phys.* [2], lii. 352). 3. Cevadilline, called *Sabadilline* by Wergelin a. Dragendorff (*Jahresb. f. Pharm.* xxxvii. 94). This alteration of the names of the three bases is made in accordance with their products of saponification, veratrine being thereby converted into veratric acid; cevadine and cevadilline into cevadic acid (i. 843).

Preparation.—The *sabadilla* seeds were exhausted with alcohol holding in solution 1 per cent. tartaric acid; and the concentrated extract, freed from resin by precipitation with water, was treated with sodium carbonate and ether to dissolve out the alkaloïds, which were then redissolved in aqueous tartaric acid, and again taken up by addition of sodium carbonate and agitation with ether. The ethereal solution, mixed with benzolin, left on evaporation a syrupy mass, in which crystals ultimately formed; and these crystals, mixed with viscid matter, were stirred up with a few drops of alcohol, then well drained and slightly washed with alcohol on a vacuum-filter, and finally purified by two or three crystallisations from hot alcohol. They then melted at 205° (like Merck's veratrine), and were converted by saponification into cevadic acid; for this reason, as above mentioned, Wright a. Luff designate the base thus obtained as *cevadine*. The syrupy mass from which the crystals had separated yielded by saponification a mixture of cevadic and veratric acids.

This syrupy mass is only partially soluble in ether; and on dissolving the residue left by ether in tartaric acid, reprecipitating with sodium carbonate, rapidly agitating the precipitate with ether, and repeating this treatment, cevadilline is obtained.

The ethereal solution of the syrupy mass (*infra*), again mixed with benzolin, deposits on standing a syrup, still containing a few crystals of cevadine; and the solution of this syrup in dilute sulphuric acid yields, on addition of ammonia, a precipitate of veratrine (Couerbe's), which may be purified by conversion into the sparingly soluble nitrate and then into the crystalline sulphate.

Twenty pounds of *sabadilla* seeds yielded from 60 to 70 grams of crude alkaloïds, from which were obtained 9 g. cevadine, 6 g. veratrine, and 3 g. cevadilline. The chief bulk of the basic product is uncrystallisable, and consists most probably of a mixture

of these three alkaloids. Weigelin's sabatrine and sabadilline (vii. 1063) were not found in the mother-liquors.

Cevadine, $C^{32}H^{49}NO^9$ (Schmidt a. Köppen's *Veratrine*), melts at 206° and becomes opaque on exposure to the air, but without losing weight. Its salts are mostly uncrystallisable, but the *aurochloride*, $C^{32}H^{49}NO^9.HCl.AuCl^3 + 2H^2O$, crystallises readily from hot alcohol, and gives off its water at 100° . Cevadine heated with water, or better with alcoholic soda-ley, is decomposed as represented by the equation,

into a white base called *cevine*, and methylcrotonic acid, agreeing in its melting point (64° - 65°) and mode of decomposition by heating with potash, with the methylcrotonic acid of Frankland a. Duppa (vi. 828), and with the acid called *cevadid acid* by Couerbe and by Pelletier a. Caventou (*Ann. Ch. Phys.* [2], xiv. 69).

To isolate the *cevine*, the acid liquid left after distilling off the volatile acid was filtered from resinous matter, rendered alkaline with caustic soda, and shaken with fusel-oil. The filtered fusel-oil extract left on evaporation a brownish varnish, which dissolved in acetic acid, leaving resinous flakes. The filtrate from these treated with soda and fusel-oil (after fractional precipitation to remove colouring matter), yielded *cevine* in the form of an amber-coloured varnish, melting at 45° , perfectly soluble in acids, easily soluble in alcohol and fusel-oil, sparingly in chloroform, nearly insoluble in ether. Neither the base nor its salts were obtained in the crystalline state, but on adding potassio-mercuric iodide to its solution in acetic acid, white flakes were precipitated, having, when dried at 100° , the composition $C^{27}H^{43}NO^8.HI.HgI^2$.

Cevadine heated at 100° with benzoic anhydride yields benzoyl-cevadine, $C^{32}H^{49}(C^7H^5O)NO^9 + 1\frac{1}{2}H^2O$, which crystallises from ether (cevadine does not), melts at 170° - 180° , and forms an aurochloride containing $C^{38}H^{53}NO^{10}.HCl.AuCl^3$. The formation of this benzoyl-compound shows that cevadine contains a hydroxyl-group, and as this base is converted by saponification into methylcrotonic acid:

its constitution may be represented by the formula:

which is closely related to that of pseudaconitine (p. 1695)

Veratrine, $C^{37}H^{53}NO^{11}$ (Couerbe's), is always amorphous, and melts after purification with ether at 180° (corr.). Its *gold-salt*, $C^{37}H^{53}NO^{11}.HCl.AuCl^3$, is amorphous and shrinks up on drying to a horny mass. The *nitrate* is amorphous. The *hydrochloride* and the *acid sulphate* crystallise, though with difficulty; the latter has the composition $(C^{37}H^{53}NO^{11})H^2SO^4 + 10H^2O$, but has not been obtained quite free from the normal salt. Veratrine is converted by saponification into veratric (dimethylprotocatechuic) acid, $C^6H^4(OCH^3)^2COOH$, and a base called *verine*, which may be extracted by ether in the manner above described for *cevine*, and obtained in the form of a varnish-like mass, which frits at about 95° , melts between 130° and 145° , and forms amorphous salts; its formula is $C^{28}H^{43}NO^8$. From this mode of decomposition it may be inferred that the constitutional formula of veratrine is:

Cevadilline, $C^{34}H^{52}NO^8$, when purified by conversion into tartrate and extraction with ether or benzene, after the liquid has been made alkaline, is amorphous, sparingly soluble in ether, more freely in benzene, during the evaporation of which it separates in amorphous flocks. By saponification it yields a volatile acid, most probably methylcrotonic acid, so that its decomposition may perhaps be represented by the equation $C^{34}H^{52}NO^8 + H^2O = C^5H^6O^2 + C^{29}H^{47}NO^7$, this last formula representing a base which may be called *cevilline*.

The uncrystallisable mother-liquors of the three bases above described probably consist for the most part of *verine* and *cevine*. The isomeric modifications of cevadine (veratrine) mentioned by some chemists* were probably nothing but impure or decomposed cevadine. Weigelin's *sabadilline* (vii. 1063) was perhaps cevadilline;

* Schmidt a. Köppen (*Ber.* ix. 1115) distinguish three modifications of the base which they call veratrine (Wright a. Luff's cevadine), viz. *crystallised*, *resinous*, and *soluble*, to all of which they assign the formula $C^{32}H^{49}NO^9$.

O. Hesse (*Li-big's Annalen*, xcxi. 186) represents sabadilline (cevadilline) by the formula $C^{31}H^{52}NO^7$, Weigelin's sabatrine by $C^{30}H^{51}O^8$, and Merck's veratrine (cevadine) by $C^{32}H^{47}NO^9$.

The following formulæ are given by Tobien (*Pharm. J. Trans.* [3], viii. 808):—*Sabadilline*, $C^{31}H^{50}N^2O^{12}$; *sabatrine*, $C^{31}H^{50}N^2O^{17}$; *veratroidine*, $C^{31}H^{57}N^2O^{16}$ or $C^{32}H^{57}NO^7$; *veratrine*, $C^{32}H^{50}N^2O^{14}$.

and his *sabatrine*, as well as Couerbe's *sabadilline-hydrate*, merely mixtures of decomposition-products (Wright & Luff).

B. Bases from *Veratrum Album*.

The rhizomes of this plant have been examined by several chemists. Weppen obtained from them an alkaloid which he called *veratramarine*, together with *jervine acid*, $C^{14}H^{10}O^{12}$ (vii. 641). *Jervine* was obtained from them by Simon (iii. 443), who assigned to it the formula $C^{90}H^{46}N^2O^8$, afterwards by Mitchell (vii. 709). C. Bullock (*Pharm. J. Trans.* [3], vi. 1009) also found *jervine* in these rhizomes, together with a resin, to the presence of which he ascribed the partial solubility of *jervine* in ether, the similarity of its reaction with sulphuric acid to that exhibited by *veratrine* (*cevadine*), and its physiological action. Pure *jervine*, according to his observations, melts at 196° – 199° , crystallises in prisms resembling *morphine sulphate*, and is completely precipitated from its solution in acetic acid by ammonia and the fixed alkalis.

A. Tobien (*Pharm. J. Trans.* [3], viii. 808) finds in the rhizomes of *Veratrum album* and *V. lobelianum*, of the most various origin, only two alkaloids, viz. *jervine* and *veratroidine*. The rhizomes were soaked in water to which was added 36.8 g. phosphoric acid solution (sp. gr. 1.28) to 2 kg. of solid substance, then repeatedly digested with warm alcohol of 95 per cent., and the extracts were evaporated in a vacuum. The residue, diluted with water, deposited a resin, which was dried, mixed with quicklime, moistened with water, and exhausted with alcohol. The extract was then evaporated; the residual *jervine* dissolved in acetic acid, precipitated with sodium carbonate, and redissolved in alcohol, these operations being several times repeated; and finally the *jervine* was converted into nitrate by precipitation with excess of salt-petre and separated therefrom by decomposition with sodium carbonate. By evaporation of its alcoholic solution it is obtained in dazzling white groups of needle-shaped crystals. The same treatment may be employed for the separation of the *jervine* which is precipitated by sodium carbonate from the filtrate of the above-mentioned resin.

Jervine has, according to Tobien, the composition $C^{27}H^{47}N^2O^8$. The formula of its *hydrochloride* is $C^{27}H^{47}N^2O^8.HCl$; of its *sulphate*, $C^{27}H^{47}N^2O^8.H^2SO^4$. It is very sparingly soluble in water, readily soluble in alcohol, and dissolves with successively decreasing facility in chloroform, amyl alcohol, benzene, ether, and petroleum. Strong sulphuric acid dissolves it with yellow colour, afterwards changing to yellowish-green; its *hydrochloride* is dissolved by nitric acid with transient rose colour. Its salts are precipitated by potassium nitrate from solutions containing only 1 pt. of salt in 1,200 water.

Veratroidine, $C^{51}H^{78}N^2O^{16}$ or $C^{24}H^{37}NO^7$, is obtained from the filtrates of *jervine* and its salts by supersaturation with caustic alkali and agitation with chloroform. It may be freed from the last portions of *jervine* by addition of nitric acid to its solution in acetic acid, the filtrate being then treated as above. It crystallises from alcohol and ether more readily than *veratrine* (? Merck's or Couerbe's), dissolves to a considerable amount in water, readily in alcohol, ether, and chloroform, less easily in amyl alcohol and benzene, not at all in light petroleum. It is not turned blue by sulphuric acid and sugar (distinction from *veratrine*), and is further distinguished from *veratrine*, *sabatrine*, and *sabadilline*, which it resembles in its reaction with sulphuric acid, by producing a fine but transient red colour with concentrated hydrochloric acid.

The alkaloids of *Veratrum album* have also been examined by Wright and Luff (*Chem. Soc. J.* xxxv. 405). The extract obtained with alcohol containing tartaric acid, which was several times used to macerate fresh portions of the root, so as to obtain a solution as concentrated as possible, gave, when fractionally precipitated by sodium carbonate, and fractionally taken up by ether, four different fractions of alkaloid, of which the fraction first precipitated on addition of sodium carbonate, and least soluble in ether, will be called 1, and the most soluble in ether, 4. The fractions 1, 2, and 3 are crystallised, 4 is amorphous (12 kg. of root yielded 50 g. alkaloids, or 0.42 per cent.)

Fraction 3. The base recrystallised from ether was converted by treatment with dilute sulphuric acid into a semi-gelatinous, very sparingly soluble sulphate, which, when decomposed by boiling with sodium carbonate and alcohol, yielded the base, on cooling, in loosely coherent crystals having the composition $C^{20}H^{22}NO^3 + 1\frac{1}{2}H^2O$ (probably $2H^2O$ if quite undecomposed). This base, identical with the *jervine* of Simon and of Will (according to whose analysis, however, it has the composition $C^{30}H^{46}N^2O^8$; see *ibid.* 446), yields a crystallised *hydrochloride* sparingly soluble in water, whether

cold or boiling, still less soluble in hydrochloric acid, more soluble in acetic acid; the *nitrate* is also but slightly soluble in water. The pure base boils at 237°, but the boiling point is often found lower (231°). Jervine dissolves in strong sulphuric acid with yellow colour, changing through brown to greenish-brown.

Rubijervine, $C^{26}H^{48}NO^2$, is contained as sulphate in the filtrate from the jervine sulphate, and may be separated therefrom by precipitation with caustic soda. It crystallises anhydrous from alcohol, and dissolves in strong sulphuric acid with yellow colour, changing through brown-yellow to brownish-red. The *sulphate* thus formed is crystalline, easily soluble in cold dilute sulphuric acid, sparingly in cold water. The *hydrochloride* is crystalline and easily soluble. The free base dissolves in strong sulphuric acid with yellow colour, changing through brown-yellow to brown-red. The *aurochloride* has the composition $C^{26}H^{48}NO^2.HCl.AuCl^3$.

Pseudojervine, $C^{29}H^{48}NO^7$.—The crude crystals of fraction 1 consist chiefly of this base, which may be separated from adhering jervine by conversion into sulphate, and from rubijervine by subsequent conversion into hydrochloride. Pseudojervine sulphate is sparingly soluble in cold, easily in hot water; whereas its hydrochloride is only slightly soluble in water, either hot or cold, but more easily soluble in dilute hydrochloric acid. Pseudojervine, when quite pure, melts with transient brown coloration at 299°, and reacts with strong sulphuric acid in the same manner as jervine. It is the least soluble in ether of all the crystallised alkaloids of *Veratrum album*.

Veratralbine, $C^{28}H^{48}NO^5$, is an amorphous base contained in fraction 2, together with jervine, a small quantity of pseudojervine, and a still smaller proportion of rubijervine. It is likewise the chief constituent of fraction 4, which, moreover, was once found to contain a small quantity of jervine, and probably also veratrine, inasmuch as it yielded by saponification a small quantity of veratric acid, its powerful sternutatory action being at the same time removed. Cevadic acid was not found in it.

Jervine, pseudojervine, and veratralbine are not saponifiable. The attempt to prepare a benzoyl-derivative from jervine was likewise unsuccessful, although the existence of such a derivative cannot be regarded as impossible. The sternutatory action of *V. album* appears to be due exclusively to veratrine, the amount of which does not exceed 1.25 per cent. of the total alkaloids contained in the root.

C. Bases from *Veratrum viride* (Wright, *Chem. Soc. J.* xxxv. 421).

The rhizome of this plant treated in the manner above described for *Veratrum album* yielded *cevadine* as chief constituent, together with traces of jervine, pseudojervine, rubijervine, veratralbine, and veratrine. The sternutatory action of this rhizome is due to the cevadine. 1 kilogram of the rhizomes of *V. album* and *V. viride* yielded the following quantities of the several bases:

	V. album.	V. viride.
Jervine	1.3	0.2
Pseudojervine	0.4	0.15
Rubijervine	0.25	0.02
Veratralbine	2.2	trace
Veratrine	0.05	trace (less than 0.004)
Cevadine	0.0	0.43
	4.20 g.	0.80 g.

C. Bullock (*Pharm. J. Trans.* [3], x. 186) finds that the resinous substances which separate during the concentration of the extracts of *Veratrum viride* contain the largest portion of the bases existing in that plant. These bases may be separated by treating the resin with milk of lime, concentrating, and exhausting the residue with alcohol, then converting them into acetates and precipitating with caustic soda. In this manner he obtained from a kilogram of the rhizome 6.612 g. of alkaloids; whereas Wright, probably from overlooking the circumstance just mentioned, obtained only 0.8 g.

VERINE, $C^{28}H^{48}NO^8$. A base formed, together with veratric acid, by saponification of veratrine (p. 2099).

VERMICULITE. This name, originally given to a chloritic mineral from Vermont, in North America, containing, according to Thomson, 49.08 per cent. SiO_2 , 7.28 Al_2O_3 , 16.12 FeO, 16.96 MgO, and 10.27 water (v. 997), has been extended by J. P. Cooke (*Phil. Mag.* xlvii. 241; 7, 135) to a family of hydrous silicates, including Culsageeite, Hallite and Jefferisite. These minerals, when heated,

swell up enormously, like alum and borax, in consequence of the escape of their water of crystallisation, after which they undergo complete disintegration.

Analyses. 1. *Sterlingite*, from Massachusetts, a mineral nearly related to Damourite, and differing therefrom only in the angle of the optic axes. Yellow to yellowish-white with nacreous lustre; analysed by C. E. Munroe. 2-4. *Culsageeite*, a variety of Jefferisite from the Culsagee mine, Macon County, North Carolina; lighter in colour and more easily cleavable than Jefferisite. Cooke's analyses differ from those given by Genth (p. 1142) only in the amount of water. 5-8. *Hallite*, a green or yellow micaceous mineral, probably crystallising in the hexagonal system; found in the serpentine of East Nottingham, south of Oxford, Chester County, Massachusetts. The analyses (by C. E. Munroe) 5 and 6 apply to the green, 7 and 8 to the yellow variety. 9. From Lerni, Delaware County, Pennsylvania, sea-green hexagonal plates; analysed by F. A. Gooch. 10. Pelham, Massachusetts; greenish-yellow, resembling Culsageeite (Gooch).

VESBIUM. This name (from Vesbio, an old name of Vesuvius) is given by Scacchi (*Gazz. Chim. ital.* 1880, 21) to a metal which he has discovered in an extremely thin green crust, found coating the fissures of the Vesuvian lava torrent of 1631. The crust being too thin to separate mechanically, the pieces of lava are treated with very dilute hydrochloric acid, which dissolves off the crust, forming a blue solution containing abundance of copper, silica, and other constituents of the lava; the acid solution is evaporated to dryness, heated to 170°, and exhausted with water. The residue consists principally of silica and a vesbium compound, together with a finely divided pulverulent matter which can easily be separated by elutriation; after this has been done, the product is treated with hydrochloric acid, filtered from undissolved silica, and again evaporated to dryness and heated to 170°; and on removing the small quantity of copper present by repeated washing with hot water, the purified vesbium compound remains as a dark-green powder, designated by Scacchi as *vesbine*. This substance is hygroscopic, and when ignited becomes brown without fusing. It is soluble in acids, yielding a green solution; the addition of potash or ammonia to this solution precipitates a ferric compound of vesbium, partly soluble in excess of the precipitant, forming a yellow solution. When vesbine is fused with an alkaline carbonate or nitrate, it dissolves with effervescence, forming an alkaline vesbiate soluble in water; on adding an acid to the colourless solution, it acquires a yellow colour similar to that of a chromate, and becoming bluish-green on heating. Alkaline vesbiates give precipitates of various colours with solutions of metallic salts, that with silver being bright red, whilst the zinc salt is greenish. Attempts to obtain potassium vesbiate in the crystalline state were unsuccessful.

On passing hydrogen sulphide through an acid solution of vesbine, a brown precipitate is formed, consisting chiefly of sulphur, but containing also small quantities of lead and copper sulphides; the filtrate from this is of a bright blue colour, but becomes colourless on adding excess of ammonia, whilst a brown precipitate is thrown down. When a plate of zinc is immersed in the blue solution, the colour is changed to deep brown, the liquid then appearing almost opaque. Even a very large excess of hydrogen sulphide produces no change in the blue solution. All the vesbium compounds, when fused with microcosmic salt, give a yellow bead tinged with brown in the outer flame, and a green bead in the reducing flame.

VESUVIAN. This mineral occurs on the Rammelsberg, near Deutsch-Tschamendorf, south of Strehlen, Silesia, forming veins in a limestone rich in diopside, titanite, and quartz. It contains calcite and diopside microscopically intermixed, but is free from titanite, so that the titanium contained in it must be regarded as isomorphously replacing a part of the silica (E. Schumacher, *Jahrb. f. Min.* 1878, 817).

SiO ²	ThO ²	Al ² O ³	Fe ² O ³	Mn ² O ³	FeO	CaO	MgO	H ² O
37·80	1·77	16·28	1·56	0·94	3·11	34·76	2·42	2·29 = 100·93

Crystals of vesuvian occur at Drammen in Norway, lining the walls of cavities

which have been formed in a silurian rock by the weathering of coral residues (W. C. Brögger, *Jahrb. f. Min.* 1876, 661).

The crystallographic constants of a honey-yellow and a black variety of vesuvian from Latium have been determined by J. Strüver (*Zeitschr. f. Kryst.* i. 251; *Jahresb. f. Chem.* 1877, 1307). The vesuvian of Latium occurs only in ejected blocks, mostly well crystallised, sometimes, however, in imperfect crystals and granular masses.

VICIN, $C^8H^{10}N^2O^6$. This substance, which Ritthausen a. Kreusler obtain from vetch-seeds (*J. pr. Chem.* [2], ii. 333), exhibits the following reactions: (1) It is not changed by boiling with baryta-water or with aqueous potash. (2) It dissolves in dilute sulphuric and in hydrochloric acid, the solutions depositing crystals which contain respectively 10·85 per cent. sulphuric acid and 10·02 per cent. chlorine. (3) When solutions of vicin in dilute acids are boiled for some time, they give off small quantities of gas, acquire the odour of decayed fruit, and exhibit the following reactions: (a) With baryta-water in excess, a violet-blue precipitate decolorised on boiling; (b) with ferric chloride and ammonia, a blue coloration, gradually changing to yellow in contact with the air; (c) the solution in sulphuric acid immediately reduces silver nitrate. (4) The solution of vicin in sulphuric acid becomes turbid after heating on the water-bath for twenty or thirty minutes, and on cooling deposits crystals which have the composition $2C^{11}H^{13}N^2O^6 \cdot 5SO^3$, and exhibit the reactions a, b, c, above described. In ammonia gas this substance becomes purple; in an atmosphere containing moist ammonia the colour changes through blue to bluish-grey; and the substance then forms with water a yellow solution, which, when decomposed by baryta-water, yields a deep yellow pulverulent body not yet examined. On separating the sulphuric acid by the calculated quantity of baryta-water, a colourless solution is obtained, which exhibits all the preceding reactions, but yields on evaporation a soft brownish mass which exhibits none of them. (5) The action of sulphuric acid upon vicin also gives rise to a small quantity of a volatile base and a larger quantity of a syrupy uncrystallisable body. (6) The solution of vicin in hydrochloric acid is precipitated by mercuric, but not by platonic chloride (Ritthausen, *Ber.* ix. 301).

VINYL- or ETHENYL-COMPOUNDS. The pungent liquid called *Vinyl Alcohol*, which Berthelot obtained by agitating acetylene with sulphuric acid and distilling the product with water (vi. 66), appears, from the experiments of Lagermarck a. Eltekoff (*Ber.* x. 637), not to be an alcohol, but to consist of crotonic aldehyde, C^4H^4O , formed by condensation of acetaldehyde, the first product of the reaction $[2C^2H^4O - H^2O = C^4H^4O]$, and convertible by oxidation with silver oxide into crotonic acid. According to S. Zeisel, on the other hand (*Liebig's Annalen*, exci. 366), the formation of acetaldehyde and crotonaldehyde in the experiments of Lagermarck a. Eltekoff must have been due to the presence of vinyl bromide in the acetylene employed. Vinyl bromide is in fact converted by strong sulphuric acid into crotonaldehyde and a body having the composition $C^2H^4Br^2$, whereas acetylene, after purification by moderate heating with soda-lime and subsequent washing with alcohol and water, is absorbed by sulphuric acid, probably with formation of a sulpho-acid.

The polymerisation of vinyl bromide (b. p. $15^\circ-16^\circ$), observed by Baumann (vii. 1202), is best effected by the most refrangible rays of the spectrum, and more readily when the compound is in the liquid than when it is in the solid state. The condensed product dissolves readily in methyl iodide and most other primary alkyl iodides, also in bromoform, benzaldehyde, and aniline. It is dissolved by strong nitric acid, with formation of a bromo-nitro-compound; reduced by fuming hydriodic acid at 150° .

Vinyl Ethylate or Vinyl-ethyl Oxide, $C^4H^8 = CH^2 \cdot CH \cdot O \cdot C^2H^5$, is formed by the action of sodium at $130^\circ-140^\circ$ on chloroacetal. It is a very mobile liquid which boils at $35\cdot5^\circ$; smells like ethyl oxide, ethylene, and allyl alcohol; dissolves sparingly in water, and, on the other hand, takes up a small quantity of that liquid. Sp. gr. = $0\cdot7625$ at $14\cdot5^\circ$, referred to water at $17\cdot5^\circ$ as unity. It unites with *chlorine* and *bromine* (most readily when they are diluted with carbon dioxide), forming dichloro or dibromomethyl oxide (e.g. $CH^2Cl \cdot CHCl \cdot O \cdot C^2H^5$). With small quantities of *iodine* it thickens, from formation of products of polymerisation or condensation. Moderately dilute *sulphuric* acid converts vinyl ethylate into aldehyde and ethylsulphuric acid. The same transformation appears to be gradually produced by the action of water, or better by an ammoniacal solution of silver nitrate (Wislicenus, *Liebig's Annalen*, excii. 106).

Vinyl-anisöl, $C^9H^{10}O = C^8H^4 \cdot \begin{smallmatrix} OCH^3 \\ \diagup \\ CH=CH^2 \end{smallmatrix}$ See PHENOL-ETHERS (p. 1521).

Vinyl-diacetonamine, $C^8H^{15}NO = C^8H^{12}(C^2H^3)NO$ (Heintz, *Liebig's Annalen*, clxxxix. 214; exci. 122). The *normal oxalate* of this base, $C^{16}H^{28}N^2O^6 =$

$(C^6H^{15}NO)^2, C^2H^2O^4$, separates out when 1 pt. of acid diacetonamine oxalate, 12 pts. alcohol, and 4 pts. acetone are heated together for thirty to sixty hours, the ethyl-oxalate of the same base remaining in solution. The formation of vinyl-diacetonamine in this reaction appears to be due to the presence of aldehyde in the acetone employed, the same compound being, in fact, produced in larger quantity by boiling 10 g. acid diacetonamine oxalate with 10 g. aldehyde and 120 g. alcohol in a reflux apparatus for sixty hours. The separated mass (vinyl-diacetonamine oxalate) may be purified by washing with hot alcohol.

Vinyl-diacetonamine separated from the pure oxalate by potash is a colourless, somewhat viscid liquid, which has a burning taste, smells like trimethylamine when cold, like camphor when warm, fumes with hydrochloric acid, and boils almost without decomposition at 199° – 200° . The distilled base turns yellowish after some time. It solidifies at -15° , forming rectangular or six-sided plates or long prisms, which melt at $+27^{\circ}$. It is extremely hygroscopic. The normal sulphate forms microscopic needles, easily soluble in water, sparingly in alcohol, insoluble in ether; it does not lose weight at 100° . An acid oxalate, $C^{18}H^{36}N^4O^{16} = 4C^{18}H^{18}N^4O, 3C^2H^2O^4$, is obtained by dissolving the normal oxalate (*supra*) and oxalic acid in molecular proportions in the smallest possible quantity of hot water, and separates on cooling in short microscopic prisms. Three pts. of this salt and 1 pt. oxalic acid dissolved together in water unite and form a new salt, which loses weight and turns brown at 100° , and is reconverted into the normal oxalate by boiling with alcohol. On evaporating an aqueous solution of 1 pt. of the normal oxalate and 2 pts. platonic chloride in a vacuum, exhausting the residue with alcohol and ether, and crystallising it from water, short flat prisms are obtained, often grouped in hexagonal plates, apparently belonging to the rhombic system and having the composition $2C^6H^{15}NO, PtCl^6H^2, 3H^2O$.

Vinyl-diacetonamine is related to triacetonamine in the same manner as acetone to aldehyde, being, in fact, the next lower homologue of triacetonamine, and containing two acetone residues and an aldehyde residue, whereas triacetonamine contains three acetone residues.

The two bodies may perhaps be represented by the following structural formulae (compare p. 32):

VINYL-TOLUIDINE, C^8H^9N . This base, which Wurtz obtained by heating toluidine with ethylene-chlorhydrin (vi. 1105), is also formed by decomposition of α -xethylene-toluidine. See ADDENDA.

VISCUM ALBUM. See MISTLETOE (p. 1331).

VITELLIN. See PROTEIDS (p. 1684).

VIVIANITE. *Native Ferrous Phosphate*. This mineral has been found within and upon the bones of animals on the peat moor of Larbach; partly in tabular groups of crystals grown together in parallel layers, partly in small needle-shaped monoclinic crystals exhibiting the combination $\infty P \infty \cdot \infty R \infty \cdot \infty P \cdot P \cdot P \infty$, partly also in radio-fibrous groups. It is blue by reflected light, but by transmitted light it appears almost colourless—merely with a coloured border (F. Becke, *Jahrb. f. Min.* 1878, 79). O. Fraas (*ibid.* 80) found the bones of a saurian from the keuper of Stuttgart converted into vivianite. Vivianite has been found also in somewhat considerable quantity in the pores of the bog iron ore of Leskowitz, near Friedeg, in Austrian Silesia (Neminar, *Min. Mitth.* 1875, 207).

VOLBORTETHE. See VANADATES (p. 2092).

VOLCANIC PRODUCTS. The term *Volcano* is commonly used to denote any orifice in the crust of the earth giving vent to materials which afford either direct or indirect evidence of the internal dynamic activity and the inherent heat of our planet. Such orifices are usually found on the flanks or the summit of a conical mound, hill, or mountain. The ejected materials are heated gases, steam, water, mud, dust, scorix, and molten rock. The accompaniments are frequently tremors in the earth, and loud noises produced by the concussion of rocks, and the escape of large quantities or gaseous matter in a high state of tension. Volcanic vents vary in size from the smallest *bocche del fuoco* on the flanks of a larger volcanic cone, or the little mud volcanoes of the Caspian, two or three feet in diameter, and the *volcanitos* of New Granada, to the gigantic volcanoes of the Andes, nearly 20,000 feet in height. The commonest form of volcano is that of a conical mound, terminated by a cup-shaped depression or crater, from which a tube descends to unknown depths, and by means of which volcanic products are brought to the surface.

The various kinds of volcanic vent may be conveniently classified as follows:

1. *Extinct Volcanoes*—that is, those which have never been known to be in a state of activity, such as the volcanoes of Auvergne.

2. *Dormant Volcanoes*—that is, those which have been in activity during the historical period, but have given no signs of life for a long term of years, such as Monte Epomeo in the Island of Ischia.

3. *Active Volcanoes*—that is, those which are constantly or at frequent intervals in a state of activity, such as Etna or Stromboli.

4. To these we may add the less common forms of *mud volcanoes*, sometimes called *macalube*, or *salses*, which occur in Mexico, on the shores of the Caspian Sea, in Iceland, Sicily, and elsewhere. Pools of boiling mud, which give off quantities of carbonic acid gas, and sometimes also hydrogen and sulphuretted hydrogen, are not uncommon in volcanic countries. *Air volcanoes* (the *volcanitos* of the natives), which eject boiling mud and gaseous products at frequent intervals, were found by Humboldt near Turbaco, in New Granada.

5. *Fumeroli* are small fissures or orifices frequently found within the craters of dormant and active volcanoes, and in recently emitted beds of lava. They give vent to various gaseous products, among which steam usually predominates, and to solid bodies which are carried along mechanically, or volatilised together with the issuing gases. When sulphur and sulphur-products predominate, the fumeroli are called *solfatare*. The *soffioni* of Tuscany are fumeroli by which quantities of boric acid are brought to the surface with the effluent steam. *Mofette* are exhalations of gaseous substances, usually carbonic acid, from hollows in the soil.

6. *Thermal Springs* are closely connected with volcanic phenomena, and their products are properly considered under the head of volcanic products.

In this category may also be placed the *Geysirs* and *Laugs* of Iceland, New Zealand, and North America.

The products—solid, liquid, and gaseous—which are emitted from these various forms of volcanic vent are very varied both as to character and composition, ranging from the commonest elementary bodies to some of the most complex minerals with which we are acquainted. This can scarcely be wondered at when we remember the conditions under which these bodies have been formed. Not only has fire effected a multitude of changes in the composition of volcanic products, but also water and various gases both at high and low temperatures and pressures, acting for short and long durations of time.

I. SOLID PRODUCTS OF VOLCANIC ACTION.

The most plentiful volcanic product is *Lava*, molten rock poured from a crater or from great fissures, and often closely resembling certain iron-furnace slags. Many millions of cubic feet of this substance are often ejected during a single eruption, and we read of a flow of lava which issued from Skapta, in Iceland, in 1783, which was fifty miles long and seven broad. It is important to bear in mind that certain apparently different volcanic products are chemically the same substance in different states of aggregation, or ejected under different conditions of pressure. Thus the compact lava which flows directly from the crater, and the ashes, sand, and scoriae resulting from the same molten lava being blown out of the crater by superheated steam, have precisely the same composition, as the following analyses by Silvestri of substances ejected during the eruption of Etna in 1865 clearly prove:

	Ashes	Sand	Scoriae	Compact Lava
Silica	50.00	49.80	50.00	49.95
Alumina	19.08	18.20	19.00	18.75
Ferrous oxide	12.16	12.42	11.70	11.21
Manganous oxide40	.45	.50	.49
Lime	9.98	11.00	10.28	11.10
Magnesia	4.12	4.00	4.20	4.05
Potash60	.49	.69	.70
Soda	3.72	3.60	3.40	3.71
Water36	.29	.33	.23
Phosphoric acid				
Titanic acid				
Vanadic acid				
Ferric oxide				
	traces	traces	traces	traces

Moreover, lavas which have been ejected at intervals of many centuries of time have frequently almost precisely the same composition; thus, we may compare one of the lavas of Etna ejected in very ancient times, with the lavas of 1669 and 1865. Microscopic analysis justifies the same conclusion.

Analysis: 1. Very ancient Etna lava. 2. Lava of 1669. 3. Lava of 1865.

	SiO ²	Al ² O ³	FeO	MnO	CaO	MgO	K ² O	Na ² O
1.	49.63	22.47	16.80	0.63	9.05	2.68	0.98	3.07
2.	48.33	16.15	16.32	0.54	9.31	4.58	0.77	3.45
3.	49.95	18.75	11.21	0.49	11.10	4.05	0.70	3.71

The Vesuvian lavas of 1631, 1767, and 1868, as analysed by Haughton, likewise exhibit a close agreement in composition.

SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	TiO	CaO	MgO	K ² O	Na ² O	H ² O
48.12	17.16	5.69	5.13	1.20	0.22	9.84	3.99	7.24	2.77	0.08
48.20	17.92	5.48	4.75	1.33	0.27	8.97	3.51	7.70	2.61	6.16
46.58	20.00	3.20	5.69	1.07	0.27	9.09	3.16	7.35	2.74	0.32

These lavas also contain small undetermined quantities of phosphoric acid and fluorine; and those of 1767 and 1868 contain in addition traces of fluorine.

Bunsen has divided all volcanic rocks into—

a. Normal Trachytic—that is to say, the trachytic rocks which are richest in silica, and represent a mixture of bisilicates of alumina and of potash and soda, while lime, magnesia, and ferrous oxide are almost entirely absent.

b. Normal Pyroxenic—that is to say, basaltic and doleritic rocks which contain the smallest quantity of silica, and are basic silicates of alumina and ferrous oxide in combination with lime, magnesia, potash, and soda.

The following is the composition of these two characteristic volcanic products:

	Normal Trachytic	Normal Pyroxenic
Silica	76.67	48.47
Alumina and Ferrous oxide	14.23	30.16
Lime	1.44	11.87
Magnesia	0.28	6.89
Potash	3.20	0.65
Soda	4.18	1.96

It will be at once obvious that the Etna and Vesuvius lavas, the composition of which is given above, closely approximate to the normal pyroxenic type, while obsidian and pumice belong to the normal trachytic type.

Bunsen, moreover, considers that the great number and variety of volcanic rocks containing percentages of silica included between the 76 per cent. of the normal trachytic and the 48 per cent. of the normal pyroxenic, result from mixtures of these rocks in varying proportions, and that 'the great mineralogical and petrographical differences which these rocks present are only consequences of the varying proportions in which the mixtures took place, and of the prevailing physical conditions under which the rocks reached their present situation and assumed their present form.'

The following are examples of some typical lavas, both ancient and modern, of different compositions and from different parts of the world, made in Bunsen's laboratory:

	Hrafnaberg, near Kribla, north- east of Iceland Black Stony Lava	Summit of Elburz	Black Basalt from the Source of the Euphrates	Hekla, Ash of 1846	Compact Grey Volcanic Rock from Kilmaununga, Iceland	Ancient Lava from Hekla
Silica	75.77	69.65	64.76	56.76	53.08	49.37
Alumina and Ferrous oxide	14.14	19.85	22.31	27.47	28.70	28.66
Lime	1.82	4.40	5.13	6.75	9.92	13.01
Magnesia	0.25	2.27	1.91	4.04	5.32	7.52
Potash	2.46	3.83	2.51	2.63	0.61	0.20
Soda	5.56		3.38	2.35	2.37	1.24

Bunsen regards those rocks which contain less than 60 per cent. of silica as *basic*, and those which contain more than 60 per cent. as *acid*. Thus the normal trachytic rock is the extreme acid member, and the normal pyroxenic the extreme basic member. The decomposition of these various rocks, under the influence of heat, air, water, superheated steam, sulphurous acid, hydrochloric acid, and other volcanic products and actions, gives rise to a great number of secondary products.

Elements and Compounds found in Volcanic Products.

Of the fifteen non-metallic elements *twelve* have been found in volcanic products; viz. boron, carbon, chlorine, fluorine, hydrogen, iodine, nitrogen, oxygen, phosphorus, selenium, sulphur, silicon. Of these oxygen and silicon are the most abundant.

Of the fifty-one metallic elements *nineteen* have been found; viz. aluminium, arsenic, caesium, calcium, cobalt, copper, iron, lead, lithium, magnesium, manganese, potassium, rubidium, sodium, thallium, titanium, uranium, zinc, zirconium. Of these aluminium and iron are the most abundant.

The island of Vulcano, one of the Lipari group, has furnished some of the rarest and most complex of volcanic products. To take a single example, a spongy crystalline substance found on the edges of a small fumerole at the bottom of the crater was found to consist of arsenious sulphide, selenium sulphide, boric acid, ammonium chloride, lithium sulphate, thallium alum, caesium alum, rubidium alum, potassium alum. Thus this one substance contained no fewer than seven non-metals and eight metals (see MINERALS, p. 1331).

Native Elements. Few of the elements have been found in the native state among volcanic products. *Oxygen, hydrogen, nitrogen, and chlorine* have been collected from fumeroles. *Sulphur* is found in solfatara in every part of the world, and in the craters of active and dormant volcanoes. It is frequently produced by the interaction of sulphurous acid and hydrogen sulphide. *Selensulphur*, i.e. indefinite mixtures of selenium and sulphur, has been found in the crater of Vulcano, and in that of Kilauea in the Sandwich Islands. This is the *volcanite* of Haidinger. *Carbon* in the form of graphite was found by Monticelli in an ejected block of Vesuvius, but it is a very rare volcanic product. Native metals, and native metallic alloys, are not found among the products of volcanoes, if we except *metallic copper*, which has been found in the palagonite tuff of the Faroe Islands, and is considered by Bunsen to have been reduced by hydrogen from the chloride.

The following simple combinations of non-metals with metals have been found:

Sulphides. *Red Sulphide of Arsenic, Realgar*, As_2S_3 , occurs in the fumeroles of Vesuvius, and at the solfatara of Puzzuoli. A specimen in the writer's possession from Puzzuoli was raked out of the 'bocca grande,' and was found to consist of microscopic crystals of both the sulphides of arsenic coating a white pumiceous substance. *Yellow Sulphide of Arsenic, Orpiment*, As_2S_3 . Crater of Vulcano. Solfatara of Puzzuoli. *Dimorphite*, the 'Dimorfina' of Scacchi, has been found at the solfatara of Puzzuoli. It is said to contain As_2S_3 , but may perhaps be only a mixture of sulphides. *Iron Bisulphide, Ordinary Iron Pyrites*, FeS_2 , has been found on Vesuvius, at Kriuvik in Iceland, and elsewhere; but it is an uncommon volcanic product. *Nickeliferous Pyrrhotite*, or *Magnetio Iron Pyrites*, $\text{Fe}^{\text{Ni}}\text{S}$, has been found on Vesuvius, having the composition: iron, 58.9; sulphur, 39.9; nickel, 2.6. *Lead Sulphide*, Galena, PbS , has been found in ejected blocks from Vesuvius. *Zinc Sulphide*, Blende, ZnS . Ejected blocks from Vesuvius. *Covellite*, a blue sulphide of copper, CuS , named after Covelli, who first detected it on Vesuvian lavas, is a rare volcanic product. *Dolerophanite* or *Cuprous Sulphide*, Cu_2S , was found by Scacchi as a sublimation produced during the eruption of Vesuvius in 1868. *Chalcocopyrite*, or *Copper Pyrites*, $\text{Cu}_2\text{S} \cdot \text{Fe}^{\text{Cu}}\text{S}$, has been occasionally found in blocks ejected from Vesuvius, but it is uncommon. It contains copper, 34.5; iron, 30.5; sulphur, 35.0.

Chlorides. *Potassium Chloride, Sylvite*. Fumeroles of Vesuvius and elsewhere. *Sodium Chloride, Halite*. Lavas of Vesuvius and Hekla, and probably existing as a sublimate on the lavas of all volcanoes situated near the sea, shortly after their emission and before rain has fallen. The writer noticed quantities of sublimed salt on the lava of Vesuvius emitted in November 1878. *Lithium Chloride*. Palmieri has detected lithium by means of the spectroscope in the fumerole sublimes of the eruption of Vesuvius of November 1878, associated with ferric chloride. *Calcium Chloride*, found by Bunsen in the sublimes from fumeroles in the Hekla lava of 1845, and by Palmieri in sublimes formed during the eruption of Vesuvius in 1872. *Aluminium Chloride*, $\text{Al}^{\text{Fe}}\text{Cl}_3$, found by Silliman in a sublimate from the volcano of Kilauea, and by Bunsen in a sublimation from the Hekla lava of 1845, associated

with chlorides of ammonium and iron. *Ammonium Chloride* is a frequent sublimation on lavas, and is often associated with ammonium sulphate and ferric chloride; it has been found at Etna, Hekla, Stromboli, Vulcano, Vesuvius, Kilauea, and elsewhere. When Bunsen visited Hekla, a few months after the eruption of 1845, he observed that the lower part of the lava stream was studded with fumeroles, in which large quantities of beautifully crystallised sal-ammoniac appeared, so that, 'notwithstanding the incessant torrents of rain, hundreds of pounds of this valuable salt might have been collected.' The occurrence of this substance was entirely confined to that portion of the lava stream which had overflowed meadow-land; higher up the stream all traces of the chloride disappeared at the point where vegetation ceased. By submitting a cubic meter of the meadow-land to dry distillation, Bunsen proved that a quantity of ammonia equivalent to 223.3 grams of ammonium chloride was produced. He considers that the ammonium chloride which is found among the fumerole sublimations is derived either from ammonia in the air, which is carried down by rain and converted into chloride by the hydrochloric acid of the fumeroles, or from the distillation of organic matter in the soil over which the lava passes. Daubeny, on the other hand, and Palmieri, consider that, under the conditions of temperature and pressure which must often prevail beneath lava, nitrogen and hydrogen may combine directly. Without attempting to account for the large quantities of ammonia which appear as fumerole sublimations, we may point out that the theory of Daubeny and Palmieri is quite at variance with recent discoveries concerning the dissociation of bodies. The following analysis of a sublimation from the Hekla lava of 1845, taken from fumeroles near the lower part of the stream, was made by Bunsen:

NH ⁺ Cl	4Fe ⁺ O ⁺ , Fe ⁺ Cl ⁺	4Al ⁺ O ⁺ , Al ⁺ Cl ⁺	MgCl ⁺	CaCl ⁺	NaCl	KCl	X*
81.68	5.04	3.73	1.69	0.53	1.73	0.95	3.12

* Water and stony residue.

With this we may compare an analysis of an ammonium chloride sublimate from Kilauea, made by Silliman:

NH ⁺ Cl	Fe ⁺ Cl ⁺	Al ⁺ Cl ⁺	Fe ⁺ O ⁺	Insol.
65.53	12.14	13.00	8.10	1.23

The composition of these sublimate is not surprising when we remember that hot hydrochloric acid is frequently evolved in abundance from fumeroli in newly ejected lava. The writer found that on passing dry hydrochloric acid over fragments of lava heated to redness in a porcelain tube, the chlorides of iron and aluminium were copiously evolved, while the lava became nearly white and friable, like the masses of decomposed lava frequently met with near hydrochloric acid fumeroli.

Ferric Chloride. Molysite. Fe⁺Cl⁺, found by Haussman on Vesuvian lavas in 1819, and by Scacchi in 1855. A common volcanic product, produced by the action of hydrochloric acid on lava. The writer of this article found large cavities containing several hundred square feet of surface, in the lava emitted by Vesuvius in November 1878, completely coated by a sublimate containing a large percentage of ferric chloride, while hot fumes of hydrochloric acid issued from fissures in the sides of the cavities. He also noticed it as a sublimation on the lava emitted from Hekla in February 1878. It is, of course, very deliquescent, and the first shower of rain may remove all traces of it.

Monticelli asserts the existence of *Ferrous Chloride*, FeCl⁺, as a sublimate on Vesuvian lavas, but his statement is not confirmed by Scacchi.

Kremersite, KCl, NH⁺Cl, 2Fe⁺Cl⁺ + 6H⁺O, a substance first analysed by Kremers, found as a product of sublimation from fumeroles, contains 55.86 per cent. Cl, 17.65 Fe, 12.32 K, 5.67 NH⁺, and 8.50 water.

Lead Chloride. Cotunnite, PbCl⁺.—Found by Monticelli and Covelli in the crater of Vesuvius, after the eruption of 1822, accompanied by copper chloride and sodium chloride; also by Scacchi and Guiscard as a product of the eruption of 1855.

Lead Oxychloride, Matlockite, PbCl⁺2PbO, was found as a sublimation product of a fumerole of Vesuvius after the eruption of 1855.

Hydrated Cupric Oxychloride, Atacamite, Cu⁺O⁺Cl⁺ + 4H⁺O, has been found incrusting Vesuvian lavas of 1820 and 1822. The writer found in the lava of November 1878 cavities lined with microscopic greenish crystals containing copper, in all probability existing as chloride.

Potassium Iodide has been found at Vulcano. The bromide would in all probability be detected if carefully sought for.

Calcium Fluoride has been found in blocks ejected from Vesuvius, and in a few volcanic minerals.

Iron Nitride. Siderazote, Fe⁺N⁺.—Found by Silvestri on the surface of the hot

lava of Etna (1874); formed artificially by exposing fragments of lava to the alternate action of hydrochloric acid and ammonia at a red heat. See p. 1097.

Oxides. *Black Copper Oxide*, *Melaconite*, or *Tenorite*, CuO , has been found by Semola, Scacchi, and Palmieri on the lavas of Vesuvius, sometimes in crystals. *Red Copper Oxide*, *Cuprite*, Cu_2O , has also been occasionally found on the scoræ of Vesuvius.

Ferric Oxide. Hematite. Found on the lavas of Etna and Vesuvius in the neighbourhood of fumeroles. *Ferric Hydroxide*, *Gothite*, $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, has been found in the ejected blocks of Somma. *Magnetic Iron Oxide*, *Magnetite*, is a frequent constituent of lavas, as may be shown by the microscopic examination of their sections; it is also found in volcanic sand and in the ejected blocks of Somma. *Magnesianoferrite*, $\text{MgO} \cdot \text{Fe}_2\text{O}_3$, has been found in crystals and laminae near the fumeroles of Vesuvius, particularly those of the eruption of 1855.

		Vesuvius. Old Eruption.	Vesuvius. Eruption of 1855.
Ferric oxide		84.20	85.05
Magnesia		16.00	13.95
Cupric oxide		—	1.01

Periclasite, $\text{MgO} = 93.86$, $\text{FeO} = 5.97$, has been found in clustered crystals in blocks ejected from Somma and Vesuvius.

Spinel, $\text{MgO} \cdot \text{Al}_2\text{O}_3$, found in ejected blocks from Somma and Vesuvius. A specimen from the latter volcano was found to contain 67.46 per cent. Al_2O_3 , 25.94 MgO , 5.06 FeO , and 2.38 SiO_2 .

Titanic Oxide, TiO_2 , both in the form of 'Brookite' and of 'Rutile,' has been occasionally found in the Val del Bove, on the east side of Etna. *Titaniferous Magnetite*, or *Iserine*, $\text{FeO} \cdot \text{TiO}_2 + \text{Fe}_2\text{O}_3$, is frequently found disseminated through lavas, scoræ, and tufas; in the eruptive rocks at Arthur's Seat, at Unkel on the Rhine, in basalt, and elsewhere.

Silica is found in the form of quartz in cavities of basalts; occasionally also, according to Monticelli, in the cavities of blocks ejected from Vesuvius (A.D. 79). Silica is also deposited from the *geysirs* of Iceland, New Zealand, and California, and is then known as *Geyserite*. The following analyses show the composition of these deposits:

	Iceland	Iceland	Iceland	New Zealand
Silica	98.00	91.56	88.26	94.20
Alumina	0.50	1.04	0.69	1.58
Ferric oxide	—	0.18	3.26	0.17
Lime	—	0.33	0.29	trace
Soda and Potash . .	—	0.35	0.22	0.85
Sulphuric acid . . .	—	—	2.49	—
Water	1.5	5.76	4.79	3.06

Silicates. The majority of volcanic products, as indeed of the whole mineral kingdom, consists of silicates of various degrees of complexity. Of these we shall first consider the most simple monosilicates, and afterwards those of more elaborate character and composition.

Calcium Silicate. Wollastonite. CaOSiO_2 .—Found in lavas and basalts in various parts of the world.

Pyroxene, or *Augite*, $(\text{CaO}, \text{MgO}, \text{FeO})\text{SiO}_2$, is an essential constituent of many volcanic rocks. The following analyses show the composition of various specimens from different volcanic centres:

	Vesuvius, 1831	Vesuvius, 1855	Etna, Mt. Rossi	Iceland	Teneriffe	Azores
Silica	48.86	49.61	47.38	49.87	48.05	50.40
Alumina	8.63	4.42	5.52	6.05	4.18	2.99
Ferrous oxide . . .	4.54	9.08	7.89	5.92	23.41	22.00
Magnesia	14.01	14.22	15.29	16.16	9.40	2.40
Lime	20.62	20.83	19.10	22.00	14.96	21.10
Ferric oxide	2.73	—	3.85	—	—	—

Breislakite is a capillary or woolly form of pyroxene, occurring in the lavas of Vesuvius and those of Capo di Bove.

A number of minerals result from the alteration of pyroxene. The following table, from Rutley's 'Study of Rocks,' shows the composition of the principal of these substances.

Name of Mineral	SiO ²	Al ² O ³	Cr ² O ³	Fe ² O ³	FeO	MnO	MgO	CaO	Na ² O	K ² O	TiO ²	H ² O	Authority
Augite .	51	3	—	—	6	3	13	24	—	—	—	—	Rammels- berg

Among these products we may specially notice *Palagonite*, a substance which Bunsen regards as the basis of the basaltic tufas of Germany, France, the Azores, Canaries, Cape Verde Islands, and of the numerous volcanic islands of the Pacific. Dana places palagonite among the hydrous silicates. Bunsen gives it the approximate formula $3\text{RO}, 2\text{SiO}^2 + 3\text{Al}^2\text{O}^3, \text{SiO}^2 + \text{Aq}$. It is met with in an amorphous form in grains and fragments aggregated into a tufa-like rock, and as a constituent of tufa and volcanic conglomerate. The hardness is from 4 to 5. Sp. gr. 2·47–2·7. The colour varies from amber-yellow, through red and brown to black. It melts easily to a black magnetic glass. As to its formation Bunsen remarks, 'Tufas are formed through the action of waters, and often that of heated waters or steam, accompanying an eruption of lavas, on the granulated volcanic rock or volcanic sand; and in this process the ferrous oxide of the pyroxene becomes more or less completely changed to ferric oxide, and water is taken up, and thus palagonite is produced. As the volcanic rock is generally made up of pyroxene and a felspar in very variable proportions, uniformity in such cases of alteration is not possible.' (For analyses see iv. 324.)

Glauconite, a hydrous silicate of iron and potassium, sometimes containing small quantities of silicates of magnesium and aluminium, is found more frequently in sedimentary than in volcanic rocks. It has been found, however, in the latter at Monte Baldo near Verona, and at Berufjord in Iceland. *Celadonite*, in which the iron is in the state of higher oxidation, is found in close proximity at Monte Baldo (see also ii. 846).

	Glauconite, Berufjord	Celadonite, Monte Baldo
Silica	52·04	53·0
Alumina	4·93	—
Ferric oxide	—	28·0
Ferrous oxide	25·54	—
Magnesia	4·26	2·0
Potash	6·03	10·0
Water	5·19	6·0

Hornblende, or *Amphibole*.—Silicates of various monoxides, and of alumina, found in the volcanic rocks of Etna, Vesuvius, Teneriffe, and elsewhere. A specimen from Etna contained silica 40·91, alumina 13·68, ferrous oxide 17·49, magnesia 13·19, lime 13·44. Sometimes contains small quantities of fluorine and of water (see further iii. 167–170).

• *Magnesium Silicate*, *Forsterite*, or *White Olivine* (*peridoto bianco* of Scacchi), has

been found in Vesuvian lavas associated with spinell and pyroxene. Silica 42.41, magnesia 53.80, protoxide of iron 2.33 (iv. 201).

Monticellite, a double silicate of calcium and magnesium, exists in certain lavas of Vesuvius and Somma. It contains silica 37.89, magnesia 22.04, lime 34.92, ferrous oxide 5.61.

Olivine, $(\text{MgO}, \text{FeO}) \cdot 2\text{SiO}_2$, is a common product of many eruptive rocks.

	Etna	Hekla	Vesuvius	Elifel
Silica	41.01	43.44	40.35	42.21
Ferrous oxide	10.06	6.93	12.34	8.91
Magnesia	47.27	49.31	46.70	49.29
Alumina	0.64	trace	—	0.18
Nickel	0.20	0.32	—	—

(See further iv. 201.)

Topaz, a tribasic aluminium silicate having part of the oxygen replaced by fluorine, is said by Monticelli to be occasionally met with as a volcanic product.

Garnet is found in the lavas of Vesuvius, in the volcanic soil near Frascati, and elsewhere in volcanic districts. The iron-alumina-lime garnet is most common. It contains silica 39.93 SiO_2 , 13.45 Al_2O_3 , 10.95 Fe_2O_3 , 3.35 FeO , 1.40 MnO , and 31.66 CaO (ii. 772).

Zircon, ZrSiO_4 , has been found in Vesuvian lavas associated with rhyacolite.

Idocrase, or *Vesuvianite*, is found among the ancient ejected blocks of Vesuvius and the dolomites of Somma. It resembles some of the lime-alumina garnets in composition. General formula $6(2\text{RO}, \text{SiO}_2) + 2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$. Contains 37.75 SiO_2 , 17.23 Al_2O_3 , 4.43 Fe_2O_3 , 3.79 MgO , 37.35 CaO (v. 998).

Melilite, *Zurite*, *Somervillite*, *Humboldtite*, are closely related minerals which are frequently met with in the lavas of Vesuvius and Somma, and in the slags of iron furnaces. Humboldtite contains 40.6 SiO_2 , 10.88 Al_2O_3 , 4.43 Fe_2O_3 , 4.54 MgO , 31.81 CaO , 4.43 Na_2O , 0.36 K_2O .

Biotite, or *Magnesia Mica*, $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + 3\text{RO} \cdot 2\text{SiO}_2$, is a common constituent of eruptive rocks. It has been found in blocks ejected from Monte Somma, in brilliant crystals. For analyses see iii. 1013.

Common or *Potash Mica* is sometimes found in the blocks ejected from Somma.

Talc, $6\text{MgO} \cdot 7\text{SiO}_2$, is mentioned by Monticelli as a constituent of some of the rocks of Somma.

Sarcolite, the *Analeima carnea* of Monticelli and Covelli, is a volcanic mineral of somewhat rare occurrence, found in ejected blocks, and having a composition somewhat like that of *Idocrase* (v. 196).

Meionite (called also *Scapolite* and *White Hyacinth*) and *Mizzonite* are minerals resembling each other, found in the rocks of Somma. They are silicates of aluminium and calcium, with a small percentage of sodium silicate (iii. 865).

	SiO_2	Al_2O_3	MgO	CaO	Na_2O	K_2O
Meionite	41.80	30.40	0.46	19.00	2.51	0.86 = 95.03
Mizzonite	54.70	23.80	0.22	8.77	9.83	2.14 = 99.46

Marialite, a mineral found in a volcanic rock called *piperno*, at Pianura, near Naples, contains 59.50 SiO_2 , 20.70 Al_2O_3 , 4.45 Fe_2O_3 , 0.29 MgO , 4.39 CaO , soda 8.90 Na_2O , 1.09 K_2O .

Nephelite, *Davyne*, *Carolinite*, and *Sommite*, very similar minerals, consisting essentially of silicates of alumina and of soda or potash, are found in both ancient and modern lavas, and may be represented by the general formula $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + \text{R}_2\text{O} \cdot \text{SiO}_2$ (iv. 30).

Tourmaline, $3\text{R}_2\text{O}_3 \cdot \text{SiO}_2 + 3\text{RO} \cdot \text{SiO}_2$; general composition 38 SiO_2 , 36 Al_2O_3 , 8 R_2O_3 ; was found by Brocchi in lava at La Scala and Fosso Grande.

Sodalite with Sodium Chloride, $3(\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 + \text{Na}_2\text{O} \cdot \text{SiO}_2) + 2\text{NaCl}$, has been found in trap, basalt, and modern volcanic rocks in Italy, Sicily, and elsewhere (v. 328).

Lapis Lazuli is said to have been found in an ejected block from Monte Somma. Composition somewhat variable (iii. 470).

Häuynite, or *Hauyne*.—Silicates of aluminium and sodium, silicate with sulphate of calcium, has been found among volcanic products at Vesuvius, Auvergne, Monte Vulture, Mount Albano, and the Azores (iii. 15).

Leucite, *White Garnet*, or *Amphigene*, $\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2 + \text{K}_2\text{O} \cdot \text{SiO}_2$, is a mineral confined to volcanic rocks (iii. 583).

	SiO ²	Al ² O ³	Na ² O	K ² O	
Vesuvius (1811)	56.10	23.22	0.57	20.59	= 100.48
Rocca Monfina	56.36	23.15	0.25	19.31	= 99.07

Lithia has been detected in Vesuvian leucite.

Leucitophyr is a name given to lavas which contain leucite disseminated through them in grains. Felspar, nephelite, and kaolin occur with the form of leucite (pseudomorphs) as a result of its alteration.

Anorthite, $\text{Al}^2\text{O}^3, \text{SiO}^2 + \text{CaO}, \text{SiO}^2$, is a common volcanic product of Hekla, Vesuvius, Etna, the Faroe Islands, Iceland, and elsewhere. *Analyses*: (1) From the plains of the Thjorsa, Iceland. (2) From the Isole dei Ciclopi, Sicily (for others see i. 308).

	SiO ²	Al ² O ³	Fe ² O ³	MgO	CaO	Na ² O	K ² O	
1.	48.36	30.59	1.37	0.97	17.16	1.13	0.62	= 100.20
2.	41.45	29.83	2.20	0.66	20.83	2.32	1.72	= 99.01

The anorthite from the plains of the Thjorsa is the *Thiorsaite* of Genth; that from the Cyclops Islands, off the east coast of Sicily, is the *Ciclopit* of Sartorius von Waltershausen.

Labradorite, $\text{Al}^2\text{O}^3, 2\text{SiO}^2 + \text{RO}, \text{SiO}^2 [\text{R} = \text{Ca}, \text{Na}]$.—Found in dolerites and basalts in Antrim, Iceland, Italy, Sicily, and elsewhere. It easily undergoes decomposition under the influence of air, water containing carbonic acid, and alkalis. For analyses see ii. 451; vii. 512; viii. 772, 774.

Oligoclase, $2(\text{Al}^2\text{O}^3, 3\text{SiO}^2) + 2\text{Na}^2\text{O}, 3\text{SiO}^2$.—Found in many volcanic products in Teneriffe and Iceland; in obsidian at Zimapan, in Mexico; in pumice at Arequipa, in Peru, and in various lavas and trachytes. For analyses see iii. 198; vii. 512, 513; viii. 774.

Orthoclase, or *Potash Felspar*, $\text{K}^2\text{Al}^2\text{Si}^6\text{O}^{16}$, or $\text{K}^2\text{O}, \text{Al}^2\text{O}^3, 6\text{SiO}^2$, and its glassy varieties, *sanidin* and *ryacolite*, occur in trachyte and many other volcanic rocks. *Aibite*, or *Soda-felspar*, $\text{Na}^2\text{Al}^2\text{Si}^6\text{O}^{16}$, is found in trachyte in the island of Pantellaria, at Langufjall in Iceland, and many other localities (ii. 620–622; vii. 508–510; viii. 773).

On *Obsidian* and *Pumice* see iv. 169; viii. 1422. Almost any lava may be converted into obsidian by melting and rapid cooling. The writer found that on fusing Giant's Causeway basalt in a gas furnace, and cooling it rapidly, a perfect glass, structureless and transparent under the microscope, was produced. By cooling less quickly, a substance was obtained which was absolutely opaque in the thinnest sections that could be procured.

Krabbite, or *Baulite*, is the obsidian of Mount Krabla in Iceland, and is similar in composition to pitchstones and obsidians. Contains 80.23 per cent. SiO^2 , 12.08 Al^2O^3 , 0.95 MgO , and 7.18 K^2O and Na^2O .

The following silicates, described in this or the preceding volumes of this Dictionary, have also been found amongst volcanic products:

Analcime	Herschelite
Apophyllite	Mesolite
Brewsterite	Natrolite
Chabazite	Okenite
Chondrodite or Humite	Prehnite
Epistilbite	Scolecite
Gehlenite	Thomsonite
Guarinite	Titanite or Sphene
Gismondin	

Borates. Boron occurs in only a few minerals. *Sassolite*, or native boric acid, occurs abundantly in the crater of Vulcano as a layer upon sulphur; also on Vesuvius, at Krisuvik in Iceland, at Atacama, at Sasso near Siena, in boracic acid lagoons and soffioni, and elsewhere. Ammonium sulphate often condenses with it in the soffioni. In a hot spring at Krisuvik 1,426 grains of crystallised boric acid have been found.

Ammonium Borate, or *Larderellite*, and *Iron Borate*, or *Lagonite*, are found as incrustations around the lagoons of Tuscany.

Sulphates. *Sulphuric Acid*, mineralogically *Sulphatite*, is noticed below under 'Liquid Volcanic Products.'

Aphthitalite, or *Potassium Sulphate*, the 'Vesuvian Salt' of Smithson, called also *Glaserite* and *Arcanite*, has been found in the form of crystals on Vesuvian lava. A specimen gave, on analysis, 71.4 K^2SO^4 , 18.6 Na^2SO^4 , 4.6 NaCl , and 5.4 $\text{CuCl}^2, \text{NH}^4\text{Cl}$ and Fe^2Cl^2 .

Misenite, or *Potassium-hydrogen Sulphate*, has been found by Scacchi in a hot tufa cavern near Cape Misenum, in the volcanic district around Naples. *Thenardite*, Na_2SO_4 , was found by Scacchi on the scoræ of Vesuvius after the eruption of 1855. *Mascagnite*, $(\text{NH}_4)^2\text{SO}_4$, has been found in the fissures of the lavas of Etna, Vesuvius, and Lipari, and in the boric acid lagoons of Tuscany. *Boussingaultite*, a double sulphate of ammonia and magnesia, has also been found in the Tuscany lagoons. *Mirabilite*, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, is abundant in a cavern of the volcano of Kilauea, in the Sandwich Islands. It has also been found on Vesuvius. The *Exanthalose* of Bendant found on Vesuvius contained $\text{Na}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$. *Gypsum* has been found near fumeroles from which sulphurous acid escapes, also around the mud cauldrons of Krisuvik. *Picromerite*, a magnesium-potassium sulphate, was found on Vesuvius among the salts produced during the eruption of 1855. *Chalcantkäte*, or *Cyanosite*, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, was observed among the Vesuvian minerals after the eruption of 1855. *Cyanochroite*, the *Cianocroma* of Scacchi, a hydrous sulphate of potassium and copper, was found on the lavas of Vesuvius after the eruption of 1855. *Alunogen*, $\text{Al}_2\text{SO}_4 \cdot 18\text{H}_2\text{O}$, has been found at Pasto in the crater of a volcano, at Krisuvik in Iceland, and at Vesuvius. *Coquimbite*, $\text{Fe}^2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$, was found by Scacchi around the fumeroles of Vesuvius after the eruption of 1855. *Kalinite*, or potash-alum, has been found in Vulcano associated with the *alums* of *Thallium*, *Rubidium*, and *Cæsium*. (See MINERALS OF VULCANO, p. 1330.) *Voltaite*, a ferroso-ferric sulphate (v. 1005), has been found at the solfatara of Puzzuoli. *Halotrichite*, $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$, in silky fibres, has been found at the solfatara of Puzzuoli and elsewhere. *Alunite*, $\text{AlK}(\text{SO}_4)_2 \cdot \text{AlH}_3\text{O}_3 \cdot 3\text{H}_2\text{O}$, is sometimes found in seams in trachytic and allied rocks, as a result of the alteration of the rock by sulphurous vapours. *Brochantite*, $\text{CuSO}_4 \cdot 3\text{CuH}_2\text{O}^2$, also called *Krisuvigite*, is occasionally met with among volcanic products, e.g. in small quantities at Krisuvik.

Carbonates. It is questionable to what extent we are justified in regarding any carbonate as a volcanic product. The *carbonates of copper, calcium, and magnesium* have, however, been found in blocks ejected from Monte Somma.

Phosphates. *Apatite*, $\text{Ca}_3(\text{PO}_4)_2$, containing also chlorine and fluorine, has been found in crystals in ejected blocks on Somma near Pollena. *Copper-Uranite*, $(\text{UO}_2)_2\text{Cu}(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$, is mentioned by Monticelli as having been found in green laminae in cavities of certain lavas of Vesuvius, but the statement wants verification.

Proximate Composition of Lava.

The ultimate composition of various typical lavas and mixed volcanic products has already been given (p. 2105). The determination of their proximate constitution is a matter of greater difficulty; the microscopic examination of thin sections of the rock often reveals to us which minerals preponderate, but no more than this.

Haughton and Hull have recently endeavoured to answer, in regard to Vesuvian lavas, the question, 'What is the proportion of each mineral present in the lava, and why does that proportion exist?' The various lavas which have flowed from Vesuvius are mainly made up of nine minerals of known composition, viz. *leucite*, *plagioclase* (triclinic feldspar), *magnetite*, *olivine*, *augite*, *hornblende*, *mica*, *nephelite*, and *sodalite*, together with an unknown quantity of a *paste* of unknown composition. This paste is the chemical residuum which remains over and above the chemical elements used up in the formation of the minerals. The question of the proximate composition of the lavas has been discussed by Haughton as a branch of the indeterminate analysis, and he assumes as his starting point the following principle: 'Of the numerous solutions possible, that one will occur in nature which involves the largest amount of definite minerals and the least amount of indefinite paste.' This principle has been applied by Haughton to twenty of the Vesuvian lavas, whose date of eruption ranges between 1631 and 1868. The lavas vary but slightly in composition. The following tables show the ultimate and proximate composition of two lavas separated by more than 200 years.

Ultimate analysis: a. Lava della Scala, 1631; b. Fosso Grande, 1858.

	SiO_2	P_2O_5	F	Cl	Al_2O_3	Fe_2O_3	FeO	MnO	TiO	CaO	MgO	K ₂ O	Na ₂ O	H ₂ O
a.	47.47	0.45	0.08	0.89	16.67	4.20	5.90	1.16	0.23	9.98	4.34	7.46	2.28	0.08
b.	46.36	—*	0.06	—*	18.60	4.12	4.94	1.00	0.29	9.09	4.00	7.18	2.96	0.40

* Not determined.

The proximate constitution of the same lavas, determined by the method of indeterminate analysis, and Haughton's principle above alluded to, is:

	Leucite	Anorthite	Magnetite	Olivine	Augite	Nephelite	Sodalite	Apatite	Paste
a.	40·6	6·9	4·9	trace	31·1	6·5	trace	1·1	8·9
b.	40·8	12·3	4·8	trace	28·6	—	7·1	—	6·34

The paste of 1631 contained 37·2 per cent. SiO_2 , 16·1 CaO , and 46·7 FeO , and may therefore be represented by the formula $\text{CaO}, \text{FeO}, \text{SiO}_2$.

Nodules in the Lava of Santorin, Grecian Archipelago.—According to Fouqué (*Compt. rend.* lxxx. 631), some of these nodules are hollow, while others are completely filled. The hollow nodules contain wollastonite, together with fassaite, less frequently with melanite; they also contain several undetermined minerals, including a chlorinated calcio-sodic silicate. In the perfectly filled nodules melanite is wanting, but quartz is said to occur. The nodules are traversed by greyish veins of lava, in which a vitreous ground-mass predominates. The following are analyses of these bodies:

Wollastonite.				
	Very pure	Cracked, with Enclosures	Associated with Fassaite	Associated with Garnet (Melanite)
Silica . . .	46·2	45·5	43·9	45·7
Lime . . .	41·8	43·0	41·3	42·2
Magnesia . .	1·5	0·8	2·0	1·9
Alumina . . .	7·1	7·2	9·5	8·6
Sesquioxide of iron .	2·9	2·8	2·5	2·5
	99·5	99·3	99·2	100·9
		Melanite Garnet	Fassaite Pyroxene	
Silica . . .		35·6	46·8	
Alumina . . .		12·2	10·1	
Sesquioxide of iron .		16·8	10·4	
Lime . . .		33·3	24·9	
Magnesia . . .		1·2	6·8	
		99·1	99·0	

Fouqué has also analysed masses rich in oligoclase, which are enclosed in the Santorin lavas. These masses, which to the naked eye appear compact, are resolved by microscopic examination into aggregates of predominant feldspar, less abundant pyroxene, and a small proportion of magnetic iron oxide, all irregularly imbedded in a greenish-brown vitreous mass. The majority of the pyroxene crystals are found, on closer optical examination, to be rhombic, and have been recognised by Des Cloizeaux as *hypersthene*; the minority are monoclinic, and consist of true *augites*. *Analyses*: (1) Oligoclase; (2) Hypersthene; (3) the entire aggregates.

	SiO_2	Fe^{O}_2	Al^{O}_2	CaO	MgO	Na^{O}	K^{O}	Sp. gr.
1.	59·7	0·4	23·2	7·9	1·0	6·6	0·8 =	99·6
2.	48·6	21·3	6·0	3·2	20·0	trace	— =	99·1
3.	58·4	8·1	20·7	6·0	2·7	3·7	0·5 =	100·3
								2·629
								3·472
								2·687

The species of feldspar recognised by Fouqué in the latest eruption of Santorin are albite, oligoclase, labradorite, and anorthite.

On the volcanic phenomena of Santorin, see further '*Santorin et ses Éruptions*,' par F. Fouqué, 4to. Paris, 1879; abstr. *Jahrbuch für Mineralogie*, 1880; ii. *Band. Reference*, 305-309; *Chem. Soc. J.*, July 1881.

II. LIQUID VOLCANIC PRODUCTS.

Water is the liquid which most frequently makes its appearance in all manifestations of volcanic activity. Indeed, it is frequently asserted that volcanic phenomena depend upon the presence of water, and that superheated steam is the cause of all the phenomena of ejection which volcanoes present. Steam is sometimes continuously emitted for years from the craters of volcanoes, or from fissures or orifices on their flanks, or from the floors of otherwise dormant craters. 'That the lava of volcanoes,' says Professor Judd, 'is a fluid mass containing imprisoned water, which, as it is relieved from pressure, flashes into steam, is now recognised by all geologists.' The changes of composition produced by the action of superheated water upon rocks are very various. These changes can be very advantageously studied in Iceland, and Bunsen has done much to extend our knowledge of thermal springs and water-metamorphism in that country. The springs of Iceland are distinguished from all other

European thermal springs by the large quantity of silica which they contain. They are either acid or alkaline. The former are connected with the solfataras, or *namars*, and owe their acidity to the presence of ammonia, soda, or potash alums. They contain various sulphates and chlorides, and deposit sulphur and gypsum. The alkaline springs are the commoner of the two, and constitute *Geysirs*, *Laugs*, and *Hvers*. Their alkaline reaction is due to the presence of alkaline sulphides and carbonates, which serve as solvents for the silica, and produce deposits of siliceous sinter or *geyserite*.

The following is an analysis by Bunsen of a slightly acid water taken in August 1846 from one of the largest of the mud cauldrons of the Reykjahlidder solfataras, between the N.E. declivity of the Namarfjall and the Burfell lava stream, in 10,000 parts:

CaSO ⁴	MgSO ⁴	(NH ⁴) ² SO ⁴	Al ³ (SO ⁴) ³	Na ² SO ⁴	K ² SO ⁴	SiO ²	Al ² O ³	H ² S
1·2712	1·0662	0·7333	0·3261	0·2674	0·1363	0·4171	0·0537	0·0820

The water of the Great Geysir, analysed in Bunsen's laboratory by Dr. Sandberger in 1846, gave in 10,000 parts:

SiO ²	Na ² CO ³	(NH ⁴) ² CO ³	Na ² SO ⁴	K ² SO ⁴	MgSO ⁴	NaCl	Na ² S	CO ²
0·5097	0·1939	0·0083	0·1070	0·0475	0·0042	0·2521	0·0088	0·0577

None of the rocks of Iceland resist the decomposing action of thermal waters, and these decompositions may be traced in the rocks of all ages. A variety of products is the result. The siliceous compounds with which these waters come into contact are formed into acid or basic silicates; the former are dissolved by the waters, the latter give rise to insoluble strata of clay.

Mud.—Certain small volcanic vents in various parts of the world bring to the surface quantities of hot argillaceous mud, resulting from the action of water containing various substances in solution, upon different kinds of rock, at varying temperatures and pressures.

Sulphuric acid is often found in the neighbourhood of volcanoes, containing in solution various sulphates, which it has dissolved out of the different rocks with which it has been in contact. It is found in cavities in the small volcanic mountain called Zoccolino, near Siena; in the stream issuing from Mount Purace, between Quito and Bogoto; in a stream proceeding from Mount Idienne, in Java; and elsewhere. The water of the Rio Vinagre, which rises near the Volcano Purace, has been found by Boussingault to contain in 100,000 parts:

SO ²	HCl	SiO ²	Al ² O ³	CaO	Na ² O
134·75	121·70	2·37	40·28	13·33	12·32 = 324·75

A torrent near Pasto was sufficiently acid to evolve hydrogen in contact with zinc. Near the Rio Guali a thermal spring was met with which contained 634·6 parts of sulphuric acid in 100,000. The sulphuric acid is undoubtedly produced by the action of hydrochloric acid at a temperature of from 700° to 900° upon sulphates; and the hydrochloric acid results from the action of aqueous vapour and silica upon chlorides at a red heat (*Compt. rend.* 78, p. 455 *et seq.*; *Chem. Soc. J.* 1874, p. 562).

Liquid Hydrocarbons.—Various liquid hydrocarbons have been found from time to time in the neighbourhood of volcanoes, as by Breislak at the foot of Vesuvius, in the Val di Noto in Sicily, and among the extinct volcanoes of Auvergne. Quite recently Silvestri has detected a mineral oil in the cavities of a prehistoric doleritic lava found near Paternò, on the flanks of Etna (see PARAFFINS, p. 1489). It was found in close proximity to the clay deposits of a mud volcano. The lava consisted mainly of augite with crystals of olivine and labradorite. It contained numerous cavities lined with arragonite and filled with a mineral oil, which latter was found to constitute about 1 per cent. of the whole weight of the lava. The mineral oil was taken from the lava at a temp. of 24° C., and it solidified at 17° to a yellowish-green mass, which on analysis gave the following composition: *

Liquid hydrocarbons boiling at 79°	= 17·97
Hydrocarbons solidifying below 0°, and boiling between 280° and 400°	}	= 31·95
Paraffin melting between 52° and 57°	= 42·79
Asphalt containing 12 per cent. of ash	= 2·90
Sulphur	= 4·32

99·92

III. GASEOUS VOLCANIC PRODUCTS.

The principal gaseous products of volcanoes are oxygen, hydrogen, nitrogen, chlorine, steam, hydrochloric acid, ammonia, sulphurous acid, hydrogen sulphide, carbonic acid, and marsh gas. The gases which are evolved from the principal vent after the issue of lava frequently consist of little else than atmospheric air. Hydrochloric acid and sulphurous acid, particularly the former, are products of intense volcanic activity. Carbonic acid and nitrogen appear during the more languid periods of activity, while hydrogen sulphide holds an intermediate position, and is never evolved during the most active stage.

The following analysis by Bunsen of the gases of a fumerole in the great crater of Hekla, in 1845, will illustrate the general nature of the gases evolved after the emission of lava:

N	O	CO ²	SO ²
81.81	14.21	2.44	1.54 = 100

At the solfatara of Krisuvik, in Iceland, jets of steam mixed with other gases issue from the ground with sufficient force to project stones as large as the fist to a height of several feet. The jets of vapour were found by Bunsen to contain in 100 parts: 82.30 H²O, 15.47 CO², 1.17 H²S, 0.76 H, and 0.30 N. The mixed gases separated from the aqueous vapour contained in 100 parts: 87.43 CO², 6.60 H²S, 4.30 H, and 1.67 N.

In the course of twenty-four hours this fumerole yields approximately 223 cubic meters of hydrogen sulphide and 12 cubic meters of hydrogen. A neighbouring fumerole gave a mixture of gases containing 15.71 per cent. of sulphuretted hydrogen.

The following is the analysis by Bunsen of a fumerole gas from Reykjahlidh, in the north of Iceland, remarkable for the large amount of hydrogen which it contains:

CO ²	H	H ² S	N
30.00	25.13	24.13	0.72* = 100

Fumerole gas from the immediate neighbourhood of the great geyssir at Haukadalr gave:

N	CO ²	H	H ² S
84.11	8.92	6.59	0.38 = 100

Silvestri analysed some of the fumerole gases of the eruption of Etna in 1865, and found them to consist of:

CO ²	H ² S	O	N
50.5	11.9	7.0	30.5

The gas evolved from a fumerole in the volcanic island of Santorin after the eruption of 1866 was found by Gorceix (*Compt. rend.* lxxv. 270) in 1870 to contain 19.4 HCl, 12.0 SO², and 68.5 CO². Gorceix has also analysed the gases emitted from the fumeroles of Nisyros (*Compt. rend.* lxxviii. 444-6). Fumerole No. 1 was situated within the aperture formed in June 1873; No. 2, on the lateral wall; Nos. 3-6 were on the flanks of the original crater. The carbonic acid and sulphuretted hydrogen obviously decrease with the increase of distance from the centre of activity.

	Temperatures 100°	100°	96°	92°	70°	55°
	I	II	III	IV	V	VI
Sulphuretted hydrogen . . .	48.8	44.5	4.6	1.5	—	—
Carbonic acid	40.9	49.2	1.8	14.7	7.0	5.5
Oxygen	1.1	1.0	13.8	15.6	18.1	18.2
Nitrogen	3.2	5.2	63.5	67.8	74.8	79.2

Of the various gaseous volcanic products *free hydrogen* is at first sight the most difficult to account for. Bunsen has shown that the conversion of pyroxenic rocks into palagonite is accompanied by a considerable disengagement of pure hydrogen, which results from the oxidation of ferrous silicate into ferric silicate. This change, however, presupposes so high a temperature that carbonic acid could not exist in contact with hydrogen without suffering partial reduction to carbonic oxide; but no trace of this gas is found in volcanic emanations. The formation of hydrogen and the other fumerole gases may, however, be supposed to take place as follows. When sulphur-vapour and steam come into contact with pyroxenic rocks at a red heat, a partial decomposition of ferric oxide takes place, and the sulphur is divided between the iron and the oxygen, forming sulphurous acid and sulphide of iron, FeS². If steam now comes into contact with the sulphide at a red heat, hydrogen sulphide is formed together with magnetic iron oxide, Fe³O⁴. If the temperature slightly exceeds a red heat, a part of the hydrogen sulphide is decomposed into hydrogen and sulphur. Bunsen found that when basalt is heated to redness in hydrogen sulphide, and after-

* So in the original paper; probably a misprint for 20.72.

wards raised to a higher temperature in a current of steam, a gaseous mixture is evolved, giving by analysis 93.99 per cent. H^2S and 6.01 H. This reaction explains the occurrence of hydrogen in fumerole gases. Bunsen considers that the metallic copper found in the palagonite tuff of the Faroe Islands has been reduced by hydrogen from copper-chloride.

Diego Franco (*Ann. Chim. Phys.* [4], xxx. 87; *Jahresb. f. Chem.* 1873, 1229) has demonstrated the emission of carbon dioxide in all stages of volcanic action, especially from Vesuvius, in which he has found this gas both in the central cone and in the flowing lavas. He has also given numerous analyses of gases emitted from flowing and from hardened lava, and found carbon dioxide in them all.

G. F. R.

VOLUME, SPECIFIC. *Atomic Volume.*—(1). **Of Liquids.** By dividing the specific gravities of liquids taken at the temperatures at which their vapour-tensions are equal to the standard atmospheric pressure—that is, at their ordinary boiling points—into their molecular weights, certain comparable values are obtained which are known as specific volumes. If the specific gravities are referred to water at $4^\circ C.$, these values represent the number of cubic centimeters occupied by the relative molecular weights of liquids, expressed in gram, at their respective boiling points under the standard pressure. The numbers so obtained were first shown by Kopp to exhibit certain definite relations which may be briefly indicated as follows:

1. *In many instances differences in specific volume are proportional to differences in corresponding chemical formula.* Thus a difference of CH^2 in a homologous series corresponds to a difference of about 22 in the specific volume, or $(CH^2)x = 22x$. On comparing the specific volumes of similarly constituted haloid compounds, it is seen that the substitution of n atoms of bromine for an equal number of chlorine atoms increases the specific volume by $5n$.

2. Isomeric and metameric liquids have, as a rule, the same specific volume.

3. The substitution of an atom of carbon for 2 of hydrogen makes no alteration in the specific volume of members of certain groups of organic liquids.

It would seem to follow, from Kopp's observations, that the specific volume of a liquid formed by the union of two other liquids is equal to the sum of the specific volumes of its components. It may also be inferred that the members of the same family of elements possess identical specific volumes; thus the common value of phosphorus, arsenic, and antimony would appear to be about 27; that of silicon, titanium, and tin would seem to be about 35.

On the basis of these conclusions Kopp was able to calculate certain fundamental values for the specific volumes of the elements in combination. These values are as a rule constant for the particular element; thus carbon has invariably the value 11, hydrogen that of 5.5. Exceptions are observed in the case of the chemical analogues oxygen and sulphur. Each of these bodies has two values, depending, it would seem, on its mode of combination, or on its relation to the remaining atoms in the molecule. For example, acetone and allyl alcohol have each the empirical formula C^3H^6O , but the specific volume of acetone is 78.2, whilst that of allyl alcohol is 73.8. The constitution of acetone may be expressed by the formula $CH^3.CO.CH^3$, whilst that of allyl alcohol is $CH^2=CH-CH^2OH$. In the case of acetone the affinities of the oxygen are wholly satisfied by the carbon—that is, we have reason to think that the oxygen-atom is more intimately associated with one of the carbon atoms than it is with any one of those of the other elements, whereas in allyl alcohol a moiety of the combining value would seem to be satisfied by carbon and the remainder by hydrogen. It appears, then, that when oxygen is united to an element by both its affinities, its specific volume is 12.2; when it is attached by only one combining unit, its specific volume is 7.8. The corresponding values for sulphur are 28.6 and 22.6.

Thorpe has pointed out (*Proc. Roy. Soc.* clx. 1875) that these differences in the values for the specific volumes of oxygen and sulphur may be employed to throw light upon the constitution of such bodies as phosphoryl trichloride and thiophosphoryl trichloride. If the phosphorus in these substances be regarded as trivalent, they must possess the constitution

If, on the other hand, the phosphorus is quinquivalent, they must be written

It is obvious that the knowledge of the specific volumes of PCl^3 , $POCl^3$, and $PSCl^3$ will serve to indicate the mode of combination of the oxygen and sulphur, and hence to determine the atomic value of the phosphorus in these compounds, provided that

the specific volume of the phosphorus is invariable, or is independent of its atomic value.

The sp. vol. of PCl_3 , according to Thorpe, is 93.3; Pierre found 93.5; Buff, 93.3; the mean of these numbers is 93.4. Buff and Thorpe found the sp. vol. of POCl_3 101.4; whilst that of PSCl_3 , according to Thorpe, is 116.1.

Sp. vol. of POCl_3	—	Sp. vol. PCl_3	=	Sp. vol. of O	Calc. sp. vol.
101.4	—	93.4	=	8.0	7.8
Sp. vol. PSCl_3	—	Sp. vol. PCl_3	=	Sp. vol. of S	
116.1	—	93.4	=	22.7	22.6

That this close agreement between the observed and calculated values is not a mere coincidence is seen from the fact of the difference between the two values respectively of oxygen and of sulphur; in the one case the difference is 4.4, in the other it is 6.0.

The observations of Pisati and De Franchis (*Gazz. Chim. ital.* 1874; *Ber. deutsch Chem. Ges.* 1875, 70; *Jahr.* 1875, 50) of the thermal expansion of solid and liquid phosphorus afford a determination of the specific volume of this element in the free state. The phosphorus melted at 44.4° , and boiled at 278.3° under a pressure of 762 mm. The following numbers, selected from the numerous observations of Pisati and De Franchis, show its specific gravity at various temperatures:

	Solid		Liquid
0°	1.83676	40°	1.74924
20°	1.82321	100°	1.69490
44°	1.80681	200°	1.60270
		280°	1.52867

The ratio of the volumes of solid and liquid phosphorus at 40° was 1.03446, and at 44° 1.0504. Kopp found 1.0343 at 44° . The volume of the solid phosphorus at t° referred to that at 0° is expressed by

$$V_t = V_0 + 0.000200t + 0.000000115t^2.$$

The expansion of liquid phosphorus between 50° and 280° is given by the expression

$$V_t = V_{50} + 0.0002969(t - 50) + 0.0000002115(t - 50)^2.$$

Pisati and De Franchis found some difficulty in preventing a partial transformation of the yellow phosphorus into the red modification, and the numbers denoting the specific gravity at higher temperatures are probably slightly too high on this account. The observation of Schrötter that melted phosphorus at 44° has a higher specific gravity (1.88) than when solid at 10° (1.83) was probably owing to the same cause. The specific volume of phosphorus calculated from the observations of Pisati and De Franchis is 20.2. A similar result has recently been obtained by Masson and Ramsay, who found the specific gravity of phosphorus at its boiling point to be 1.485, whence the specific volume = 20.91. The sp. vol. of phosphorus in the free state is therefore different from that which it possesses in such compounds as PCl_3 , PBr_3 , and $\text{PCl}_3 \cdot \text{CH}_3\text{O}$. Whether it is different from that of the element as existing in POCl_3 , POBrCl_2 , and PSCl_3 depends upon the view which is taken of the constitution of these bodies; but there is no *a priori* reason for supposing that the volume of the combined phosphorus would be different in the two series of compounds. It may be contended, from the well-known anomaly in the vapour-density of the element, that free phosphorus and combined phosphorus are not in comparable molecular states.

The specific volume of nitrogen also appears to be variable. According to Kopp in the amines it is 2.3; in cyanogen and certain nitro-compounds it is about 17. No rational explanation of this difference has yet been given. In fact, the observations of Ramsay (*infra*) seem to afford widely different values for the specific volume of nitrogen in different amines, and appear also to show that this element has a distinct value in the pyridine series of bases. On the supposition that the atomic value of an element is variable, Buff has suggested (*Ann. Chem. Pharm. Suppl.* iv. 129) that its specific volume is a function of that value. So far as we know there is no *a priori* reason why oxygen, sulphur, and nitrogen should alone possess variable specific volumes. (Compare i. 440-452 and vi. 235-237.)

Thorpe has recently determined the sp. vol. of a large number of specially selected liquid substances (*Chem. Soc. J.* 1880, xxxvii. 145-394), with the view of obtaining facts for a discussion of the following points:

1. Is it definitely established that an element in combination has, as a rule, an invariable specific volume? May not the volume be modified by the number of the atoms of that particular element in the molecule? Is it altogether independent of the

general complexity of the molecule, or may not the specific volume of the molecule be a function of its weight?

2. Do the various members of a given family of elements possess identical specific volumes, or may not the volume be a function of the atomic weight?

3. Would a re-examination of the cases of so-called variable atomic value serve to show that the specific volume of an element is a function of that value, as Buff supposes?

4. The hypotheses of Mendelejeff and Meyer indicate the need for additional and more exact determinations of the values for the specific volumes of the elementary bodies.

The method of observation was essentially that employed by Kopp, which involves the determination of the sp. gr., boiling point, and rate of thermal expansion of the liquid. For the details of the modes of experiment, which differed in many respects from those hitherto adopted, we must refer to the original memoir (*loc. cit.*) The sp. grs. were taken at 0°, and are compared with water at 4°; the boiling points are corrected and reduced to the standard pressure, and the rates of expansion are represented by expressions of the form

$$V = 1 + at + bt^2 + ct^3.$$

All temperatures are expressed in air-thermometer degrees.

The results are contained in the following tables. Table I. gives the several values of the coefficients in the expression representing the thermal expansion of the particular liquids investigated.

Table II. shows the relative volumes of the several liquids at every 10° between 0° and their boiling points.

Table III. shows the formulæ and molecular weights of these bodies, their boiling points under the standard pressure, their relative volumes at this temperature, their specific gravities at 0°, and at their respective boiling points, and lastly their specific volumes.

The conclusions which Thorpe deduces from his observations may be stated as follows.

1. It does not seem absolutely proved that isomeric liquids of the same chemical type, using that phrase in the sense in which Kopp employs it, have invariably the same specific volume. It is certain, for example, that ethylidene chloride and Dutch liquid have not the same specific gravity at their boiling points, and accordingly have not the same specific volume. The observations have given for—

	Sp. gr. at b.p.	Sp. vol.
Ethylene chloride . . .	1.15635	85.34
Ethylidene chloride . . .	1.10923	88.96
		<hr/> 3.62

This difference of 3.62 cannot be attributed to errors of observation. Moreover the specific volumes of ethylene chloride and of its analogues, $C^2H^1Br^2$ and C^2H^1Cl , are considerably below the numbers calculated by means of Kopp's values.

	Observed	Calculated	Diff.
Ethylene chloride . . .	85.3	89.5	4.2
„ bromide . . .	97.1	99.5	2.4
„ chloridide . . .	101.0	104.2	3.2

It seems not improbable that the specific volume of carbon or of hydrogen, or of both, may be slightly modified by the mode in which the atoms are grouped in a compound; that we may have, in fact, variations of a kind analogous to that which Gladstone, and more recently Brühl, have shown to exist in the atomic refraction of carbon, dependent on the manner of its combination. Indeed, it is not improbable that an intimate connection exists between the refractive power of such compounds and their specific volumes. Landolt has inferred that differences of molecular grouping in no way affect the refractive index of the constituent atoms, and Gladstone has shown that as a general law the molecular refractive power of a body is equal to the sum of the refraction of the atoms, just as it has been inferred that the specific volume of carbon is invariable, and that the specific volume of a compound liquid is equal to the sum of the specific volumes of its constituent elements or compound radicles. Exceptions, however, are known to this law. Thus the molecular refraction of many benzene derivatives, ethereal oils, and terpenes, and other bodies relatively rich in carbon, is considerably greater than that calculated from their atomic refractions. Brühl has succeeded in detecting the relation between the constitution of these bodies and their optical character; he has shown that their refractive power depends upon the mode of combination of the constituent atoms. It appears, for example, that in the

case of unsaturated bodies the atoms, which are more than once directly united to each other, exert a greater influence in propagating light than atoms which with the same atomic value are united to other atoms. Gladstone has pointed out that isomeric bodies occasionally differ widely in their optical properties. Thus aniline and picoline, each C^6H^7N , have widely different refraction equivalents. It is also certain that they have totally distinct specific volumes; thus:

Aniline	Picoline
106.2	111.5

It may be further noted that a large number of these bodies, of which the molecular refraction is greater than the computed value, have also a specific volume considerably

less than the calculated numbers. The specific gravity, boiling point, and rate of thermal expansion of benzene are known with great accuracy from the experiments of Kopp (i. 542), Louguinine (*Jahres.* vi. 260, 1867, 48), Pisati and Paternò, and Adrieez (viii. 159).

Their observations afford the following values for the specific volume of benzene :

Kopp	Louguinine	Pisati a. Paternò	Adrieez	Mean
95.94	95.98	95.94	95.90	95.94
Calculated sp. vol.			99.0	

The observed values are extremely concordant, but they differ by more than 3 per cent. from the computed value. Differences of the same order are exhibited by a number of aromatic compounds.

Specific Volume.

	Observed (Kopp)	Computed	Diff.
Phenol . . .	103.6	106.8	3.2
Benzyl alcohol . . .	123.7	128.8	5.1
Benzoic acid . . .	126.9	130.0	3.1
Benzoic aldehyde . . .	118.4	122.2	3.8
Cymene . . .	183.5	187.0	3.5
Napthalene . . .	149.2	154.0	4.8

Our views as to the constitution of the aromatic compounds would lead us to expect that the specific volume of benzene (and the derivatives in which the benzene group functions) would in all probability be different from that deduced from observations made for the most part on compounds of totally different constitution. Kopp (*Liebig's Annalen*, Supp. vi. 303) has shown, from Louguinine's observations, that whilst benzene has an abnormally low specific volume, its homologues show the constant increase of 22 in the volume for an increment of CH_2 , which is what might be anticipated, since these bodies are produced by the addition (substitution) of methyl, ethyl, &c., to the benzene group. Other values have, indeed, been calculated for carbon and hydrogen: Lothar Meyer makes $\text{H}=3$, and Loschmidt $\text{C}=14$ and $\text{H}=3.5$; and, by assuming that half the carbon-atoms in benzene have the value 11, and the remainder the value 14, and that hydrogen has the constant value 3.5, we obtain a value for this hydrocarbon which is identical with the observed number.

2. The observations furnish additional evidence in support of the assumption already regarded by Kopp and others as highly probable, that an element or a compound radicle occupies the same volume in combination as in the free state. Direct observation shows that the sp. vol. of nitrogen tetroxide is 64; hence $\text{NO}^2=32$. The sp. vol. of chloroform is 84.5; that of chloropierin is 110.5. Chloropierin may be regarded as derived from chloroform by the replacement of an atom of hydrogen by an equivalent amount of NO^2 .

Sp. vol. of $\text{C}(\text{NO}^2)\text{Cl}^3$	110.5
CHCl^3	84.5
	<hr/>
Add sp. vol. of H	26.0
	<hr/>
Calculated vol. of NO^2	31.5
Observed	32.0

Similar evidence is afforded by ethylene bromide, ethylene chloriodide, and propionitril.

Thorpe further concludes that there is at present no evidence in support of the hypothesis that the specific volume of an element in combination is modified by any possible variation in the affinity value which it may possess. It may turn out that the particular value to be assigned to carbon, for example, in the aromatic compounds is slightly different from that which it is found to possess in the fatty acids, or the corresponding alcohols and ethers, but there is no question as to the quantivalence of the carbon in these several groups of compounds. It is not, however, clearly established that any element, with the exception of oxygen, sulphur, and nitrogen, has a variable specific volume in combination. Hence the specific volume is altogether independent of the general complexity of the molecule, inasmuch as it is not modified by the number of the atoms of the particular element in the molecule. Lastly, it is proved that the different members of a family of elements do not possess identical specific volumes; the volumes of the elements are periodic functions of their atomic weights. The values deduced by Thorpe from a discussion of his observations,

together with those of previous investigators, are contained in the following table. It also shows the relation of the specific volume to the atomic weight.

Atomic Weights.

^I H = 1	^{II} C = 11.97	^{III} Si = 28.0	^{IV} Ti = 48	^V	^{VI} Sn = 117.8
	N = 14.01	P = 30.96	V = 51.2	As = 74.9	Sb = 120.0
	O = 15.96	S = 31.98	Cr = 52.4		
	F = 19.0	Cl = 35.47		Br = 79.75	I = 126.53

Specific Volumes.

^I H = 5.5	^{II} C = 11.0	^{III} Si = 30.3	^{IV} Ti = 33.6	^V —	^{VI} Sn = 40.8
	N = (?)	P = 25.3	V = 30.4 (26.0)	As = 26.3	Sb = 28.6
	O = 7.8 (12.2)	S = 22.6 (28.6)	Cr = 24.5	—	—
	F = 9.2	Cl = 22.7		Br = 23.1	I = 36.6

Ramsay (*J. C. S. July 1879*) has described a simple method of directly ascertaining the sp. gr. of a liquid at its boiling point with approximate accuracy, by means of which he has determined the specific volumes of a large number of substances. The results are contained in the table on p. 2128.

The specific volume of a considerable number of the bodies in this table has already been determined by Kopp, with whose results Ramsay's numbers show on the whole a satisfactory agreement. The specific volume of furfural indicates that both the oxygen atoms have the same value as in the aldehydes and ketones. Ramsay also points out that the specific volumes of the pyridine series of bases is very different from that of their isomerides in the aniline series. The specific volume of pyrrolone would appear to show that it approaches the nitrils in constitution, and has little or no analogy to the pyridine group.

F. D. Brown (*Proc. Roy. Soc. xxvi. 247*) has shown, from very careful determinations of the vapour-tension and specific gravity of normal propyl iodide and isopropyl iodide, that the specific volumes of the two isomerides at corresponding temperatures—that is, at temperatures at which their vapour-tensions are equal—are not identical. The results of his observations are contained in the following table:

Vapour-tension in mm.	Boiling point of normal Iodide	Boiling point of Isopropyl iodide	Density of normal Propyl iodide	Density of Isopropyl iodide	Diff.
200	62.37°	50.50°	1.66704	1.64590	0.02114
300	73.51	61.33	1.64493	1.62359	0.02134
400	81.95	69.70	1.62808	1.60646	0.02162
500	88.84	76.44	1.61446	1.59246	0.02200
600	94.70	82.11	1.60250	1.58068	0.02182
700	99.83	87.13	1.59221	1.57035	0.02186
760	102.63	89.86	1.58670	1.56497	0.02196

It will be seen from the above numbers that the density of the normal iodide is greater than that of the iso-iodide by an almost constant quantity—a fact which is in accordance with our dynamical hypotheses of the constitution of matter. The normal iodide is more stable than the iso-compound, the comparative instability of the latter compound being due, in all probability, to the greater mean distance between the molecules.

Schröder (*Ber. xiii. 1560*) has also pointed out that isomerides do not invariably possess the same specific volume. It appears that the volume of an acid is greater than that of the isomeric ethers; also that the volume of a normal compound is greater than that of the secondary compound, and that the boiling point and volume of such isomeric ethers as methyl acetate and ethyl formate are greater in the case of the ether containing the acid radicle possessing the smaller molecular weight.

(2) **Of Solids.** *Specific Volumes of Sulphates and Selenates.*—Pettersson (*Ber. ix.* 157) finds (1) that in the series of sulphates and selenates of K, Am, Rb, Cs, the spec. vol. is regularly increased by 6·6 when the group SO^4 is exchanged for the group SeO^4 ; and (2) that the substitution of Am², Rb², Cs², for K² produces an increase of volume of 9, 8, 23 in the selenates, as in the sulphates; and (3) the same regularity of increased volume shows itself in the double salts. Sodium-aluminium selenate has a smaller volume than the sulphate, a relation without example in the whole series of sulphates and selenates; thallium-aluminium selenate exhibits the opposite anomaly. The difference is possibly due to the molecules of the water of crystallisation in these two alums not being in the same state of condensation as in the other alums. The volume of a dehydrated alum exactly equals the sum of the volumes of its components.

Specific Volume of Water of Crystallisation.—Thorpe and Watts (*Chem. Soc. J.* 1880, 102) have determined the specific volumes of a number of the so-called magnesian sulphates combined with different proportions of water. The experimental results are as follows:

Copper Sulphate :

Hydrate	CuSO_4	$\text{CuSO}_4 \cdot \text{H}_2\text{O}$	$\text{CuSO}_4 \cdot 2\text{H}_2\text{O}$	$\text{CuSO}_4 \cdot 3\text{H}_2\text{O}$

These numbers, together with those obtained by previous investigators, afford the following table of specific volume :

Hydrate	0	1	2	3	4	5	6	7
Copper sulphate .	44.4	54.3	67.0	80.9	—	109.1	—	—
Magnesium sulphate .	44.8	55.6	67.0	—	—	112.4	130.8	146.6
Zinc sulphate .	45.6	54.7	66.6	—	—	113.7	130.2	146.8
Nickel sulphate .	44.6	56.5	—	—	—	—	129.0	144.6
Cobalt sulphate .	44.7	55.2	70.9	—	97.4	114.6	130.1	146.0
Manganous sulphate .	45.0	55.7	73.6	86.6	98.2	114.4	—	—
Ferrous sulphate .	44.5	56.2	67.7	—	100.5	—	—	146.7
Mean of means	44.8	55.5	68.8	83.3	98.7	112.9	130.0	146.1

On comparing the foregoing observations, it is evident that the anhydrous sulphates of copper, magnesium, zinc, nickel, cobalt, manganese, and iron have identical specific volumes ; or, since we may define specific volume as the volume in cubic centimetres occupied by the equivalent of the salt in grams, it follows that equivalent quantities of these different sulphates occupy the same bulk in space. A like conclusion as regards certain of these anhydrous sulphates has already been drawn by Playfair and Joule. It appears too that in the case of the magnesium sulphates the volume occupied by the several molecules of water varies with the degree of hydration. The first molecule of water, the constitutional water, called water of halhydration by Graham, occupies considerably less bulk than the remaining molecules ; its mean relative value is 10.7. Each additional molecule appears to occupy a gradually increasing volume. The difference between the monohydrate and dihydrate is 13.3 ; between the dihydrate and trihydrate it is 14.5 ; between the trihydrate and tetrahydrate it is 15.4, and between the hexhydrate and heptahydrate it is 16.2.

For Schröder's papers on the volume-constitution of solids, see *Ber.* x. 848 ; *Pogg. Ann.* clx. 199-219 ; also *Ber.* xi. 1109-1116 and 1142-1146 ; *J. pr. Chem.* [2], xix. 366-294.

T. E. T.

W

WAGNERITE. A specimen of this mineral from Radelgrafen, near Werfen, in Salzburg, has been examined by F. v. Kobell (*J. pr. Chem.* [2], v.i. 295). It occurs in closely packed parallel prisms with deep vertical striation. Prismatic angle = 120° – 121° . Cleavage imperfect. Dissolves, though slowly, in hydrochloric, nitric, and sulphuric acids. Analysis gave:

P ₂ O ₅	MgO	CaO	Na ₂ O, K ₂ O	Fe ₂ O ₃	Al ₂ O ₃	F	H ₂ O
40.30	32.78	2.24	5.12	8.00	1.11	10.00	0.50 = 100.05

from which the essential part of the mineral appears to have the composition $2\text{Mg}(\text{PO}_4)^2 + \frac{2}{3}\text{Na}^2 \left\{ \text{F}^2 \right.$, the double atom Na² replacing Ca isomorphously. The presence of the alkalis appears to have been overlooked by Fuchs and Rammelsberg (iv. 509).

WALPURGIN, $5\text{Bi}_2\text{O}_3, 3\text{U}_2\text{O}_3, 2\text{As}_2\text{O}_5 + 10\text{H}_2\text{O}$. See URANIC ARSENATES (vii. 1191).

WAPPLERITE. A calcium arsenate, $2\text{CaO}, \text{As}_2\text{O}_5 + 8\text{H}_2\text{O}$, or $(\text{Ca}^2\text{H}^2)\text{AsO}_4 + 7\text{H}_2\text{O}$, having part of the lime replaced by magnesia. It occurs at Joachimsthal in crystalline crusts resembling hyalite, in small botryoidal or dentiform aggregates, and in crude vitreous deposits. It is white and translucent in the mass, limpid in separate crystals. The crystals, mostly grouped in rows, are monoclinic, very small, and exhibit various faces, and an augitic or wolframite habit; they have a bright vitreous lustre, and cleave parallel to the clinodagonal. Sp. gr. = 2.48. Hardness = 2–2.5. Analysis gave:

	CaO	MgO	As ₂ O ₅	H ₂ O
(1)	14.19	8.29	47.70	29.40 = 99.58
(2)	15.60	7.35	47.69	29.49 = 100.13

The formula above given requires 23.04 CaO, 47.33 As₂O₅, and 29.63 water. The mineral gives off 5 mol. (18–20 per cent.) water at 100° , and the remainder at 360° , no further loss of weight occurring at a higher temperature. At 100° it is converted, like pharmacolite, $(2\text{CaO}, \text{H}_2\text{O})\text{As}_2\text{O}_5 + 5\text{H}_2\text{O}$, which at this temperature loses 3 mol. water (11–12 per cent.), into haidingerite, $(2\text{CaO}, \text{H}_2\text{O})\text{As}_2\text{O}_5 + 2\text{H}_2\text{O}$.

Wapplerite appears also to occur in Saxony, certain specimens of hydrated calcium arsenate from Schneeberg and Johann-Georgenstadt, regarded by Breithaupt as haidingerite, most probably belonging to this species.

The crystals have been accurately measured by Schrauf (*Jahrb. f. Min.* 1875, 290), who also finds them to be monoclinic with the axial ratio $a : b : c = 0.9125 : 1 : 0.2660$ and the axial angle $ac = 95^{\circ} 25'$. Observed faces $\infty\text{P}\infty$, $\infty\text{P}2$, ∞P , $\infty\text{P}2$, $\infty\text{P}\infty$, $\text{P}\infty$, $3\text{P}\infty$, $+2\text{P}2$, $-2\text{P}2$, $+2\text{P}\frac{3}{2}$, $+2\text{P}\frac{3}{2}$, $+4\text{P}4$, $-4\text{P}4$. The prism-zone is mostly predominant; the faces $-2\text{P}2$ and $-4\text{P}4$ occur but seldom. The crystals are rarely symmetrical, single quadrants with irregular hemisymmetric development of faces, or rather confused groups of crystals, more frequently projecting from the crystalline crusts.

From pharmacolite, which accompanies it, wapplerite is essentially distinguished by its conchoidal fracture and greater hardness = 3 to 3.5.

The crystals of calcio-magnesian arsenate called *roesslerite* (v. 114), which were first described by Haidinger, in 1825, as occurring, together with haidingerite and pharmacolite, and were found by Turner (*Pogg. Ann.* vi. 193) to contain 29.06 and 34.06 per cent. water, appear, from their form and composition, to be nothing but wapplerite metamorphosed by the addition of a small quantity of magnesia and 1 molecule of water.

WARRINGTONITE. A basic cupric sulphate, $3\text{CuH}_2\text{O}^2, \text{CuSO}_4, \text{H}_2\text{O}$, from Cornwall, belonging to the brochantite group (p. 349).

WARWICKITE. This mineral, occurring at Warwick, in New York (v. 1009), has been re-examined by J. L. Smith (*Sill. Am. J.* [3], viii. 432), who finds it to have the composition A, agreeing nearly with the formula $5\text{MgO}, 3\text{B}_2\text{O}_3 + (\text{MgO}, \text{FeO}), 2\text{TiO}_2$ (B):

	B ₂ O ₃	TiO ₂	MgO	FeO	SiO ₂	Al ₂ O ₃	Sp. gr.
A.	27.80	23.82	36.80	7.02	1.00	2.21 = 98.65	3.362
B.	30.57	23.58	35.36	10.49	—	— = 100	—

WATER. *Distance between the Molecules of Liquid Water.*—Herwig (*Ann. Phys. Chem.* [2], iv. 465) finds that the quantity of electricity required for the complete charging of a platinum-water-cell to the potential difference of 1 volt is equal to 0.000186 farad, when the plates have a surface of 1 square cm. This value is independent of the distance between the plates and of the external resistance. In order to derive from this the charging value for a potential difference of 1.7 volt, it is necessary to multiply by (1.7×1.25) , which gives 0.000395 farad. By means of this value and the application of the theory of rotary electrolytic molecules (*Ann. Phys. Chem.* [2], 566, iv. 187) Herwig has determined directly the distance between the molecules of water, and finds it to be at most $\frac{186}{1,000,000,000}$ mm.

Lorenz (*Pogg. Ann.* cxl. 644) found by a similar, although less direct method, the superior limit, $\frac{100}{1,000,000,000}$ mm; and W. Thomson (*Nature*, 1870), by an entirely different method, $\frac{50}{100,000,000}$ mm. (*Chem. Soc. J.* xxxvi. 194).

Compressibility.—Amaury and Descamps (*Compt. rend.* lxxviii. 1564) have obtained 0.0000457 as the coefficient of compressibility at 15°. Cailliet (*Compt. rend.* lxxv. 77) observed 0.0000451 at 8°. These numbers agree almost exactly with those previously obtained by Grassi. The addition of 5 per cent. of salt diminishes the compressibility to 0.0000419; with 15 per cent. it is 0.000356; with 30 per cent. it is 0.000306.

Buchanan (*Chem. Soc. J.* xxxiv. 452) has determined the relative apparent compressibility of sea-water and of a 4 per cent. solution of sodium chloride at different temperatures, the compressibility of distilled water at the same temperature being taken as unity.

Relative Apparent Compressibility.

Temp. C.	Sea-water	4 per cent. NaCl sol.	Distilled water
26.5°	0.9360	0.9051	1
25.8	0.9191	0.8813	1
22.8	0.9214	—	1
22.1	0.9283	0.8661	1
13.7	0.9264	0.8684	1
13.3	0.9203	—	1
2.5	0.8950	—	1

Point of Maximum Density.—Exner has redetermined the point of maximum density of water according to the method of Despretz, substituting a thermo-pile of peculiar construction for the ordinary mercurial thermometer. Five series of observations gave forty-one independent values, of which the mean was 3.945°, the maximum difference being only 0.082°. This value agrees exactly with that of Playfair and Joule. The following table has some historical interest, as showing the determinations hitherto recorded:

3.945 Exner.	3.68 Neumann (<i>Jahresb.</i> 1861, 60).
4.07 Rossetti (<i>Jahresb.</i> 1867, 45).	3.46–4.04 Pierre (<i>Ann. Chim. phys.</i> [3], xiii.)
4.08 Kopp (<i>Jahr.</i> 1847–48, 66).	3.40–4.85 Hallström (<i>Pogg. Ann.</i> i.)
4.00 Despretz (<i>Ann. Chim. phys.</i> [2], i. 70).	3.47–4.38 Rumford (<i>Phil. Trans.</i> 1792).
3.945 Joule and Playfair (<i>Pogg. Ann.</i> lxxi.)	3.33–4.16 Hope (<i>Edin. Soc. Trans.</i> 5, 1805).
3.87 Hagen (<i>Jahresb.</i> 1856, 49).	4.35 Tralles (<i>Gilb. Ann.</i> xxvii.)
3.8 Plücker and Geissler (<i>Jahresb.</i> 1852, 50).	3.6–3.9 Eckstrand (<i>Diss. Acad.</i> 1819).

Thermal Conductivity.—The thermal conductivity of water for heat in absolute measure has been determined by A. Winkelmann (*Pogg. Ann.* cliii. 481) to be 0.00154 in square centimeters per second. Bottomley (*Proc. Roy. Soc.* xxviii. 462), by a method devised by Thomson, originally obtained values varying from .0022 to .00245; in later experiments (*Proc. Roy. Soc.* xxxi. 300) he has obtained numbers more nearly in accord with those of Winkelmann, viz. .00134 and .00154.

Specific Heat.—Baumgartner has recently redetermined the specific heat of water at 100° by the method of mixtures (*Ann. Phys. Chem.* [27], viii. 648). The following table shows the value obtained, together with those of previous observers, the specific heat at 0° being taken as unity:

Regnault	1.0130	Henrichsen	1.0720
„ recalcd. by Bosscha	1.0220	Jamin and Amaury	1.1220
Münchhausen	1.0302	Marie Stame	1.1255
Baumgartner	1.0307		

Lowering of the Freezing Point by Pressure. See Dewar (*Chem. News*, xlii. 1, 2).

Existence of Ice at Temperatures far above its ordinary Melting Point.—Carnelley (*Proc. Roy. Soc.* xxxi. 284) has made the remarkable observation that ice heated in the Torricellian vacuum under such circumstances that the pressure in the containing vessel is maintained below 4.6 mm.—i.e. the tension of aqueous vapour at the freezing point—may have its temperature raised many degrees above its ordinary melting point without liquefying. The ice, under these conditions, passes directly to the gaseous state without intermediate liquefaction. In this respect ice is analogous to arsenic, which, under ordinary pressures, passes directly from the solid to the gaseous state on heating; on increasing the pressure the arsenic fuses. Carnelley has made similar experiments with mercuric chloride, which, under ordinary pressure, melts at 288°, resolidifies at 270°–275°, and boils at 303°; on reducing the pressure to 420 mm. the boiling point falls to 275°, when the mercuric chloride begins to solidify, and at 270° becomes completely solid, the pressure being 376 mm.

The experiments of Lothar and Meyer (*Ber.* xiv. 718), Hannay and McLeod, however, render it almost certain that the ice is actually at no higher temperature than that of its ordinary melting point, and it is not improbable that the higher thermometer readings observed by Carnelley were due to the action of radiation on the exposed ball, that is, when it is denuded of ice by volatilisation. De la Rivière and van Hasselt also were unable to observe that the ice could be raised above 0°, so long as care was taken to keep the thermometer bulb covered with ice.

Absolute Boiling Point.—Mendeleeff calculates the *absolute boiling point* of water, the temperature corresponding to the critical point of Andrews, to be 580°.

Thermal Expansion.—The coefficient of thermal expansion of a liquid is, as a rule, diminished by pressure and increased by dilatation. The behaviour of water is, however, anomalous in this respect, as its coefficient of expansion is found to increase with compression; it must follow, therefore, that the temperature of its maximum density diminishes with pressure. This conclusion has been experimentally verified by Van der Waals.

Thermal Expansion of Sea-water.—It is well known that the addition of saline matter to water alters both its rate of thermal expansion and its point of maximum density. Thorpe and Rücker (*Phil. Trans.* clxvi. 405) have recently studied the behaviour of sea-water in this respect, as a knowledge of the law of its expansion by heat is of great importance in relation to oceanic circulation and the distribution of ocean currents. The expansion of Atlantic Ocean water, of sp. gr. 1.02807 at 0°, compared with distilled water at the same temperature, was found to be expressed between 0° and 36°—the limits of the observations—by the formula:

$$V = 1 + 0.000057682t + 0.0000060715t^2 - 0.000000032983t^3.$$

In order to study the effect of different degrees of salinity on the thermal expansion, a portion of the water was concentrated, and a second portion was diluted with different amounts of pure water, and the rate of dilatation again determined, with the following results:

Specific gravity, 1.033015 at 0°:

$$V = 1 + 0.000081272t + 0.0000050987t^2 - 0.000000018227t^3.$$

Specific gravity, 1.024915 at 0°:

$$V = 1 + 0.000040939t + 0.0000062559t^2 - 0.000000033167t^3.$$

Specific gravity, 1.020755 at 0°:

$$V = 1 + 0.000024955t + 0.0000066723t^2 - 0.000000039065t^3.$$

The authors have investigated a formula, based upon these expressions, for the expansions of these solutions, which should embrace them all as particular cases of a relation between the temperature, volume, and salinity of sea-water, as measured by its specific gravity at 0°, and in the following table are given all the data necessary to calculate the specific gravity of sea-water of any degree of salinity at any temperature between 0° and 36°. Column II. contains the specific gravities at the temperatures given in column I. of a solution the specific gravity of which, at 0° C., is 1.02000; column III. contains the numbers which must be subtracted from those in column I. for each increase of 1° over the temperatures opposite to which they are placed; and column IV. the numbers which must be added for each increase of .00001 of the specific gravity of the solutions at zero. At the head of columns III. and IV. are the number of ciphers which must be prefixed to the figures written in them in the unit place:

Temp. C.	Sp. gr.	Prop. parts for 1° C.	P. parts for ·00001 incr. in sp. gr.	Temp. C.	Sp. gr.	Prop. parts for 1° C.	P. parts for ·00001 incr. in sp. gr.
		·0000	·0000			·0000	·0000
0	1·02000	3	1	19	1·01740	25	·944
1	1·01997	4	·995	20	1·01715	25	·943
2	1·01993	5	·990	21	1·01690	26	·941
3	1·01988	6	·986	22	1·01664	27	·940
4	1·01982	8	·982	23	1·01637	28	·938
5	1·01974	9	·979	24	1·01609	29	·937
6	1·01965	11	·975	25	1·01580	29	·935
7	1·01954	12	·972	26	1·01551	30	·934
8	1·01942	13	·969	27	1·01521	30	·932
9	1·01929	14	·966	28	1·01491	31	·930
10	1·01915	15	·963	29	1·01460	32	·928
11	1·01900	17	·961	30	1·01428	32	·925
12	1·01883	17	·958	31	1·01396	32	·922
13	1·01866	19	·956	32	1·01364	33	·919
14	1·01847	20	·954	33	1·01331	33	·915
15	1·01827	21	·952	34	1·01298	33	·912
16	1·01806	21	·950	35	1·01265	34	·908
17	1·01785	22	·948	36	1·01231	34	·903
18	1·01763	23	·946	—	—	—	—

The use of this table will be evident from the following example: *Given the sp. gr. of a sample of sea-water at any temperature t , to find it at 0° C.* Look out in col. I. the figures giving the number of entire degrees of temperature; multiply the fraction (if any) by which the observed temperature exceeds that number by the corresponding number in col. III., and subtract the result from the corresponding number in col. II. Subtract the difference from the observed specific gravity, and divide the number so obtained by that corresponding to the observed temperature in col. IV. (without prefixing the ciphers at the top of the column); add the quotient to 1·02000, and the sum will be the sp. gr. required.

Sp. gr. observed at 18·5 = 1·02475. To find it at 0° C., number opposite in col. III. is ·00023, which, multiplied by ·5, is ·000115; and 1·017630 - ·000115 = 1·017515. Subtract this from the observed sp. gr. 1·024750 - 1·017515 = ·007235. Divide by ·945, and the quotient is ·00765, which, added to 1·02000, gives 1·02765 as the sp. gr. at 0° C.

Pure Water.—Absolutely pure water can only be obtained, according to Stas (*Recherches sur les Rapports réciproques des Poids atomiques*), by mixing a cold saturated solution of potassium permanganate, rendered strongly alkaline by pure potash, with ordinary distilled water, redistilling in platinum vessels, and collecting the distillate when about $\frac{1}{20}$ th has passed over.

Action of Water upon Metals.—The action of water upon metals generally is greater than is usually supposed. That it acts upon lead is of course well known; the conditions which influence this action have recently been made the subject of careful study by Muir. In the case of this particular metal its solvent action seems to be largely dependent upon the presence of free carbonic acid; aerated waters containing comparatively large quantities of carbonic acid under pressure are found to act rapidly upon lead and its alloys. From this cause the soda-water in gazogenes and syphons is liable to be contaminated with the metal. Bischof has shown (*Chem. Soc. J.* xxxi. 428) that the 'composition' tube, which is employed by plumbers, and is an alloy of lead and antimony, is even more rapidly acted upon by ordinary water than tubes of soft lead. Carnelley (*Chem. Soc. J.* xxx. 1) has observed that pure water dissolves appreciable quantities of copper, thus confirming the statements of Reichart and Roux. Carnelley finds that the weight of copper dissolved by the action of distilled water is increased by the time of exposure and by the extent of metallic surface exposed; on the other hand, it is diminished by the presence of a more positive metal, as in the case of solder, and also by rise of temperature. The quantity of water in contact with a fixed amount of copper seems to have little or no effect upon the proportion dissolved. In the case of water containing salts in solution it is found that, with the exception of the ammoniacal salts, which appear to exert a strong specific

action, the nature of the base has only a comparatively small effect, the action of the salt depending chiefly on the nature of its acid radicle. The following is the order of action of certain of these combined acid radicles, beginning with that which has the least: nitrates, sulphates, carbonates, and chlorides. The order of this action is very different in the case of lead; in this case nitrate exerts by far the strongest effect, whilst that of carbonates and sulphates is almost *nil*.

Production of Ozone by Pulverisation of Water.—Leuder has already noticed that in the concentration of brine at Kissingen by the method of graduation the air in the immediate neighbourhood of the columns readily gives the ozone reaction, and Gorup-Besanez found that the quantity of ozone which is produced by a spray of water issuing under pressure depended upon the rate of evaporation. Morin and Monte have obtained similar results from experiments made by douche sprays in bathing establishments. Bellucci found relatively large quantities of ozone (or some substance giving the ozone reaction) in the air in the immediate neighbourhood of the falling water of the Falls of Terni. The production of ozone under these conditions is ascribed to the electrical state of the air induced by the friction of minute drops of water (compare p. 1479).

Contrary to the statement of Schönbein, it appears that ammonium nitrite is never formed by the evaporation of pure water in contact with nitrogen; when produced naturally it is due to the reaction of atmospheric hydrogen dioxide and ammonia.

Ammonia in Rain-water.—Lévy (*Compt. rend.* xci. 94) finds that although individual analyses of rain-water, collected from different quarters of Paris, show varying proportions of ammoniacal nitrogen, the mean monthly and yearly results are sensibly identical. The quantity of nitrogen decreases pretty regularly in passing from the cold to the warm season of the year, generally reaching its minimum in July; the mean result for that month in 1879 was 0.93 mgm. in 1 litre of water, and the mean for the year, with 4 recording stations, 1.17 mgm. The results of 4 years' analyses of rain-water collected at the observatory of Mont Souris give:

	Rain-gauge	Mean per litre	Nitrogen per sq. meter
1875-1876 . . .	541.5	1.98 mgm.	1074.78 mgm.
1876-1877 . . .	601.7	1.54 „	929.65 „
1877-1878 . . .	600.1	1.91 „	1149.40 „
1878-1879 . . .	655.3	1.20 „	787.32 „

Oxidation of Sewage in River-water.—Tidy (*Chem. Soc. J.* 1880, xxxvii. 268) has published a large number of analyses of river-water, viz. filtered and unfiltered Thames water; water of river Lea (filtered); of the Nile, Severn, and Shannon. As the result of his observations on these rivers and of experiments made specially on running water containing sewage, he concludes that when sewage is discharged into running water, provided the primary dilution of the sewage with pure water be sufficient, the run of a few miles, the precise distance of travel being dependent on several conditions, effects the removal of the whole of the organic impurity; and that whatever may be the actual cause of certain diseases—*i.e.* whether germs or chemical poisons—the *materies morbi* which finds its way into the river at the sewage outfall is destroyed, together with the organic impurity, after a certain flow.

These observations have been critically examined by Frankland. From experiments made in conjunction with Miss Lucy Halcrow (*Chem. Soc. J.* 1880, xxxvii. 506), he concludes that if peaty matter dissolved in river-water is spontaneously oxidised at all, the process takes place with extreme slowness, and cannot be accomplished to any considerable extent in the flow of a river, the results showing that peaty matter is even less oxidisable than animal matters under the same conditions. Additional evidence upon these points is contained in the analytical results of the examination of rivers made in the course of the inquiry instituted by the second Rivers Pollution Commission in 1868.

Composition of Irish Sea Water.—Thorpe and Morton (*Chem. Soc. J.* xxiv. 506) have given the following numbers as showing the composition of the water of the Irish Channel:

One thousand grams contain—

Sodium chloride	26.43918
Potassium chloride	0.74619
Magnesium chloride	3.15083
Magnesium bromide	0.07052
Magnesium sulphate	2.06608
Magnesium carbonate	traces
Magnesium nitrate	0.00207
Calcium sulphate	1.33158
Calcium carbonate	0.04754
Lithium chloride	traces
Ammonium chloride	0.00044
Ferrous carbonate	0.00503
Silicic acid	traces
	<hr/>
	33.85946
Amount directly determined	33.83855

Sp. gr.	1.02721 at 0°
	1.02484 at 15°

The total quantity of soluble salts contained in the water of the Irish Sea in the summer is rather larger than in winter, owing to the greater evaporation and diminished influx of fresh water in the former season.

The effect of the season is seen in the following table. The results of Forchhammer's numerous analyses of ocean-water are annexed for the sake of comparison:

	Water of Irish Sea	Cl	SO ³	CaO	MgO	Total salts
Absolute amount { Summer .	18.735	2.187	—	—	—	34.082
in 1,000 grams { Winter .	18.627	2.161	0.575	2.032	—	33.838
Relative amount { Summer .	100	11.67	—	—	—	181.91
{ Winter .	100	11.63	3.09	10.93	—	182.09
	Water of Atlantic Ocean					
Absolute amount {						
in 1,000 grams { . . .	19.865	2.362	0.588	2.199	—	35.976
Relative amount . . .	100	11.89	2.96	11.07	—	181.10

T. E. T.

WAVELLITE. A specimen of this mineral from the county of Cork has been analysed by A. H. Church (*Chem. Soc. J.* xxvi. 110), with the following result:

P ₂ O ₅	F	Al ₂ O ₃	Fe ₂ O ₃	CaO	SiO ₂	H ₂ O*	H ₂ O†	X‡
32.00	2.09	37.18	trace	trace	0.19	22.15	4.30	2.09 = 100

* At 200°. † At a low red heat. ‡ Loss.

Church considers that the amount of fluorine given by the analysis is too low, also that part of the loss ought to be reckoned as fluorine. He regards wavellite as a fluophosphate of aluminium.

WAX. The electrical properties of wax have been investigated by W. E. Ayrton (*Phil. Mag.* [5], vi. 132). The electric conductivity of wax does not change during fusion; its specific inductive capacity rises as the temperature falls slowly from 80° to 60°, but decreases on further lowering of temperature. The refractive index of wax likewise diminishes on solidification.

The wax of *Ficus gummiiflua*, used in some districts of Java as an illuminating material, has been examined by F. Kessel (*Ber.* xi. 2112). It is brown, brittle, melts between 60° and 70°, and yields to boiling water considerable quantities of a brown colouring matter, after the removal of which it is colourless. The colourless wax is resolved by ether into two bodies, one sparingly, the other easily soluble. The sparingly soluble constituent has the composition C²²H³⁶O, and is therefore isomeric with ceryl alcohol; it is crystalline, melts at 62°, is converted by PCl₅ into a chloride, and by acetyl chloride into an acetate melting at 57°. The easily soluble constituent (C¹⁵H³⁰O) crystallises in small nodules, melts at 73°, and likewise yields a chloride and an acetate. On subjecting the decolorised resin to dry distillation, there was obtained, together with other products, a body having the composition xC⁶H¹²O, which melted at 62°, crystallised in laminae, and was converted by oxidation with dilute nitric acid into an acid which crystallised in nodules.

British and Irish Mineral Waters.—Supplementary List (comp. v. 1017).

WILUEWITE. A variety of xanthophyllite from the Nikolajew-Maximilianowsk mine, near Achmatowsk, in the southern Ural. From clinoclhor it is distinguished by its greater hardness (4·5), and from xanthophyllite by the very large angle of its optic axes lying in the brachydiagonal principal section, whereas xanthophyllite is regarded as uniaxial. It occurs, together with perowskite, in chlorite-slate, possesses marked dichroism, and is similar in its crystallographic relations to mica (according to Kokscharow), being rhombic, with a tendency to the development of monoclinic hemihedral forms, and a prismatic angle which gives to the combination $\infty P. \infty \bar{P}\infty$ the form of a hexagonal prism. $a : b : c = 1 : 1.73205 : 0.70729$, or $0.5773 : 1 : 0.4926$ (c nearly $\frac{2}{3}$ of the principal axis of mica). Ordinary combination $0P. - \frac{4\bar{P}\infty}{2} + \frac{6\bar{P}3}{2}$. An analysis by P. v. Nikolajew gave:

SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	H ² O
16.90	43.55	2.31	0.33	13.00	17.47	5.07 = 98.63

WINE. On the natural constituents of wine see A. Dupré (*Chem. News*, xxxi. 125, 137).

The composition of a considerable number of Italian wines (520 samples) from the Vienna Exhibition has been examined by Sestini, Del Torre a. Baldi (*Ber. vii.* 1294). The mean proportion of alcohol in these wines is between 13 and 14 per cent.; a few contain less than 10 per cent. The quantity of free acid, even in the sourest (the Venetian) wines, does not exceed 1 per cent. The amount of solid residue is greater in the northern than in the southern wines. The average quantity of ash is 3 to 4 per cent. The quantity of sugar in Sicilian wines varies from 13 to 20 per cent. The wines of northern Italy contain only 1 to 2 per cent. sugar. The amount of tannin appears to vary inversely as that of sugar, the average proportion being 1 to 2 per cent. The greatest amount of glycerol ($\frac{1}{2}$ per cent.) is found in Sicilian wines. The proportion of volatile acids is greatest in the aromatic wines, amounting to one-fourth of the total quantity of free acids.

Analyses of *wine marc*, which had lain for 30 days in the vat with the must, and had then been well pressed, gave the following results in grams per kilogram:

	Red	White
Alcohol	58.5	39.0
Water	332.2	347.5
Dry substance at 100°	609.3	613.3
Nitrogen	1.032	1.016
Ash	71.08	60.03
Seeds	172.8	236.25
Bitartrate of potassium	83.8	81.7

On the composition of Hungarian wines, see Wartha (*J. pr. Chem.* [2], vii. 350); of wines from the neighbourhood of Verona: G. dal Sie (*Gazz. chim. ital.* 1873, 257); of Californian wines: Merrick (*Amer. Chemist*, vi. 85); of Virginian wines: Cooper (*Chem. News*, xxxii. 160).

On the composition of the Must of wine prepared from grapes of different degrees of ripeness, see Cossa, Pecile a. Porro (*Biedermann's Centralblatt f. Agriculturchemie*, 1875, 341; *Dingl. pol. J.* ccxvii. 342; *Jahresb. f. Chem.* 1875, 1130).

Preservation.—Favourable reports on Pasteur's method of preserving wine by heating it to 60°–65° C. (vii. 1208) are given by C. Neubauer (*Dingl. pol. J.* ccvii. 175). Red wine keeps particularly well after this treatment, but white wines, which are richer in albumin, sometimes become turbid.

On the Neutralisation of the Free Acid in wine by the addition of Calcium Carbonate to the must after fermentation (Chaptal's process), see Moschini a. Sestini (*Gazz. Chim. ital.* 1873, 195; *Chem. Soc. J.* xxvi. 1275).

On the treatment of wine with Air during Fermentation, see A. Ott (*Dingl. pol. J.* clvii. 155; *Chem. Soc. J.* xxvi. 660).

On the Classification of wines, see B. Hoff (*Dingl. pol. J.* ccxiii. 451); P. Wagner (*Berichte d. landw. Versuchsstation, Darmstadt*, 1874; *Jahresb. f. Chem.* 1874, 1178); L. Weigert (*Chem. Centr.* 1878, 702; *Chem. Soc. J.* xxxvi. 290); also E. Mach (*Biedermann's Centralblatt f. Agriculturchemie*, 1879, 453; *Chem. Soc. J.* xxxvi. 1078).

On the Preparation of Red wine, see F. Kernlter (*Chem. Soc. J.* xxxvi. 581). On the pressing of red wine, Nessler (*ibid.* 681).

On the Plastering of wines, Pollacci (*Gazz. Chim. ital.* 1878, 379; *Chem. Soc. J.* xxxvi. 681, 762).

On the Changes which wine undergoes in keeping, see Berthelot (*J. Pharm. Chim.* [4], xxix. 489; *Chem. Soc. J.* xxxvi. 763).

Analysis of Wines. 1. *Estimation of Alcohol.*—E. Duclaux (*Compt. rend.* lxxviii. 251; *Ann. Ch. phys.* [5], ii. 233) estimates the amount of alcohol in wine by a method based upon the fact that when alcohol is added to water, the density and surface-tension of the liquid are diminished, and consequently the number of drops yielded by a given volume of the liquid from an orifice of constant width is increased. The instrument used for the purpose is a pipette of 5 c.c. volume. It is filled with the alcoholic liquid under examination, the drops are counted, and the alcoholic value is then determined from the tables which have been calculated for various temperatures. The alcoholic value of wines may thus be estimated with considerable accuracy without previous distillation. In these liquids the density varies very little, and is always near that of water; and as their superficial tension depends solely upon the alcohol which they contain, it is but necessary to count the drops which they yield, and refer to the tables for the result.

If to alcohol or water slight traces of an organic substance having a high molecular weight be added, such as acetic ether, butylic or amylie alcohol, &c., the number of drops yielded by the alcohol or water rises very sensibly. A measurable effect can be produced with $\frac{1}{4000}$ th part of acetic ether. This process is thus available for detecting and approximately estimating certain substances when present in such small proportions as would not be indicated by any other method.

See further *Ann. Chim. phys.* [5], ii. 289; *Compt. rend.* lxxviii. 1159; *Dingl. pol. J.* ccxiii. 257, 261; *Chem. Soc. J.* xxvii. 1012.

Estimation of Sugar.—Béchamp (*Compt. rend.* lxxx. 967) remarks that wine, after being decolorised, slightly concentrated, and freed from acid potassium tartrate, contains, in addition to sugar, two substances possessed of optical rotatory power. The same substances affect also the quantity of copper precipitated from an alkaline cupric solution, so that the fermentation method is the only one that can be depended upon for the exact determination of the amount of sugar in wine. According to Chancel (*Compt. rend.* lxxxi. 46) these bodies are identical with the gummy substance found in wine by Pasteur (*Etudes sur le Vin*, 1866, p. 213). See also Maumené (*Compt. rend.* lxxx. 1026).

On the estimation of Glycerol in wine, see GLYCERIN (p. 873); also E. Reichardt (*Arch. Pharm.* x. [3], xi. 142; *Jahresb. f. Chem.* 1877, 1200).

Detection of Adulterations.—Elaborate memoirs were published a few years ago on the fraudulent coloration of wines by vegetable colouring matters of various kinds, e.g. extract of Brazil wood and logwood, cochineal, Portugal berries, berries of *Phytolacca decandra*, beet-root, hollyhock flowers, fuchsine, &c.; but as most of these alleged adulterations are harmless, and the extent to which they are employed appears to have been greatly exaggerated, a reference to the memoirs describing the mode of detecting them will be sufficient. See Gautier (*Bull. Soc. Chim.* [2], xxv. 435, 483, 530; *Analyst*, i. 109, 131; *Chem. Soc. J.* xxx. 330, 428); Chancel (*Compt. rend.* lxxxiv. 348; *Jahresb. f. Chem.* 1877, 1202; *Chem. Soc. J.* xxxii. 371); Griessmayer (*Dingl. pol. J.* ccxxiii. 531; *Chem. Soc. J.* xxxii. 368); Vogel (*Ber.* ix. 1906); Hilger (*Dingl. pol. J.* ccxv. 310; *Chem. Soc. J.* xxxii. 928).

On the detection of Tannin in red wines by Ammonium-vanadate, see VANADATES (p. 2090).

On the examination of wines sophisticated with Glucose, see Neubauer (*Dingl. pol. J.* ccxv. 309; *Chem. Soc. J.* xxxii. 939).

WOLFRAM. See TUNGSTEN (p. 2066).

WOLLASTONITE. This mineral occurs, together with fassaite, less frequently with melanite and other minerals, in the lava of Santorin (Fouqué, *Compt. rend.* lxxx. 63; *Jahresb. f. Chem.* 1875, 1275). See VOLCANIC PRODUCTS (p. 2114).

WOOD. On the Electric Conductivity of various kinds of wood, see ELECTRICITY (p. 720).

Heat-conductivity.—The following determinations of the specific gravity and heat-conductivity of box, maple, and oak have been made by E. Less (*Ann. Phys. Ergänzbd.* viii. 617):

	Sp. gr.	Heat-conductivity.
Box, parallel to the fibres	0·790	135
Maple " "	0·634	192
Oak " "	0·621	161
Oak, perpendicular to the fibres, parallel to the annual rings	0·568	86
Maple, perpendicular to the fibres, parallel to the annual rings	0·607	85
Oak, perpendicular to the fibres and to the annual rings	0·571	75

On the Expansion-coefficients of various kinds of wood, see HEAT (p. 935).

On the Absorption-power for Water of various kinds of wood, see Maumené (*Compt. rend.* lxxvii. 943).

Composition of the Gases contained in the Cells and Vessels of Wood.—Experiments by J. Böhm (*Landw. Versuchsst.* xxi. 373) have led to the following conclusions:

1. The gas collected by boiling in water living branches containing air only, is poor in oxygen, and always contains over 30 per cent. of carbonic anhydride, whilst fresh branches, killed by hot steam and then heated up to 90° in pure oxygen for 6 to 7 hours, form very little carbonic anhydride. These results seem to show that the inner cells are but slowly killed in the first case, owing to the low heat-conductivity of the wood, and that the contained oxygen is converted into carbonic anhydride during the process.

2. The best method for extracting the air is to seal one end of the branch, immerse it in water at a low temperature, and connect the other end with a Sprengel pump.

3. In consequence of the low tension of the air in the cells of living plants, only that portion is extracted which has been absorbed by the branch whilst being cut off. Only in one case has the air obtained approximately the composition of that in the living plants. The cells of *Syringa* in a frozen branch are almost impermeable to compressed air, whilst, when they are thawed, air easily permeates them.

4. Numerous analyses show that the total percentage of oxygen and carbonic anhydride obtained from thawed branches is always less than the amount of oxygen contained in the atmosphere. During slow experiments carbonic anhydride is always formed by internal respiration. The remarkable composition of the cell-gas bears some relation to its low tension, and is evidently a consequence of the relatively easy permeability of moist membranes for carbonic anhydride.

5. During the experiment a little air is absorbed and a little gas escapes.

6. In the first portions of gas extracted, the total percentage of oxygen and carbonic anhydride is always greater than in the following portions, and is greater than the oxygen contents of the atmosphere. This is a consequence of the relatively easy permeability of moist membranes for oxygen, and of the greater absorbability of this gas by water as compared with nitrogen. The gas obtained from branches during the first five minutes often contained over 24 per cent. of oxygen.

7. *Syringa* branches which had hung for eight days during winter within a moistened cylinder, at an ordinary room temperature, gave very little gas, as was also the case with gas from thawed branches; the total percentage of carbonic anhydride and oxygen was always less than that of the atmosphere.

8. The gas obtained as quickly as possible from freshly-cut willow branches in summer contained from 9 to 12 per cent. of carbonic anhydride, showing that the cell-gas of plants in active growth is rich in carbonic anhydride.

9. The gas obtained from the roots of willow-plants always contains a total percentage of carbonic anhydride and oxygen less than that of the oxygen in the atmosphere. The cause of this must be that a part of the carbonic anhydride formed by the permeation of the air is carried away by the ascending sap-current. This agrees with the fact that gas extracted from the branches is richer in carbonic anhydride as the transpiration is more active.

Distillation at Low Temperatures.—H. B. Heill (*Ber.* x. 936) found amongst the products of distillation of wood at temperatures below 200°, as practised at a wood-vinegar factory at Brooklyn, furfural, and an orange-yellow crystalline body, agreeing in composition and properties with Scanlan's pyroxanthin (iv. 776).

On the Preservation of wood by Impregnation with various liquids, see *Dingl. pol. J.* ccvii. 515; ccxv. 472; ccxviii. 370, 527; *Jahresb. f. Chem.* 1873, 1105; 1875, 1158–1160; *Chem. Soc. J.* xxvi. 1072; xxvii. 726, 728, 1189; xxviii. 491, 792; xxxii. 244.

On the manufacture of Paper from wood, see Rosenheim (*Dingl. pol. J.* ccxx. 81; *Chem. Soc. J.* xxx. 234); also *Chem. Soc. J.* xxv. 1048; xxvi. 1069.

Wood-gum. This name is applied by J. Thomsen (*J. für Chem.* [2], xix. 146) to a substance—isomeric with cellulose and identical with the 'pectin-substance' of

Poumarède a. Figuier (iv. 364), which is obtained by the action of cold dilute caustic alkali on wood. It is most readily prepared from beech sawdust, by digesting with aqueous ammonia, washing, again digesting with caustic soda, filtering, precipitating the filtrate with alcohol, washing with alcohol, digesting with a little dilute hydrochloric acid to remove mineral matter, repeatedly washing with alcohol, and finally with ether.

As thus prepared, wood-gum is a colourless powder, insoluble in cold water, but soluble in about 50 parts of boiling water, forming a liquid which becomes opalescent on cooling, and yields a copious precipitate on addition of a drop of dilute hydrochloric acid, acetic acid, sodium chloride, caustic soda, or sodium acetate solution: it is insoluble in alcohol. No coloration is produced by addition of iodine tincture to a solution of pure wood-gum.

Wood-gum is found in the wood of leafy trees, but is not present in that of conifers: the quantity of this substance in the wood of any tree increases as the axis of the trunk or branch is approached: old wood contains smaller quantities of it than new wood. The following table shows the amount per cent. separated from different woods:

	Birch	Beech (old)	Beech (young)	Ash	Elm	Oak	Cherry
Periphery . .	13·9	8·2	11·9	13·8	9·7	8·9	14·4
Middle . . .	19·7	15·0	11·3	15·9	10·7	12·0	10·7
							15·4

Wood-oil, the volatile oil of *Dipterocarpus-balsam* or *Gurjun-balsam* (p. 918), may be recognised by the splendid violet colour produced on adding a drop of a cooled mixture of equal parts of sulphuric and nitric acid to a solution of 1 pt. of the oil in 20 pts. carbon bisulphide. This coloration is not interfered with by the presence of copaiba-balsam, and it remains permanent for several hours, whereas the similar colorations produced by cod-liver and valerian oils disappear very quickly (Flückiger, *Analyst*, i. 94).

Wood-tar. G. Thenius, by fractional distillation of large quantities of wood-tar, has obtained a series of hydrocarbons boiling below 80°, together with benzene at 80°. All these hydrocarbons are said to yield nitro-amido-derivatives, and likewise dye-stuffs (*Dingl. pol. J.* cccxvii. 374; *Chem. Soc. J.* xxxiv. 664). See further **Tar** (p. 1889).

WOOL. The heat-conducting power of wool is 12, that of air being taken as unity (J. Schulmeister, *Dingl. pol. J.* cccxvi. 326).

Air-dried wool contains 14·35 per cent. of water (Bernard, *ibid.* 216).

Decomposition by Barium Hydrate.—Schützenberger (*Compt. rend.* lxxxvi. 767), by decomposing 100 grams of purified wool with an aqueous solution of barium hydrate (300–400 grams) at 170°, has obtained the following products:

Nitrogen (evolved as ammonia)	5·25
Carbonic acid (separated as BaCO ₃)	4·27
Oxalic „ (separated as BaC ² O ⁴)	5·72
Acetic „ (by distillation and titration)	3·2
Pyrraline and volatile products	1 to 1·5
Elementary composition of fixed residue, containing leucine, tyrosine, and other nitrogenous products	{ C . . .	47·85
	{ H . . .	7·69
	{ N . . .	12·63
	{ O . . .	31·83

100·00

Oxidation in Alkaline Solution.—Wool, dissolved in aqueous potash and oxidised by potassium permanganate is converted into cyanopropionic acid, C³H⁵(CN)O² (Wanklyn a. Cooper, p. 1676).

Bleaching.—The following directions for the bleaching of wool are given in Reiman's *Farbezeitung*, 1873, No. 31. One hundred kg. wool are treated with a solution of 5 kg. acid sodium sulphite, and 2 kg. hydrochloric acid are added; or the wool is sprinkled with the solution of the same quantity of the salt in 100 litres of water and then dipped in a bath of hydrochloric acid.

J. Persoz (*Monit. scient.* [3], iv. 862) discusses the difficulties which have to be overcome in the bleaching of wool. The sulphurous acid, either gaseous or in aqueous solution, unites with the colouring matters of the wool, forming colourless compounds. The bleached wool consequently contains sulphurous acid, and must therefore be very carefully treated, otherwise the sulphurous acid will escape and the colours will reappear. The sulphurous acid may, by the action of atmospheric oxygen, especially if assisted by sunlight, be converted into sulphuric acid, which affects the course of

the subsequent operations (dyeing, printing), besides acting on the tissue itself. The presence of sulphurous acid destroys the faint tint usually given to bleached fabrics by aniline-dyes. *Bleu de Lyons* (dissolved in alcohol) is not altered by sulphurous acid; Nicholson's alkali-blue is darkened by it; fuchsine-violet is turned blue; *violet de Paris* is first turned blue and then disappears altogether; aniline-red is completely decolorised. *Bleu de Lyons* and fuchsine-violet are therefore the colours which best withstand the action of sulphurous acid, and should accordingly be used for the blueing of bleached wool. The water used for washing has a very great influence on the fabrics, and no cheap method has yet been discovered of preventing the injurious action which it sometimes exerts. Very great care must be bestowed on the glazing of the tissues. The smallest trace of lead-compounds in the glaze is sure, sooner or later, to exert a disturbing action. The addition of paraffin to the glaze must be avoided, as paraffin cannot be subsequently removed from the tissue. If the woollen fabric is wound on rollers, it is not advisable to lay a number of such rollers one on the other, as the tissue is thereby prevented from expanding and contracting freely, and consequently becomes dragged. The rolls should be as far as possible set up on end and frequently reversed; otherwise the water will collect at one end, thereby causing the cloth to dry unequally and become spotted. On the whitening of woollen cloths see also V. Preston (*Dingl. pol. J.* cccxxv. 531; *Jahresb. f. Chem.* 1877, 1229), and A. Kiemeier (*Dingl. pol. J.* cccxxv. 389).

Dyeing.—According to C. Lauth (*Bull. Soc. Chim.* [2], xix. 401), wool may be prepared for dyeing with aniline-green by treating it with sodium thiosulphate and an acid. The sulphur thereby separated fixes itself on the wool and imparts to it the power of taking up the aniline-green. Direct experiments have shown that this action is exerted only by that portion of the sulphur which is insoluble in carbon bisulphide. Every other method of impregnating wool with sulphur has led to only negative results. It is advantageous to mix the thiosulphate solution with alum or a zinc salt. If it be desired to give the green a tinge of yellow by simultaneous dyeing with picric acid, a small quantity of zinc acetate must be added to the bath. Zinc acetate keeps up the blue tint of the aniline-green.

Alkali-blue (Nicholson's blue) may be fixed on wool, so as to stand the fulling process, by adding a little zinc sulphate to the second (acid) bath. Dyeing with other aniline colours is also greatly assisted by the addition of zinc sulphate to the dye-bath (E. Brauss, *Dingl. pol. J.* ccviii. 157).

To print a yellow colour on woollen thread previously dyed red, 40 grams of *xanthine* are dissolved in 500 g. water, and, on the other hand, 30 g. sodium sulphite are dissolved in 500 g. water, and 250 g. zinc-dust are stirred into the resulting solution. The two solutions are then mixed, the pattern is printed with the mixture, and the cloth is finally steamed. Aniline-yellow cannot be used for this purpose, since aniline-colours are destroyed by zinc-dust (*Dingl. pol. J.* ccviii. 238).

On the direct yellow-dyeing of wool with *chromic acid*, see Jacquemin (p. 460). V. Jolet (*Dingl.* ccxxix. 288) recommends for this purpose the use of chrome-alum instead of potassium dichromate, a greater regularity of tint being thereby obtained. The wool is boiled for an hour and a half in a chrome-alum bath, whereby it is coloured bluish-green. The colour is stable, and bears exposure, which is not the case when potassium dichromate is used. For blues and greens, alum and sulphuric acid are added to the bath; for blacks, the sulphuric acid is omitted. For brown, sulphuric acid is used if the material is not to be dyed with madder. Copper sulphate gives darker tones, whilst addition of tin salts is made in case of violet-blues and bluish-greens. 25 kilos. require the following proportions in the chrome-alum bath:

Colour	Alum. Grams	H ² SO ⁴ . Grams	CuSO ⁴ . Grams	Chrome-alum. Grams
Brown madder	—	—	—	650
Olive madder	—	—	50	630
Black	—	—	—	625
Coffee-brown	—	40	100	600
Dark blue	500	50	50	450
Light blue	500	50	—	400
Dark green	600	60	100	500
Light green	300	60	—	625
Violet	500	50	40	500

salts of tin.

On the removal of Vegetable fibres from Wool by the action of Acids (Chemical Purification of Wool) see Duclaux, Lechartier a. Raulin (*Bull. Soc. Chim.* [2], xxi. 337; *Jahresb. f. Chem.* 1874, 1204; *Chem. Soc. J.* xxviii. 200). On the use of Aluminium chloride for the same purpose, see Joly (*Dingl. pol. J.* cccxvi. 328).

X

XANTHAMIDE, $\text{NH}^2\text{CS}.\text{OC}^2\text{H}^5$ (v. 491), is formed, together with methylmercaptan, by the action of alcoholic ammonia on the thiocarbonic ether, $\text{CH}^3\text{S}.\text{CS}.\text{OC}^2\text{H}^5$:

(Salomon a. Manitz, *J. pr. Chem.* [2], viii. 114).

On the reaction of xanthamide with *Valeral*, see p. 2084.

Methylic Xanthamide, $\text{NH}^2\text{CS}.\text{OCH}^3$, is formed, together with methylic oxythiocarbamate, $\text{NH}^2\text{CO}.\text{SCH}^3$, by the action of thiocyanic acid on methyl alcohol.

XANTHATES, $\text{C}^2\text{H}^5\text{RS}^2 = \text{RS}.\text{CS}.\text{OC}^2\text{H}^5$ (R denoting a metal or alcohol-radicle). The products of the dry distillation of metallic xanthates have been examined by Fleischer a. Hankó (*Ber.* x. 1293). The dry potassium and sodium salts yield carbon disulphide, ethyl monosulphide, ethyl disulphide, and carbon oxy-sulphide; the hydrated salts yield mercaptan, carbon disulphide, the two sulphides of ethyl, carbon dioxide, and hydrogen sulphide. The residue consists chiefly of carbonates. *Lead xanthates* yield the same products as the dry xanthates of the alkali-metals. The compound called *xanthurin*, described by Couerbe as a product of the distillation of xanthates, is regarded by Fleischer a. Hankó as a mixture of the two ethyl sulphides with carbon oxy-sulphide.

E. A. Grete (*Ber.* x. 1039) makes use of the hydrogen sulphide evolved by the decomposition of xanthates for the reduction of nitric acid in the quantitative estimation of nitrates. For this purpose the nitrate is heated with a mixture of a xanthate and soda-lime.

On the estimation of Carbon disulphide by converting it into potassium xanthate, and titrating this salt with a normal solution of copper, see CARBON BISULPHIDE (p. 408).

According to P. Zöller (*Dingl. pol. J.* cccxi. 191; cccxii. 190) small quantities of xanthates mixed with the soil prevent the formation of fungi. Zöller a. Grete (*Ber.* viii. 802, 955) recommend potassium xanthate as a remedy against Phylloxera.

The following xanthates are described by T. L. Phipson (*Compt. rend.* lxxxiv. 1459):—The *cuprous salt* formed on mixing a cupric salt with potassium xanthate is an orange-yellow shining precipitate, insoluble in water, easily soluble in carbon sulphide, very easily in nitric acid; in the dry state it burns like tinder. It is insoluble in ammonia, a property which may be rendered available for the separation of copper from metals which form xanthates soluble in ammonia. The xanthates of *nickel* and *cobalt* are especially distinguished one from the other by their reaction with ammonia, the former being soluble therein, the latter insoluble. The *zinc salt* is easily soluble in ammonia.

When potassium xanthate and ethyl chlorocarbonate are mixed in nearly molecular proportions, a slight excess of the former being, however, advantageous, a white precipitate is formed containing chloride and ethylcarbonate of potassium, and at the same time an oily liquid is produced, which, after treatment with a large quantity of water, solidifies to a crystalline pulp; and on recrystallising this product from alcohol, splendid yellow needles are obtained, melting at 55° and consisting of diethylic dithiodicarbthionate, $\text{S}(\text{CSOC}^2\text{H}^5)^2$, analogous to the ethylic dicarbthionate, $\text{S}(\text{COOC}^2\text{H}^5)^2$, which V. Meyer obtained by the action of sodium monosulphide on ethyl chlorocarbonate (vi. 406). Its formation may perhaps be represented by the equation:

With potassium ethylate it yields $\text{CO}(\text{OC}^2\text{H}^5)\text{SK}$, and potassium xanthate:

and with alcoholic ammonia it forms xanthamide:

Potassium xanthate and ethylene bromide form ethylethylenic xanthate, $\text{C}^2\text{H}^4(\text{S}.\text{CS}.\text{OC}^2\text{H}^5)^2$, as a yellowish oil, which solidifies after washing with water, and

is obtained by recrystallisation from ether in fine strongly refractive crystals, apparently belonging to the rhombic system and melting at 42° . This body is decomposed by potassium ethylate, with formation of potassium xanthate, ethylene bromide, and water:

With alcoholic ammonia it yields xanthamide and ethylene-mercaptan:

The action of ethylene bromide on the compound $\text{CO}(\text{OC}^2\text{H}^3)(\text{SK})$ appears to be analogous to that which it exerts upon the xanthate (H. Welde, *Ber.* ix, 1044).

XANTHININE, $\text{C}^4\text{H}^3\text{N}^3\text{O}^2$. This base, which Finck obtained by the action of heat on ammonium thionurate (v. 1051), is also produced by the action of sulphuric acid at 150° on pseudouric acid (p. 1698).

XANTHIUM. According to Guichard (*Pharm. J. Trans.* [3], vii, 249), *Xanthium spinosum* contains an alkaloid; Godeffroy, on the other hand (*Ber.* ix, 1796), found in it neither alkaloid, nor glucoside, nor bitter principle. The plant yields a large quantity of ash rich in alkalis and nitrates. By distillation with water it yields a distillate smelling of chamomile, from which a small quantity of a greenish oil may be separated.

XANTHOGALLOL, $\text{C}^{18}\text{H}^4\text{Br}^{14}\text{O}^6$ (Stenhouse, *Chem. Soc. J.* xxviii, 1). This compound is formed by the action of bromine in presence of water on tribromopyrogallol (vii, 1031). It is best prepared by gradually adding 1 mol. pyrogallol to 10 pts. bromine, leaving the product at rest for two or three hours to ensure the complete transformation of the pyrogallol into tribromopyrogallol, and then shaking it with 30 pts. water till it is completely dissolved, and heating it. With a larger quantity of water the yield of xanthogallol is smaller, an oil being formed at the same time, which greatly increases the difficulty of purification. Xanthogallol is formed only by the action of bromine and water on ready-formed tribromopyrogallol, according to the equation:

Pyrogallol itself, when similarly treated, does not yield a trace of it.

Xanthogallol, purified by recrystallisation from carbon sulphide and light petroleum, forms shining yellow laminae, melts at 122° , and dissolves readily in ether, benzene, and carbon sulphide, less easily in petroleum. It is decomposed by solution in alcohol, by boiling with water, and by prolonged boiling with benzene or petroleum. When a solution of 1 pt. xanthogallol in 10 pts. ether is agitated with 2 pts. of a cold saturated solution of sodium carbonate, the liquid being cooled from time to time, the ether takes up a body which remains, on evaporation of the ether, in the form of an oil having a peculiar odour, whilst a sodium-compound separates in light yellow shining laminae. If this sodium-compound, after washing with a nearly saturated solution of sodium carbonate, be suspended in 8 pts. of water and dilute sulphuric acid added, a substance, apparently having the composition $\text{C}^{18}\text{H}^7\text{Br}^{14}\text{O}^6$, separates in long colourless needles melting at 130° , very easily soluble in alcohol and ether, soluble also in hot benzene and carbon sulphide, sparingly in petroleum, decomposing gradually at ordinary temperatures. The sodium-compound is not very soluble in cold water, but dissolves readily in alcohol. It is decomposed by drying at ordinary temperatures and by the boiling of its aqueous solution. The analogous ammonium and potassium compounds resemble the sodium-compound in their properties. The aqueous solution of the sodium-compound gives a dirty-white precipitate with cupric sulphate, yellow with silver nitrate. The solution of the silver precipitate in nitric acid decomposes on boiling, with separation of silver bromide. The chlorides of calcium and barium give white precipitates. The barium-compound becomes yellow when dried in a vacuum, and then contains 15.64 to 15.72 per cent. Ba. The white crystalline compound, agitated in ethereal solution with aqueous potassium iodide, yields a shining yellow precipitate insoluble in water, but dissolving, apparently with decomposition, in alcohol.

When tribromopyrogallol is treated with only 1 mol. bromine and then mixed with 5 to 10 pts. water, an orange-coloured solution is formed, which after a short time deposits colourless laminae of a compound decomposing slowly on standing, more quickly when gently heated. This compound is nearly insoluble in carbon sulphide, slightly soluble in water, easily in ether, and is precipitated therefrom in the crystalline state by chloroform or carbon sulphide. It does not appear to be converted into xanthogallol by the action of bromine in excess.

XANTHOPHYLL. See PLANT-COLOURS (p. 1630).

XANTHOPHYLLITE. On the variety of this mineral called *Wiluewite*, see p. 2137.

XANTHOPURPURIN, $C^{14}H^8O^4 = C^6H^4 \begin{smallmatrix} CO \\ \diagup \quad \diagdown \\ CO \end{smallmatrix} C^6H^2(OH)^2$. This unsymmetrical dihydroxyanthraquinone—better called *Purpuroxanthin*, inasmuch as xanthopurpurin would seem to imply that the compound in question is a purpurin—that is to say, a *tri*-hydroxyanthraquinone—was discovered by Schützenberger, who obtained it from madder and by reduction of purpurin; was afterwards prepared by Liebermann a. Fischer from purpuramide by the action of nitrous acid (p. 103), and has been further examined by H. Plath (*Ber.* ix. 1204). It crystallises from glacial acetic acid in thick shining needles melting at 262° – 263° . By boiling with sodium acetate it is converted into a salt which crystallises in red needles. It forms crystalline compounds with lime and baryta.

Dibromopurpuroxanthin, $C^{12}H^4Br^2(CO)^2(OH)^2$, formed by the action of bromine at ordinary temperatures on purpuroxanthin, is slightly soluble in alcohol, easily soluble in glacial acetic acid, from which it crystallises in orange-coloured needles melting at 227° – 230° . By boiling with ammonium acetate it is converted into dibromopurpuroxanthinammonium, which crystallises in felted groups of red needles having a splendid metallic lustre.

Dinitropurpuroxanthin, $C^{12}H^4(NO^2)^2(CO)^2(OH)^2$, obtained by the action of fuming nitric acid (sp. gr. 1.48) at ordinary temperatures on purpuroxanthin, is soluble in water, more readily in ether, alcohol, and glacial acetic acid, and crystallises in small light-red needles melting at 249° – 250° . Its *barium compound*, $C^{14}H^4(NO^2)^2(O^2Ba)O^2$, crystallises in dark-red needles; the *ammonium compound*, $C^{14}H^4(NO^2)^2(OH)(ONH^4)O^2$, obtained by boiling the dinitro-derivative with ammonium acetate, forms light-yellow needles having a silky lustre. By treating purpuroxanthin dissolved in strong sulphuric acid with nitrous acid, a dinitropurpuroxanthin is obtained, which also melts at 249° , but crystallises from glacial acetic acid in thick needles having a *steel-blue* colour. It dissolves readily in water, alcohol, ether, benzene, and glacial acetic acid, and dyes wool an orange colour. Whether this dinitropurpuroxanthin is identical or isomeric with the former is a question not yet decided.

Dimethylpurpuroxanthin, $C^6H^4.C^2O^2.C^6H^2(OCH^3)^2$, is formed when purpuroxanthin, methyl iodide, and potassium hydroxide in molecular proportions, with addition of a little alcohol, are heated together at 100° in a sealed tube for several hours. It crystallises from glacial acetic acid in small light-yellow needles melting at 178° – 180° . *Diethylpurpuroxanthin*, prepared in like manner, forms dark-yellow needles melting at 170° , insoluble in water, easily soluble in alcohol and in glacial acetic acid.

Purpuroxanthin-carboxylic acid, $C^{15}H^8O^6 = C^{14}O^4H^7.COOH$. *ε-Purpurin*. This acid has been found by Schunck a. Römer (*Ber.* x. 172) in a substance accompanying natural purpurin, and may be obtained from the mother-liquor which remains after the crystallisation of the crude purpurin from alcohol. This mother-liquor is evaporated to dryness; the residue is treated with boiling water; a few drops of hydrochloric acid are added to the solution; the resulting precipitate is boiled with baryta-water as long as it is acted upon thereby; the insoluble barium salt of purpuroxanthin-carboxylic acid is decomposed by hydrochloric acid; and the free acid is recrystallised from alcohol. The acid may also be prepared from the aluminium-compound of commercial purpurin by exhausting this compound with boiling dilute hydrochloric acid, which leaves part of it undecomposed, and boiling this portion with strong hydrochloric acid.

Purpuroxanthin-carboxylic acid is, according to Schunck a. Römer, the chief constituent of *ε-purpurin* and identical with Stenhouse's munjistin (iii. 1061). It crystallises in hydrated yellow needles having a golden lustre, and efflorescing even on exposure to the air, more readily at 50° . It melts at 231° , and between 232° and 233° is completely resolved into carbon dioxide and purpuroxanthin. It dissolves readily in boiling hydrated alcohol, and frequently separates from the concentrated alcoholic solution in anhydrous laminae having a golden lustre. By very slow crystallisation from glacial acetic acid, in which it is easily soluble, it is obtained in tetrahedrons. It is more soluble in boiling water than purpurin; dissolves likewise in benzene, chloroform, ether, strong sulphuric acid, potash-ley, ammonia, boiling alum-solution, and sodium carbonate. The barium salt has a crimson colour and is insoluble in water.

XANTHOROCCELLIN, $C^{21}H^{17}N^2O^2$. See ROCÉLLA (p. 1759).

XANTHORHAMNIN, $C^{48}H^{68}O^{29}$. The glucoside of *Rhamnus insectorius*. See RHAMNUS (p. 1757).

XENOTIME. This mineral occurs in the Binnenthal, in small crystals of the quadratic system, exhibiting the combination $P.\infty P.3P3$ (angle $P : P$ in the lateral edges = $82^{\circ} 22'$), and agreeing in form with the xenotime of the St. Gothard, Hitteröe, and Tavetschthal, but not with Kennigott's *wiserine* (C. Klein, *Jahrb. f. Min.* 1875, 337, 369, 852).

Xenotime from Hitteröe has been analysed by O. E. Schiötz (*ibid.* 1876, 306), with the following result :

P ² O ⁵	Y ² O ³	Ce ² O ³ .Al ² O ³	Fe ² O ³	Mn ² O ³	FeO	CaO	H ² O
31.88	54.88	8.24	2.93	0.13	0.87	0.13	1.56 = 100.62

Xenotime has been prepared artificially by F. Radominski (*Compt. rend.* lxxx. 304).

XERONIC ACID, C⁸H¹⁰O⁴. A. Prehn (*Ber.* viii. 19, 359), in preparing methacrylic (crotonic) acid from citraconic anhydride, obtained, together with the calcium methacrylate, a sparingly soluble calcium salt, the acid of which boiled at 232° and remained fluid at -20°. This acid, or rather its anhydride, C⁸H¹⁰O³, which Fittig has since obtained as a product of the decomposition of citraconic anhydride (p. 513), appears to have been contained in the citraconic anhydride used in Prehn's experiments, as on dissolving the latter in water, dark oil-drops remained, which, when distilled with steam and afterwards heated with water and pulverised calc-spar, yielded the sparingly soluble calcium salt above mentioned.

Xeronic acid exhibits the peculiarity, hitherto observed only in acid anhydrides of the lactide type, of separating in the form of an anhydride when their salts are decomposed by a stronger acid, so that the acid itself is not actually known. Some of its salts have been examined by Fittig (*Liebigs Annalen*, clxxxviii. 59). The calcium salt above mentioned has the composition C⁸H¹⁰O⁴.Ca + H²O, gives off its water at 130°-140°, and when heated with dilute hydrochloric acid yields the anhydride, C⁸H¹⁰O³, as a colourless oil, which is very slightly soluble in water, volatilises very easily with steam, may also be distilled alone, and boils without decomposition at 242°. It dissolves very slowly when agitated with a cold concentrated solution of sodium carbonate, more quickly when heated, also in ammonia. The dilute ammoniacal solution, rendered neutral by evaporation, is not precipitated by calcium chloride at ordinary temperatures, but when heated therewith yields a thick white precipitate of the calcium salt. The barium salt, C⁸H¹⁰O⁴.Ba + $\frac{1}{2}$ H²O, prepared in like manner, is very much like the calcium salt; it becomes anhydrous at 140°, and undergoes no further. The silver salt, C⁸H¹⁰O⁴.Ag², obtained in a similar manner, is a white precipitate, very slightly soluble in boiling water, not affected by light.

Xeronic acid has probably the constitution of di-methylacrylic acid:

XYLENES, C⁸H¹⁰ = C⁶H⁴(CH³)². Ortho- and para-xylene occur in coal-tar. Para-xylene is obtained by agitating crude coal-tar xylene with warm common sulphuric acid, which dissolves only traces of paraxylene, treating the undissolved residue with fuming sulphuric acid, which converts it into paraxylene-sulphonic acid, and separating this acid from the crude mass by water, which throws it down in the form of a crystalline hydrate nearly insoluble in the diluted acid. The hydrated sulphonic acid thus obtained may be purified by repeated crystallisation, or by conversion into the barium or sodium salt. When subjected to dry distillation, or heated with hydrochloric acid, it yields perfectly pure paraxylene, which for the most part remains solid at 13°.

The portion of the crude xylene which is soluble in ordinary sulphuric acid is a mixture of *ortho*- and *meta*-xylenes, the latter predominating. To separate them, the sodium salts of the sulphonic acids into which the crude sulphuric acid solution is first converted, as above mentioned, are transformed by the action of phosphorus pentachloride into chlorides, and these by Schiller a. Otto's method (p. 1851) into the corresponding sulphinic acids; and on crystallising the sodium salts of these acids, that of the orthoxylenesulphonic acid separates out first, while that of the metaxylenesulphonic acid remains in the mother-liquor.

Orthoxylene may also be obtained from the tar-oil by a shorter process, which does not involve the preparation of the sulphonic acids—namely, by saturating the portions extracted from the oil by ordinary sulphuric acid, after dilution, with calcium carbonate, converting the resulting salts into sodium salts, concentrating the solution strongly, and leaving it to crystallise. The crystals of sodium orthoxylenesulphonate thus obtained may be purified by three recrystallisations.

Orthoxylene separated from the sodium-salt of its sulphonic acid, or from the corresponding amide, by the action of hydrochloric acid at 190°–195°, boils at 142°–143° (O. Jacobsen, *Ber.* x. 1009).

Paraxylene.—In preparing this hydrocarbon by the action of methyl iodide and sodium on parabromotoluene, b. p. 28.5° (v. 1056), it is not advisable to use ether as a diluent, as the action is then extremely violent and the product small. With benzene, on the other hand, as a solvent, the reaction takes place at ordinary temperatures, and is completed in a comparatively short time. The quantity of bromotoluene acted upon in one operation should not be greater than 50 grams. The yield never exceeds one-fifth of the bromotoluene employed, a considerable quantity of ditolyl being formed at the same time.

Pure paraxylene melts at 15°, boils at 136°–137°, and is converted by oxidation with dilute nitric acid into *paratoluic acid*, melting at 178° (Jannasch, *Liebig's Annalen*, clxxi. 79).

Metaxylene is produced, together with a small quantity of paraxylene, by passing a stream of methyl chloride, dried by sulphuric acid, for forty-eight hours into two long-necked flasks containing 500–600 gr. toluene and 15–20 per cent. aluminium chloride (see *Hydrocarbons*, p. 1063), and placed in a water-bath at 70°–80°. The product, purified by fractionation and oxidised by permanganate, or in alkaline solution by chromic acid, yields isophthalic acid, together with a small quantity of terephthalic acid (Ador a. Rilliet, *Ber.* xi. 1627).

Metaxylene is also formed, together with dimethylethylbenzene, by submitting to fractional distillation those portions of crude wood-spirit which are insoluble or only slightly soluble in acid sodium sulphite, and heating the fractions 130°–140° and 165°–175° for some time in an oil-bath with zinc chloride (80 c.c. liquid with 10 gr. zinc chloride). The clear oil floating on the top of the product gave, after washing with strong sulphuric acid and rectification over sodium—from the first portion, xylene boiling at 138°–143°; from the second, dimethylethylbenzene boiling at 175°–188°. The xylene, by oxidation with chromic acid, was converted into isophthalic acid (Kraemer a. Grodzki, *Ber.* ix. 1920).

Metaxylene, heated in a sealed tube at 130°–150° with dilute nitric acid (1 acid to 2 water), is oxidised to *metatoluic acid* (Brückner, *Ber.* ix. 405).

When *carbonyl chloride* is passed into metaxylene cooled to –15°, and aluminium chloride then gradually added to the mixture, xylol ketone, $\text{CO}(\text{C}^6\text{H}^5)^2$, is formed, which remains liquid at –60°, boils at 340°, and is converted by saponification with potash into dimethyl-benzoic acid. By prolonged boiling it gives up water, and is converted into a hydrocarbon, $\text{C}^{12}\text{H}^{16}$ (Ador a. Rilliet, *Ber.* xi. 399).

Metaxylene (1 vol.), heated for forty-eight hours at 280° with 10 vol. *hydriodic acid* and *amorphous phosphorus*, is converted into hexhydrometaxylene, C^6H^{16} (p. 160). The product, after washing with soda-ley and water, drying, and rectification over sodium at 150°, boils between 115° and 120°, has a specific gravity of 0.777 at 0° and vapour-density = 3.75. With bromine and strong sulphuric acid it reacts like a saturated hydrocarbon. The same hydrocarbon is produced by heating 1 pt. camphoric acid at 280° with 12 pts. fuming hydriodic acid saturated at 0° (Wreden, *Ber.* vi. 1379).

Chlorometaxylene, or *Metaxylol Chloride*, $\text{CH}^3.\text{C}^6\text{H}^4.\text{CH}^2\text{Cl} = \text{C}^6\text{H}^3(\text{CH}^3).\text{H}.\text{CH}^2\text{Cl}.\text{H}^3$ (also called *Isotolyl Chloride*), is obtained by the action of chlorine on metaxylene at the boiling heat. It boils at 195°–196°, and has a specific gravity of 1.079 at 0° and 1.064 at 20° (Gundelach, *Compt. rend.* lxxxii. 1444).

Benzyl-xylene, $\text{C}^{10}\text{H}^{16} = \text{C}^6\text{H}^3.\text{CH}^2.\text{C}^6\text{H}^3(\text{CH}^3)^2$. Two modifications of this hydrocarbon, viz. benzyl-isoxylene and benzyl-paraxylene, are obtained by acting upon isoxylene and paraxylene with benzyl chloride in presence of zinc. Benzyl-isoxylene is a colourless liquid, of faint aromatic odour, boiling at 295°–296°. Benzyl-paraxylene is a similar liquid, boiling at 293.5°–294.5°. The former, when oxidised with potassium dichromate and sulphuric acid, yields benzoyl-isophthalic acid, $\text{C}^6\text{H}^3.\text{CO}.\text{C}^6\text{H}^3(\text{CO}^2\text{H})^2$ (p. 313) (Zincke, *Deut. Chem. Ges.* *Ber.* v. 799).

Paraxylene (1 : 4) can evidently yield but one benzyl-paraxylene, viz. that which has the structure 1 : 2 : 4 or 1 : 3 : 4; but isoxylene, 1 : 3, may yield three benzyl-isoxylenes, viz. 1 : 2 : 3, 1 : 3 : 4, and 1 : 3 : 5. Which of the three is formed by the process above mentioned there appears to be at present no means of determining.

Bromoxylenes. *Symmetrical Bromometaxylene*, $\text{C}^6\text{H}^3(\text{CH}^3)(\text{CH}^2\text{Br})_2$, is obtained by passing nitrous gas into an alcoholic solution of Genz's bromoxylidine, $\text{C}^6\text{H}^3\text{Br}.\text{NH}^2$ (vii. 1210), a dibromoxylene (b. p. 252°) being formed at the same time as a secondary product. The monobromoxylene has a specific gravity of 1.362 at 20°, remains fluid

at -20° , and boils at 204° . A mixture of this bromoxylene and ethyl bromide heated with sodium yields symmetrical ethyl-dimethyl-benzene, $\text{C}^6\text{H}^5\cdot\text{H}\cdot\text{CH}^3\cdot\text{R}\cdot\text{CH}^3\cdot\text{H}$ (Wroblewsky, *Ber.* ix. 495). See p. 751.

Bromoparaxylene, $\text{C}^6\text{H}^3\text{Br}\cdot\text{H}\cdot\text{CH}^3\cdot\text{H}^2$, prepared by dropping bromine into well-cooled paraxylene, boiling the well-washed product with alcoholic potassium sulphide, and rectifying, boils at 199.5° – 200.5° , and solidifies on cooling in shining laminae or tables melting at 10° . By oxidation with chromic acid in glacial acetic acid solution it is converted into parabromotoluic acid melting at 203.5° . By nitration it yields a liquid which after a while deposits crystals, melting, after pressure and recrystallisation from alcohol, at 70° – 71° (Jannasch).

Nitroxylenes. According to A. Rammer (*Bull. Soc. Chim.* [2], ix. 434), the portion of crude xylene insoluble in sulphuric acid (*p*-xylene) yields a dinitro-xylene, which melts at 92° , and, according to measurements by Descloizeaux, forms monoclinic crystals, whereas the xylene soluble in sulphuric acid (*o*-xylene) yields the other dinitroxylene described by Glinzer a. Fittig (v. 1058), which melts at 123.5° . According to Jannasch (*Liebigs Annalen*, clxxi. 79), paraxylene treated with fuming nitric acid in the cold yields both these dinitro-derivatives, which separate at once as a solid product, whereas Glinzer a. Fittig obtained an oil from which the dinitro-compounds crystallised out after some time.

XYLENESULPHAMIDES, $\text{C}^6\text{H}^3(\text{CH}^3)_2\text{SO}^2\text{NH}^2$ (Jacobsen, *Ber.* ix. 256; x. 1014; xi. 17). Two *metaxylenesulphamides*, distinguished as α and β , are obtained from the mother-liquors of the preparation of pseudocumene and mesitylene respectively (pp. 1283, 1285): *α -metaxylenesulphamide* [1 : 3 : 4], or $\text{C}^6\text{H}^3\cdot\text{H}\cdot\text{CH}^3\cdot\text{SO}^2\text{NH}^2\cdot\text{H}^2$, crystallises from hot alcohol in large shining laminae, from hot water in long pointed needles, and melts at 137° ; *β -metaxylenesulphamide* [1 : 2 : 3], or

crystallises from alcohol in rosettes of needles or in thicker crystals, from water in flat flexible needles, and melts at 95° – 96° .

Paraxylenesulphamide, $\text{C}^6\text{H}^3\text{SO}^2\text{NH}^2\cdot\text{H}\cdot\text{CH}^3\cdot\text{H}^2$, melts at 148° ; *orthoxylenesulphamide*, $\text{C}^6\text{H}^3\cdot\text{CH}^3\cdot\text{H}\cdot\text{SO}^2\text{NH}^2\cdot\text{H}^2$, at 144° .

The constitution of the *metaxylenesulphamides* and the corresponding sulphonic acids is established by the following transformations: (1) The potassium salt of *α -metaxylenesulphonic acid* is converted by fusion with potassium cyanide into the nitril of xylidic acid, $\text{C}^6\text{H}^3(\text{CN})(\text{CH}^3)(\text{CN})$. (2) The same potassium salt heated with sodium formate is converted into the corresponding xylidate. (3) The same potassium salt fused with potassium hydroxide yields hydroxytoluic acid, melting at 151° and convertible into paracresol (p. 2024). (4) The sulphonic acid or the amide is converted by oxidation into *α -hydroxyisophthalic acid*,

(p. 1532). (5) The *methyl ether of liquid xylenol* (p. 1541) is oxidised by potassium permanganate to methyl- *α -hydroxyisophthalic acid*. (6) The *α -amide* is oxidised by chromic acid or permanganate to a sulphaminetoluic acid,

which melts at 254° (corr.) and crystallises from hot water in long brittle anhydrous needles, sparingly soluble in cold water, also in alcohol and ether. By gentle fusion with potassium hydroxide it is converted into *o -homo- p -hydroxybenzoic acid*, $[\text{CO}^2\text{H} : \text{CH}^3 : \text{OH} = 1 : 3 : 4]$. (7) The *sulphamine-toluic acid* is oxidised by potassium permanganate to a sulphamine-isophthalic acid, convertible into *α -hydroxyisophthalic acid*.

The relations between these several products and *α -metaxylenesulphonic acid* may be more clearly shown by the following figures:

β -Xylenesulphamide (m. p. 95° – 96°) is oxidised by chromic acid to a sulphamine-toluic acid, melting at 202° – 205° , and convertible into a hydroxytoluic acid, which melts at 156° – 160° and is probably identical with Schotten's ortho-homo-sali-

cyclic acid (p. 2024). By oxidation with potassium permanganate, the β -amide is converted into a sulphamine-toluic acid, which may be separated from the acid solution by agitation with ether, and does not form a sparingly soluble acid potassium salt. The corresponding hydroxyisophthalic acid melts between 240° and 243° , and produces a cherry-red coloration with ferric chloride.

A mixture of equal parts of α - and β -xylenesulphamide melts at 110° ; a mixture of 2 parts α - and 1 part β -sulphamide at 122° – 123° (Jacobsen).

XYLENESULPHONIC ACIDS, $\text{C}^6\text{H}^3\text{SO}^3\text{H} = \text{C}^6\text{H}^3(\text{CH}^3)^2(\text{SO}^3\text{H})$ (Jacobsen, *Ber.* xi. 17). When metaxylene is dissolved in fuming sulphuric acid, the only products formed are the sulphonic acids whose amides melt at 95° – 96° and 137° (p. 2147); the same result was obtained with a metaxylene prepared from these amides.

α -Metaxylenesulphonic acid, $[\text{1 : 3 : 4}]$, or $\text{C}^6\text{H}^3\text{CH}^3\text{H}.\text{CH}^3.\text{SO}^3\text{H}.\text{H}^2$, best prepared by heating the corresponding amide (m. p. 137°) with strong sulphuric acid at 145° – 150° , crystallises in large laminae or flat prisms containing 2 mol. H^2O . Its barium salt forms small rhombic laminae or radio-crystalline groups of peculiarly-shaped lenticular bodies. The sodium salt crystallises from water in small scales, from alcohol in silvery laminae. The zinc salt, $(\text{C}^6\text{H}^3\text{SO}^3)^2\text{Zn} + 9\text{H}^2\text{O}$, is easily soluble and crystallises in stellate groups of needles or long rhombic prisms. The copper salt contains 6 mol. water.

The chloride, $\text{C}^6\text{H}^3\text{SO}^2\text{Cl}$, forms a radio-crystalline mass or prismatic crystals, melting at 34° . The sulphinic acid, $\text{C}^6\text{H}^3.\text{SO}^2\text{H}$, formed by reduction of the chloride, is also a crystalline mass, melting a little above 50° .

Potassium α -xylenesulphonate fused with sodium formate is converted into the potassium salt of xylic or xylylic acid, $\text{C}^6\text{H}^3(\text{CH}^3)^2.\text{COOK}$ (v. 1062); and by heating with potassium cyanide into the nitril of the same acid, $\text{C}^6\text{H}^3(\text{CH}^3)^2\text{CN}$.

β -Metaxylenesulphonic acid $[\text{1 : 2 : 3}]$, or $\text{C}^6\text{H}^3.\text{SO}^3\text{H}.\text{CH}^3.\text{H}^3$, prepared from the sulphamide melting at 95° – 96° , has not been obtained in the crystalline state. Its barium and potassium salts are anhydrous, the former crystallising in stellate groups of microscopic needles, the latter in silky scales. The hydrated copper salt forms light-blue needles. The chloride is an oily liquid. The dimethylbenzoic acid, $\text{C}^6\text{H}^3(\text{CH}^3)^2.\text{COOH}$, formed from this sulphonic acid, crystallises in short needles melting at 97° – 99° , and when distilled with excess of lime yields metaxylene.

Bromo-metaxylenesulphonic Acids.—When the barium salt of α -metaxylenesulphonic acid is treated with an equivalent quantity of bromine, barium monobrom- α -m-xylenesulphonate is obtained in delicate scales containing 1 mol. water. The corresponding sodium salt, $\text{C}^6\text{H}^2\text{Br}(\text{CH}^3)^2\text{SO}^3\text{Na} + \text{H}^2\text{O}$, is easily soluble and crystallises in warty groups of needles. The analogously constituted ammonium salt forms silky tufts. The zinc salt $[\text{C}^6\text{H}^2\text{Br}(\text{CH}^3)^2\text{SO}^3]^2\text{Zn} + 9\text{H}^2\text{O}$, crystallises in long rhombic prisms; the copper salt in easily soluble greenish-white scales, containing 7 mol. water. The chloride forms large limpid prisms melting at 61° , slightly soluble in alcohol, insoluble in water. The amide crystallises in thick rhombic prisms, melting at 194° , easily soluble in ether, sparingly in cold water.

When m -xylenesulphonic acid in concentrated aqueous solution is treated with bromine, sulphuric acid and tribromoxylene are produced; the sodium salt treated in like manner yields the brominated acid, together with dibromoxylene.

Monobromoxylene (b. p. 205° – 208°), treated with fuming sulphuric acid, forms monobrom- α -m-xylenesulphonic acid, $\text{C}^6\text{H}^2\text{Br}(\text{CH}^3)^2\text{SO}^3\text{H} + 2\text{H}^2\text{O}$, which crystallises in colourless laminae or prisms, and yields derivatives identical with those above described. This brominated acid dissolves easily in water, sparingly in sulphuric acid. Its constitution is represented by the formula $[\text{1 : 3 : 4 : 6}]$, or $\text{C}^6\text{H}^2\text{H}.\text{CH}^3.\text{SO}^3\text{H}.\text{H}.\text{Br}$ (R. Weinberg, *Ber.* xi. 1062).

Dibromo-m-xylenesulphonic Acid, $\text{C}^6\text{HBr}^2(\text{CH}^3)^2\text{SO}^3\text{H}$.—Jacobsen and Weinberg (*Ber.* xi. 1534) have obtained this acid by dissolving dibromo- m -xylene in fuming sulphuric acid at the temperature of 70° – 80° . It forms small anhydrous scales, having a silky lustre, slightly soluble in cold water, melting at 166° . Its barium salt is anhydrous, slightly soluble in water, and is deposited in indistinctly crystalline crusts. The sodium salt, $\text{C}^6\text{HBr}^2(\text{CH}^3)^2\text{SO}^3\text{Na} + 2\text{H}^2\text{O}$, forms nacreous laminae, slightly soluble in cold water. The chloride crystallises in colourless rhombic laminae melting at 107° ; the amide in felted needles, insoluble in alcohol, melting at 220° , decomposing at 230° .

The dibrominated acid when treated with sodium-amalgam is converted into β -metaxylenesulphonic acid melting at 96° , and the amide dissolved in alcohol is converted by similar treatment, continued for a week, into a monobromo- m -xylene-

sulphonic acid, which crystallises in long needles, often grouped in asbestiform masses, melting at 161° .

From these results and those of Weinberg (p. 2148) the following constitutional formulæ may be deduced for the compounds above described:

β -Metaxylene-sulphonic acid.

Monobrom- β -m-xylene-sulphonic acid.

Dibrom- β -m-xylene-sulphonic acid.

α -Metaxylene-sulphonic acid.

Monobrom- α -m-xylene-sulphonic acid.

Paraxylenesulphonic Acid, $\text{C}^6\text{H}_4\text{SO}_3\text{H} + 2\text{H}_2\text{O}$, forms a broadly laminar crystalline mass, or long flat prisms. From the product of the action of sulphuric acid on crude xylene, it crystallises before the ortho- and meta-acids, and may therefore be utilised for the preparation of paraxylene. Its potassium salt crystallises in flat silky needles containing 1 mol. water. The sodium salt, $\text{C}^6\text{H}_4\text{SO}_3\text{Na} + \text{H}_2\text{O}$, crystallises in flat longitudinally striated prisms of considerable size. The barium salt, $(\text{C}^6\text{H}_4\text{SO}_3)_2\text{Ba} + \text{H}_2\text{O}$, forms either small shining crystalline scales or warty groups of thick crystals. 100 pts. water dissolve 2.27 pts. of this salt at 0° , and 5.53 pts. at 100° . The copper salt crystallises in large light-blue triclinic prisms with $8\text{H}_2\text{O}$; the zinc salt in long slender efflorescent needles containing $10\text{H}_2\text{O}$. The chloride crystallises in large flat prisms melting at 24° – 26° ; the amide in long needles melting at 147° – 148° . The corresponding sulphonic acid dissolves readily in ether and alcohol, less readily in water, and crystallises in tufts of needles melting at 84° – 88° (Jacobsen).

Orthoxylenesulphonic Acid, $\text{C}^6\text{H}_4\text{CH}_3\text{H.SO}_3\text{H.H}^2$, is the only sulphonic acid formed on dissolving orthoxylene in sulphuric acid. It crystallises, more readily than either of its isomerides, in long rectangular tables, or thick flat prisms with roof-shaped summits. Its barium salt, $(\text{C}^6\text{H}_4\text{SO}_3)_2\text{Ba} + \text{H}_2\text{O}$, which may be prepared by triturating the corresponding sulphinate with barium peroxide, crystallises in large nacreous laminæ, of which 100 pts. water dissolve 5.8 pts. at 0° and 33.6 pts. at 100° . The sodium salt, $\text{C}^6\text{H}_4\text{SO}_3\text{Na} + 5\text{H}_2\text{O}$, crystallises in flat prisms. The chloride, $\text{C}^6\text{H}_4\text{SO}_3\text{Cl}$, separates from ethereal solution in prismatic crystals, melting at 51° – 52° ; the amide, $\text{C}^6\text{H}_4\text{SO}_2\text{NH}_2$, also in large prismatic crystals melting at 144° .

Orthoxylenesulphonic Acid, $\text{C}^6\text{H}_4\text{CH}_3\text{H.SO}_3\text{H.H}^2$, prepared by the action of zinc-dust on the chloride (see SULPHONIC ACIDS, p. 1851), crystallises in large, thin, silky laminæ melting at 83° (Jacobsen, *Ber.* x. 1009).

XYLENOLS, $\text{C}^6\text{H}_3(\text{CH}_3)_2\text{OH}$, and **XYLENOLSULPHONIC ACIDS**, $\text{C}^6\text{H}_2(\text{CH}_3)_2(\text{OH}).\text{SO}_3\text{H}$. See PHENOL, HOMOLOGUES OF (p. 1540).

XYLIC or **XYLYLIC ACID**, $\text{C}^6\text{H}^1\text{O}^2 = \text{C}^6\text{H}^1(\text{CO}^2\text{H})(\text{CH}^3)(\text{CH}^4)$. This acid is most readily prepared by passing carbonyl chloride into metaxylene in presence of an excess of aluminium chloride, and occasionally heating the mixture to 100° , whereby xylic chloride is formed according to the equation:

and decomposing this chloride with water (Ador a. Rilliet, *Ber.* xii. 1968). Its potassium salt is formed by heating potassium *m*-xylenesulphonate, [1 : 3 : 4] (p. 2148), with sodium formate (Picard, *Ber.* xi. 2120).

The acid prepared as above crystallises in large monoclinic prisms, melts at 126° , and boils at 267° (Ador a. Rilliet. *Comp.* v. 1062).

Ammonium Xylate is very soluble in water, and may be obtained from the aqueous solution by spontaneous evaporation in small prismatic crystals, but decomposes when dried over the water-bath. The barium salt, $(\text{C}^6\text{H}^1\text{O}^2)_2\text{Ba}$, crystallises from a very strong solution in hard laminæ, and begins to decompose at 160° . The calcium

salt crystallises in transparent monoclinic prisms, which dissolve very slowly in water. The *silver salt* is but very slightly soluble in water even at the boiling heat, somewhat more soluble in boiling absolute alcohol, from which (and from hot water) it separates on cooling in tufts of microscopic needles.

Xylic Chloride, $C^6H^3(CH^3)^2.COCl$, prepared as above described, or by treating the acid with phosphorus pentachloride, is a colourless liquid, which boils at 235° , and crystallises on cooling in needles melting at 25° .

Xylamide, $C^6H^3(CH^3)^2.CONH^2$, prepared by treating the chloride with ammonium carbonate, is almost insoluble in cold water, and separates from the hot solution in needles (m. p. 181°), which are very soluble in alcohol. After sublimation it melts at 179° . This amide is a very stable body, not being decomposed by soda even on boiling; it is, however, readily acted on by hydrochloric acid, with reproduction of xylic acid. It dissolves in acids, forming somewhat unstable salts. The *anilide*, obtained by adding the chloride gradually to aniline, consists of crystals (m. p. 138°), which are but sparingly soluble even in hot water, more easily in alcohol. On boiling with hydrochloric acid, it is partially decomposed (Ador a. Rilliet).

Xylonitril, $C^6H^3(CH^3)^2.CN$, obtained by heating potassium xylate with potassium cyanide, melts at 125° – 126° (Jacobsen, *Ber.* xi. 17).

An acid having the composition of xylic acid is formed (according to Picard, *Ber.* xi. 2120), together with other products, by heating the barium salt of cantharic acid, an isomeride of cantharidin (p. 276), formed by digesting that substance with hydriodic acid at 100° in a sealed tube. The acid thus produced melts at 140° , and is therefore different both from xylic and from paraxylic acid, the former of which melts at 126° , the latter at 163° (vi. 1130).

Appendix to Xylic Acid.

Mesitylenic Acid, $C^6H^3(CO^2H)(CH^3)(CH^3)$. The bromo-, nitro-, and amido-derivatives of this acid—the symmetrical modification of the acid $C^6H^9O^2$ —have been examined by H. J. Schmitz (*Liebig's Annalen*, xciii. 160; *Ber.* xi. 1828).

Bromomesitylenic Acids, $C^6H^2Br(CH^3)^2CO^2H$. Two of these, α and β , are formed by direct bromination of mesitylenic acid, and are separated by the different solubilities of their barium salts.

The α -acid is formed, together with a smaller quantity of the β -acid, by digesting mesitylenic acid with 1 mol. bromine for 36 hours at ordinary temperature; also from the corresponding amido-acid, by converting this compound into the diazoperbromide, and gently heating the latter with absolute alcohol. It dissolves with great difficulty in cold, but readily in hot water, and crystallises therefrom by slow cooling in slender needles an inch long. It dissolves easily in alcohol, especially when hot, and separates therefrom in large colourless orthorhombic crystals. $a : b : c = 0.9274 : 1 : 0.4695$. Observed faces, $\infty P2$, $\infty \bar{P}\infty$, $\infty \bar{P}\infty$, P . Angle $\infty \bar{P}\infty : P = 65^\circ 21'$; $\infty \bar{P}\infty$. $P = 67^\circ 17'$. It melts at 146° – 147° , resolidifies at 131° , and if again heated melts at 137° – 138° . The α -barium salt, $(C^6H^2BrO^2)^2Ba + 4H^2O$, forms large colourless monoclinic crystals, moderately soluble both in hot and in cold water. $a : b : c = 3.0683 : 1 : 0.8040$; $\beta = 63^\circ 24'$. The calcium salt, $(C^6H^2BrO^2)^2Ca + 2H^2O$, separates from hot aqueous solution in very small slender needles, easily soluble in water.

β -Bromomesitylenic Acid, identical with that which Fittig and Storer obtained by oxidation of bromomesitylene (*Liebig's Annalen*, cxlvii. 1), is easily prepared from the corresponding amido-acid by the diazo-perbromide reaction. It is nearly insoluble in cold, very slightly soluble in hot water, from which it separates in compact monoclinic crystals; $a : b : c = 1.1932 : 1 : 0.7599$; $\beta = 70^\circ 35'$. Observed forms, $0P$, ∞P , $R\infty$, $\infty \bar{P}\infty$. Angle, $\infty P : \infty P = 96^\circ 53'$; $0P : \infty P = 77^\circ 34'$; $R\infty : 0P = 35^\circ 41'$. Cleavage parallel to $\bar{P}\infty$. The acid melts at 212° – 214° . The β -barium salt, $(C^6H^2BrO^2)^2Ba$, crystallises from hot water in colourless, slender, anhydrous needles.

Nitromesitylenic Acids, $C^6H^3(NO^2)O^2$. The action of nitric acid on mesitylenic acid gives rise to two nitro-derivatives, one of which gives a sparingly soluble barium salt crystallising in tables, the other an easily soluble barium salt crystallising in needles.

α -Nitromesitylenic Acid, $C^6H^2(NO^2)(CH^3)^2.COOH$, is the acid obtained from the easily soluble barium salt, and is produced in larger quantity than the β -acid. It crystallises from water in splendid needles, melting at 210° – 212° , very difficultly soluble in cold water. From alcohol or ether it separates in large triclinic prisms. The α -barium salt, $(C^6H^2NO^2)^2Ba + 4H^2O$, crystallises in tufts of slender needles, which are

easily soluble in cold water, and dissolve in hot water in almost all proportions. The α -calcium salt is soluble in water in all proportions, and crystallises in long needles. The α -magnesium salt is also soluble in water in all proportions, and separates on evaporation in crystalline crusts. *Ethyl α -nitromesitylenate*, $C^9H^8(NO^2)O^2.C^2H^5$, crystallises in large tables, melting at 65° , insoluble in water, but easily soluble in alcohol.

β -Nitromesitylenic Acid, $C^9H^8(NO^2)(CH^3)^2.CO^2H$, is obtained from the difficultly soluble barium salt above referred to. It is insoluble in cold, and only very slightly soluble in hot water; easily soluble in hot alcohol, and separates on cooling in very large compact monoclinic crystals. This acid exhibits very characteristic properties on melting. When precipitated from the barium salt it melts at 175° , but when crystallised from alcohol it melts at 214° – 220° , and on cooling solidifies only at 162° , after which it fuses at 168° on re-heating. If a trace of alcohol be added to this fused acid, even when heated over 200° , it solidifies immediately, and begins to melt again only at 214° . The β -barium salt, $(C^9H^8NO^2)^2Ba + 4H^2O$, crystallises in monoclinic tables, sparingly soluble in cold, more readily in hot water. The β -calcium salt, $(C^9H^8NO^2)^2Ca + 6H^2O$, is sparingly soluble in hot water, and crystallises in long prismatic needles belonging to the monoclinic system.

Ethyl β -nitromesitylenate, $C^9H^8(NO^2)O^2.C^2H^5$, crystallises in long needles or thick prisms melting at 72° , insoluble in water, easily soluble in alcohol.

Amidomesitylenic Acids, $C^9H^8(NH^2)O^2$. The α -acid, prepared from the α -nitro-acid by reduction with tin and hydrochloric acid, crystallises from alcohol in long colourless needles melting at 186° – 187° . The β -acid, previously described by Fittig & Brückner (vi. 823), melts at 235° .

XYLIDIC ACID, $C^9H^8O^4 = C^9H^8(CO^2H)(CH^3)(CO^2H)$. This bibasic acid is formed by oxidation of pseudocumene, $C^9H^8(OH^2)^3$ [1 : 2 : 4] (p. 1284), with dilute nitric acid or a warm solution of potassium permanganate, or by the action of nitric acid on xyllic or paraxylic acid (vi. 1130): hence it has the constitution above indicated (Jacobsen, *Ber.* x. 855).

By the further action of potassium permanganate it is converted into trimellitic acid, $C^9H^4(CO^2H)^3$, which has therefore also the constitution 1 : 2 : 4 (G. Krinos, *Ber.* x. 1491).

Zinc Xylidate exhibits, more strikingly than any other known salt, the property of dissolving more abundantly in cold than in hot water, 100 pts. water at 0° dissolving nearly 30 pts. of it, at 100° only 0.735, and at 130° almost exactly 0.5 pt. The salt which separates at $+4^\circ$ from a solution saturated at -4° is anhydrous. At a little below -5° the entire liquid solidifies (Jacobsen, *Ber.* x. 859).

XYLIDINES, or AMIDOKYLENES, $C^9H^{11}N = C^9H^8(CH^3)^2.NH^2$. A. W. Hofmann (*Ber.* ix. 1292) has isolated, from the crude oils of high boiling point (200° – 240°) obtained in the manufacture of aniline, a xylidine which forms sparingly soluble salts with nitric and hydrochloric acids. This he calls provisionally α -xylidine, to distinguish it from an isomeride occurring together with it (β -xylidine), which forms a sparingly soluble nitrate, but an easily soluble hydrochloride. The two isomerides were separated by repeatedly crystallising from hot water the mixture of acetyl-compounds obtained by boiling them with glacial acetic acid; the α -compound, being the less soluble, was thus obtained pure.

α -Acetoxylidide forms large flat white needles, which melt at 127° – 128° and dissolve easily in alcohol. When boiled with strong hydrochloric acid, it is converted into xylidine hydrochloride. The base separated from this salt is an oil, colourless at first, but rapidly turning dark: its boiling point is 212° , and its sp. gr. 0.9184 at 25° . The *platinochloride* has the formula $[C^9H^8(CH^3)^2.HCl]^2PtCl_4$.

A xylidine having the same properties as the foregoing is obtained by the action of methyl alcohol on toluidine hydrochloride at 300° .

The following derivatives of α -xylidine have been prepared:

Dicycylthiocarbamide, $CS[NH.C^9H^8(CH^3)^2]^2$, was obtained by digesting xylidine

with carbon bisulphide till hydrogen sulphide ceased to be evolved. It is insoluble in water, and but sparingly soluble in boiling alcohol, from which it is deposited in dazzling-white hard crystals melting at 152° – 153° .

Xylyl thiocyanate is formed by distilling the preceding compound with phosphoric anhydride. It is solid at ordinary temperatures, but melts very easily.

Disylylguanidine, $\text{CNH}[\text{NH}.\text{C}^6\text{H}^3(\text{CH}^3)^2]^2$, is readily formed by the action of lead oxide on xylylthiocarbamide in presence of alcoholic ammonia. It crystallises from hot alcohol in delicate white needles, which melt at 156° – 158° , apparently undergoing decomposition. It is insoluble in water.

Nitracetoxylicide, $\text{C}^6\text{H}^2(\text{CH}^3)^2(\text{NO}^2)\text{NH}(\text{C}^2\text{H}^3\text{O})$, formed by the action of strong nitric acid on acetoxylicide, crystallises from hot water or alcohol in yellow needles melting at 172° – 173° .

Nitroxylidine, $\text{C}^6\text{H}^2(\text{CH}^3)^2(\text{NO}^2)\text{NH}^2$, is formed by boiling the last compound with strong hydrochloric acid till the liquid acquires a deep-red colour. It crystallises from hot water in fine orange-red needles melting at 69° , and dissolving sparingly in water, more freely in alcohol. It is but very slowly attacked by boiling soda-ley.

Xylene-diamine (Diamidoxylylene), $\text{C}^6\text{H}^2(\text{CH}^3)^2(\text{NH}^2)^2$, is formed by the action of tin and hydrochloric acid on nitroxylidine. It forms glittering laminae or delicate white needles, which melt at 74° – 75° . It is a faintly alkaline base, and forms crystallisable salts.

Wroblewsky (*Ber.* x. 1248) has obtained from nitracetoxylicide melting at 180° (probably identical with that above mentioned), by decomposition with strong sulphuric acid, a nitroxylidine melting at 76° ; from this a nitroxylene crystallising from alcohol in large flat needles, melting at 67° , boiling at 250° , and yielding by reduction a new xylidine, which remains liquid at 20° , has a sp. gr. of 0.9935, and boils at 220° – 221° (thermometer in the vapour). The *hydrochloride* of this xylidine crystallises in long colourless shining needles, the *nitrate* in long white needles having a nacreous lustre. The *sulphate* has the composition $(\text{C}^6\text{H}^2.\text{NH}^2)^2\text{H}^2\text{SO}^4$. The *acetyl* derivative, $\text{C}^6\text{H}^2\text{NH}(\text{C}^2\text{H}^3\text{O})$, crystallises in needles melting at 144° .

Metaxylicidines (α and β) are formed by distilling α - and β -mesitylenic acid (p. 2150) with quick-lime. The α -metaxylicidine thus obtained is a colourless oil boiling at 212° (uncorr.). Its *hydrochloride*, $\text{C}^6\text{H}^2(\text{NH}^2).\text{HCl}$, is slightly soluble in cold, more freely in hot water, and separates therefrom generally in large prismatic crystals (I.), but sometimes in tabular crystals (II.). According to measurements by Arzruni, the crystals I. belong to the monoclinic system. $a : b : c = 0.9178 : 1 : 0.2873$; $\beta = 85^{\circ} 46'$. Observed faces, ∞P , 0P , $\infty\text{R}\infty$. Angle, $\infty\text{P} : \infty\text{R}\infty = 47^{\circ} 32'$; $0\text{P} : \infty\text{R}\infty = 74^{\circ} 1'$; $0\text{P} : \infty\text{P} = 76^{\circ} 2'$. The crystals are prismatically elongated in the direction of the axis c . The crystals II. are also monoclinic. $a : b : c = 0.9807 : 1 : 0.9531$; $\beta = 83^{\circ} 37.5'$. Observed faces, 0P , ∞P , $\text{R}\infty$. Angle, $\infty\text{P} : \infty\text{P} = 88^{\circ} 31'$; $0\text{P} : \infty\text{P} = 85^{\circ} 26.5'$; $0\text{P} : \text{R}\infty = 43^{\circ} 27'$. Tabular in the direction of c . The *nitrate*, $\text{C}^6\text{H}^2(\text{NH}^2).\text{NH}^2$, forms prismatic crystals joined together so as to form large rhombic tables; it is sparingly soluble in cold, more freely in hot water. *Acet- α -metaxylicide*, $\text{C}^6\text{H}^2.\text{NH}(\text{C}^2\text{H}^3\text{O})$, crystallises from alcohol in flat colourless needles melting at 127° .

β -*Metaxylicidine* is a colourless oil boiling constantly at 216° (mercury-column wholly in the vapour). The *hydrochloride*, $\text{C}^6\text{H}^2(\text{NH}^2).\text{HCl}$, is readily soluble in water, and crystallises from hot water on cooling in large thin tables; by slow evaporation in colourless crystals, which, according to Arzruni, belong to the monoclinic system. $a : b : c = 0.5579 : 1 : 0.6175$; $\beta = 78^{\circ} 23'$. Observed faces, 0P (predominant), $\text{R}\infty$, ∞P , $\infty\text{R}\infty$. Angle, $\infty\text{P} : \infty\text{P} = 57^{\circ} 16'$; $\infty\text{P} : 0\text{P} = 79^{\circ} 39'$; $\infty\text{R}\infty : \text{R}\infty = 58^{\circ} 50'$. The plane of the optic axes coincides with the plane of symmetry; an axis is visible at the edge through 0P (Schmitz, *Liebig's Annalen*, xciii. 160).

α -*Metaxylicidine* is, according to Schmitz, identical with Hofmann's α -xylidine, also with the xylidine which Wroblewsky obtained from metaxylylene. This base, according to Wroblewsky, is converted, by substitution of methyl for the amido-group, into pseudocumene. Consequently α -metaxylicidine must be represented by the formula $\text{CH}^3 : \text{CH}^2 : \text{NH}^2 = 1 : 3 : 4$ or $\text{C}^6\text{CH}^3.\text{H}.\text{CH}^3.\text{NH}^2.\text{H}^2$, and β -metaxylicidine by $\text{CH}^3 : \text{NH}^2 : \text{CH}^3 = 1 : 2 : 3$ or $\text{C}^6\text{CH}^3.\text{NH}^2.\text{CH}^3.\text{H}^2$. Corresponding formulae likewise hold good for all the α - and β -derivatives of mesitylenic acid above described (pp. 2150, 2151).

Paraxylicidine, obtained by nitration of *p*-xylene and reduction of the nitro-compound with iron-filings and acetic acid, is an oily liquid which becomes yellow after a while, is moderately soluble in hot water, and boils at 220° – 221° . Its salts

crystallise well from acid solutions, but their neutral solutions decompose on boiling.

Paraxylylidine Sulphate, $[C^8H^{11}N]^2H^2SO_4$, crystallises in colourless plates. The *hydrochloride*, $C^8H^{11}N.HCl + H^2O$, forms large glistening plates, having a faint pink colour. It is more soluble than the sulphate. At 125° – 130° its water of crystallisation is expelled, and the anhydrous salt sublimes. The *nitrate*, $C^8H^{11}N.HNO_3$, forms pink needle-shaped crystals. The *oxalate* forms thick prisms having a pink colour. On heating to 125° – 130° , it splits up into water and *oxalparaxylylidide*, $[C^8H^9(CH^3)_2NH]^2C^2O_2$. This body is soluble in alcohol and in ether, and sublimes without melting at 125° , forming slender silky-white needles.

Acetoparaxylylidide (m. p. 138° – 139°) separates out as a crystalline mass on boiling paraxylylidine in glacial acetic acid. It is converted into *nitracetoparaxylylidide*, $[C^8H^9(CH^3)_2NO^2.NH.C^2H^3O]$, by the action of fuming nitric acid. This nitro-compound is a yellow crystalline powder melting at 192° (W. Schaumann, *Ber.* xi. 1537).

A chloroxylylidine of undetermined constitution is obtained, together with an oily xylidine, by reducing mononitroxylene with tin and hydrochloric acid. It is a solid body which dissolves with extraordinary facility in ether, alcohol, and benzene, is nearly insoluble in cold water, but dissolves in hot water, and crystallises therefrom in shining laminae melting at 92° – 93° . It volatilises readily with aqueous vapour.

Chloroxylylidine forms salts which crystallise well, but are stable only in strongly acid solutions. The *hydrochloride* crystallises with 2 mol. water, is fusible, sublimes without decomposition, and crystallises in crossed needles an inch long. The *sulphate* is but sparingly soluble in water, the *oxalate* still less soluble. The *acetate* and *nitrate* form tabular crystals (Jannasch, *Liebig's Annalen*, clxxvi. 55).

Xylidines with Chloral.—A compound having the formula $CCl^3.CH[NH.C^8H^9(CH^3)_2]^2$, analogous to those which chloral forms with other amines (vii. 311), is obtained by the action of chloral on xylidine. It forms slender needles, easily soluble in ether, less soluble in alcohol, and melting at 95° – 99° . This melting point, which is low in comparison with those of the corresponding aniline and toluidine-compounds, seems to show that the xylidine employed, which was prepared by separation as nitrate from aniline-tailings, was a mixture of several isomeric compounds (Wallach, *Liebig's Annalen*, clxxiii. 274).

XYLOQUINONE, $C^8H^8O^2$, formed by the oxidation of xylene-diamine or of xylidine, melts at 125° , and sublimes even at ordinary temperatures in golden-yellow needles. It bears a strong resemblance to its lower homologues, and is perhaps identical with the metaphlorone of Rommier a. Bouillon (iv. 496).

Xyloquinol, $C^8H^{10}O^2 = C^8H^9(CH^3)(OH)^2$, is prepared by treating the quinone with warm aqueous sulphurous acid, and separates from a hot aqueous solution in silvery plates melting at 212° . It is converted by oxidation into the quinone, and by the action of hydrochloric acid into monochlorxyloquinol (Nietzki, *Ber.* xiii. 473).

XYLYL KETONE, $C^{17}H^{18}O = C^8H^9.CO.C^8H^9$, is prepared by passing carbonyl chloride into xylene cooled to -15° , and gradually adding aluminium chloride. It remains liquid at -60° and boils at 340° . By saponification with potash it yields dimethyl-benzoic acid, convertible by oxidation into methylbenzene-dicarboxylic and benzene-tricarboxylic acids. By prolonged boiling it is resolved into water and the hydrocarbon, $C^{17}H^{18}$ (Ador a. Rilliet, *Ber.* xi. 399).

Y

YAM. *Dioscorea edulis*. The tubers of this plant yield a milky juice containing a small quantity of fat, a resin having a slight and not bitter taste, and caoutchouc. In the north of Italy they are used for making brandy, and as food for men and cattle.

The tubers, somewhat shrivelled from loss of water, gave on analysis:

	Moist	Dried
Water	60.722	—
Ash, free from C, CO ² , and SiO ²	0.895	2.273
Protein compounds	4.485	11.419

									99.64

(J. Moser, *Landw. Versuchs-Stationen*, xx. 113).

YEW. *Taxus baccata*. The green needles of this tree contain an alkaloid and other substances which have been examined by Amato a. Capparelli (*Gazz. chim. ital.* 1880, 340). The needles were exhausted successively with ether, alcohol, water, and dilute sulphuric acid. The extract left on evaporation of the ethereal solution was mixed with dilute sulphuric acid (1 : 20), and distilled in a current of steam, when an essential oil passed over, having an odour like that of wild fennel. The hot acid solution separated from the insoluble residue, deposited an amorphous powder on standing, and the filtrate from this, when treated with excess of baryta and agitated with ether, yielded the alkaloid. A colourless non-nitrogenous crystalline substance was extracted from the insoluble residue above mentioned by treating it with alcohol and small quantities of animal charcoal.

The alkaloid is a colourless, crystalline, nitrogenous substance, having a musty odour, sparingly soluble in water, easily in alcohol or ether. Dense white fumes are produced when a rod dipped in dilute hydrochloric acid is held near it. It gives a canary-yellow precipitate with phospho-molybdic acid, and with tannin a white precipitate which becomes crystalline on standing. Picric acid gives a yellow precipitate, and iodised potassium iodide reddish-brown crystals.

The non-nitrogenous crystalline substance forms stellate groups of needles, melting at 86°–87°, easily soluble in boiling alcohol, but only sparingly soluble in cold alcohol.

The solution obtained by treating the yew-needles with alcohol after they had been exhausted with ether was found to contain the same substances as the ethereal solution. From the aqueous and acid extracts, oxalic acid and small quantities of the alkaloid were obtained.

YTTRIUM. *Atomic weight*, 89.55 (yttria = Y₂O₃). See p. 736.

The probable existence of yttrium in the sun's atmosphere has been pointed out by C. A. Young (*Sill. Am. J.* [3], iv. 356), and by Lockyer (*Proc. Roy. Soc.* xxvii. 279).

An elaborate investigation of the spectra of yttrium, erbium, didymium, and lanthanum has been published by R. Thalén (*Bull. Soc. Chim.* [2], xxii. 350). one of the most important results of which is to show that the lines hitherto regarded as common to the spectra of these metals owe their existence to impurities.

On *Yttrium Salts*, see ERBIUM (p. 736). On the *Ferrocyanide*, see CYANIDES (p. 612). The *chloroplatinate* has the composition 2Y²Cl⁶.5PtCl⁴ + 51H²O; the *chlorostannate*, Y²Cl⁶.2SnCl⁴ + 16H²O (Cleve, *Bull. Soc. Chim.* [2], xxxi. 195).

METALS ALLIED TO YTTRIUM.

Erbium. *At. w.* 170.55. This element occurs as phosphate, together with didymium, in the Cornish mineral called *Rhabdophane* (p. 1756). Its probable existence in the sun has been pointed out by Lockyer. On the spectrum of Erbium Nitrate and of Erbia, see Lecoq de Boisbaudran (*Compt. rend.* lxxxviii. 1167; lxxxix. 516; *Chem. Soc. J.* xxxvi. 862; xxxviii. 6).

From recent researches by Cleve it appears that the earth commonly called erbia is a mixture of three earths, viz. the true erbia, and two others which he designates as *holmia* and *thulia* (p. 2159).

Terbium. *Tr. At. w.* 98 or 147 (Delafontaine); 99 or 148.5 (Marignac), according as the oxide is regarded as TrO or as Tr_2O_3 .

The separate existence of this metal, originally pointed out by Mosander, but called in question by Bunsen a. Bahr (v. 1064), and more recently by Cleve a. Hoeglund, has been established by the experiments of Delafontaine (*Ann. Ch. Phys.* [5], xiv. 238), and of Marignac (*ibid.* 247). Marignac prepares terbia from those portions of the mixed oxides obtained from gadolinite by Bahr a. Bunsen's process, which contain only traces of erbia. The oxides are dissolved in nitric acid, and subjected to a series of fractional precipitations with oxalic acid, the first portions of precipitate being the richest in terbia. By this treatment the whole of the yttria is separated, and the terbia is obtained mixed only with didymium oxide and erbia. The didymium is separated in the usual way by means of potassium sulphate; but for the separation of terbia from erbia no method has yet been discovered. According to Delafontaine, terbia is most advantageously prepared from samarskite, which contains but small quantities of yttria and erbia. The mixture of oxides obtained from this mineral is dissolved in nitric acid; the solution is treated with potassium sulphate to precipitate the cerium metals; and the syrupy solution of the remaining nitrates is mixed with a saturated solution of sodium sulphate, crystals of the same salt being added till no more is dissolved. A crystalline sulphate is thus obtained which, when treated with ammonium oxalate, yields an insoluble oxalate, leaving on ignition a dark yellow oxide, whereas the oxide obtained in like manner from the more soluble sulphate is of a much lighter yellow colour. The dark yellow oxide containing the greater part of the terbium is dissolved in a large excess of strong nitric acid, and a hot concentrated solution of oxalic acid is dropped into the liquid till a permanent precipitate is formed. After 24 hours the liquid is decanted, and subjected to fractional precipitation with oxalic acid, and this treatment is repeated a third, fourth, and fifth time. The united precipitates are then calcined and redissolved in nitric acid, and this solution is likewise subjected to a series of fractional precipitations with oxalic acid.

When the earths thus purified are dissolved by small quantities in dilute formic acid, and the clear solution is heated and slightly concentrated, a white pulverulent non-crystalline precipitate is obtained, yielding on ignition a base of deep orange-yellow colour, while the solution from which it has separated yields another base of somewhat lighter yellow colour; and on repeatedly dissolving the first of these bases in formic acid, and precipitating it therefrom by concentration till the percentage of base in the salt amounts to 60, a product is obtained consisting of pure terbia.

Terbia, after ignition at a moderate heat, has a deep orange-yellow colour, but becomes quite colourless when heated in a stream of hydrogen, or after very strong ignition. It dissolves slowly but completely in the most dilute acids; in hydrochloric acid with evolution of chlorine. Its solutions are colourless, and seem to possess no absorption-spectrum. The sulphate, $\text{Tr}_2(\text{SO}_4)_3 + 8\text{H}_2\text{O}$, forms colourless crystals, isomorphous with the sulphates of yttrium, erbium, and didymium (Marignac).

Terbium Formate separates from solution on the sides of the vessels as a non-crystalline, closely-adhering crust; it burns without tumefaction when ignited, dissolves in about 30 parts of cold water, and appears to be not more soluble in hot water. The acetate crystallises in small coloured transparent prisms, less soluble than didymium acetate. It cannot be completely dried without decomposition, carbonises at a temperature below redness, and burns away slowly like starch (Delafontaine).

The sparing solubility of terbium formate, the colour of the oxide, and its property of forming an insoluble double salt with sodium sulphate, might lead to the conclusion that the supposed earth is nothing but a mixture of the oxides of lanthanum and didymium. But the formation of an oxalate in presence of an excess of strong nitric acid excludes the possibility of the presence of lanthanum, and the spectroscopic character of the base in question is altogether different from that of didymium. Lastly, the atomic weight of the metal, and the colourless character and solubility of the formate, acetate, and sulphate of terbium, preclude the possibility of the identity of terbia and erbia.

Philippium. *At. w.* between 90 and 95 for PpO , or 135 and 142.5 for Pp_2O_3 . The oxide of this metal has likewise been obtained from samarskite, but not quite pure, as portions of yttria and erbia adhere to it obstinately.

Philippium formate crystallises easily, either on cooling or by spontaneous evaporation, in small shining rhomboidal prisms, less soluble than yttrium formate, which is deposited in nodular groups from a syrupy solution; terbium formate is anhydrous and soluble in 30–35 parts of water. Sodio-terbic sulphate is scarcely soluble in water; the corresponding philippium-compound is easily soluble. Philippium oxalate is more soluble in nitric acid than terbium oxalate, but less soluble than the yttrium salt. Philippium nitrate becomes dark yellow when fused; yttrium and terbium

nitrates remain colourless. Philpium salts are colourless when pure; the oxide is decolorised by heating in a current of hydrogen, or simply by a strong heat, becoming yellow again on cooling in the air. Concentrated solutions of philpium salts give in the indigo-blue ($\lambda = 460$ nearly) a broad and very dark absorption-band, with its edges, more especially the right, very well defined; this band is not seen in yttrium, erbium, or terbium solutions. In the green there are two lines, one belonging to erbium, the other and less refrangible probably to philpium; finally, in the red there is at least one narrow band (Delafontaine, *Compt. rend.* lxxxvii. 559).

Philpium appears also to occur in Sipylite (p. 1802), inasmuch as W. G. Brown (*Chem. News*, xxxviii. 269), in analysing that mineral, after separating the cerium metals from those of the yttrium-group, obtained with the solution of the latter an absorption spectrum, which exhibited bands agreeing very nearly with those observed by Delafontaine as characteristic of philpium.

Decipium. *At. w.* 106 for DpO , 159 for Dp^2O^3 . This metal, also discovered by Delafontaine (*Compt. rend.* lxxxvii. 632) in the samarskite of North Carolina, is intermediate in character between the metals of the cerium and yttrium groups. The oxide has not yet been sufficiently separated from that of didymium to exhibit its true colour. Its salts are colourless; the acetate crystallises easily, is less soluble than the didymium salt, but more so than the terbium salt; decipio-potassium sulphate is but slightly soluble in a saturated solution of potassium sulphate, but easily soluble in pure water.

Decipium nitrate gives in direct solar light an absorption-spectrum containing at least three bands in the blue and indigo. The most refrangible band is a little narrower than that of philpium or the band *m* of didymium; it is tolerably dark; its middle corresponds nearly with the wave-length 416, and is approximately in the middle of the space between Fraunhofer's lines G and H, but a little nearer to G. Neither didymium nor terbium gives bands in this part of the spectrum; the band characteristic of terbium is more to the right, and nearly out of the spectrum given by ordinary light. Under exceptional circumstances two well-defined bands, probably H and H_1 , have been observed in the violet space beyond this band.

The second decipium band is narrower, darker, and less well-defined; it is situated in the less refrangible blue, and its middle corresponds with the wave-length 478; it is nearly in the same place as one of the didymium bands, but is much darker. Finally, more to the left, and nearer the limit of blue and green, there is an ill-defined minimum of transmission, which is possibly composed of two faint bands.

Samarium. Lecoq de Boisbaudran (*Compt. rend.* lxxxviii. 322; lxxxix. 212), in a spectroscopic examination of the unpurified earths from samarskite, observed an emission and an absorption spectrum, which showed lines and absorption-bands not belonging to any previously known element. The new element *samarium*, to which these lines belong, may be separated by repeated fractional precipitation from didymium and decipium. It is characterised by two blue bands, $\lambda = 480$ and $463\cdot5$, and probably by two others, 417 and $400\cdot75$.

Two other earths, distinguished as *yttria* α and β , have been obtained by Marignac (*Ann. Chim. Phys.* [5], xx. 535) from the mixture of those samarskite earths which, like erbia, ytterbia, &c., form nitrates not readily decomposed by heat. By taking advantage of the different solubilities of their double potassium sulphates in a saturated solution of potassium sulphate, these earths were separated into the four following groups:

I. *Double Sulphates, soluble in less than 100 times their volume of K^2SO^4 solution.* Molecular weight of oxide not less than 119 for MO or 357 for M^2O^3 . *Yttria* and *terbia*, with traces of the oxides of decipium and didymium, and probably traces of the oxide of Ya found in Group II. The *terbia*, even after strong ignition, had a faint chamois tint, which disappeared on heating in a current of hydrogen, and reappeared when the oxide was again heated in the presence of air. These changes of colour were accompanied by very slight variations in weight.

II. *Double Sulphates, soluble in 100–200 vols. of K^2SO^4 solution.*—This portion consisted mainly of the oxide of the metal provisionally distinguished as Ya. Molecular weight of oxide (Ya^2O^3) about $361\cdot5$, being a maximum among those earths which most nearly approach it in their behaviour with potassium sulphate solution. This metal forms colourless salts. It is distinguished from all the metals of this class, except yttrium and ytterbium, by the very faint orange-yellow colour of its oxide, and by the fact that its salts show no absorption spectrum; from yttrium by the sparing solubility of its formate, and of its double potassium sulphate; from ytterbium by the much greater stability of its nitrate, and by the ease with which the ignited oxide dissolves in dilute acids.

III. *Double Sulphates, very slightly soluble in K²SO⁴ solution.* *Mol. weight falls from 357 to 345 as the solubility decreases.*—This group contains the oxide of Y α , a small quantity of the oxide of didymium which cannot be completely separated, and the oxide of a metal Y β , which forms a nitrate readily decomposed by heat, but is included in this group because its double potassium sulphate is very sparingly soluble in K²SO⁴ solution. The mol. w. of the oxide of Y β is probably somewhat lower than 346.8. Its sulphate forms small, short crystals similar to those of the sulphates of yttrium and didymium, but of a sulphur-yellow colour; they have the composition Y β 2(SO⁴)³ + 8H²O.

Solutions of the salts of this base give a well-defined absorption spectrum which closely resembles that ascribed by Delafontaine to decipium, or, still more closely, that described by Boisbaudran as peculiar to samarium. Since these three bodies were obtained from samarskite by the same methods, it is probable that they are essentially one and the same substance. The mol. w. of the oxide of decipium is, however, according to Delafontaine, 390, whilst that of the oxide of Y β is below 346.8. Further, the salts of decipium are colourless, those of Y β have a yellow colour, the intensity of which increases the further the purification is carried. Probably either the substance obtained by Delafontaine was mixed with a considerable proportion of some other base having a high molecular weight, or that obtained by Marignac contained a base forming yellow salts, and having a much lower molecular weight. Further investigations are necessary to decide this point.

IV. *Double Sulphates, insoluble in K²SO⁴ solution.*—This group contained only didymium, which, however, could not be completely purified from traces of other metals.

The number of earths obtained from the samarskite of North Carolina now amounts to ten, viz.:—

	Colour	Mol. weight	Characteristic absorption-band
Yttria	White	Y ² O ³ = 227.1	None
Erbia	Rose	Er ² O ³ = 389.1	λ = 520–522
Terbia	Orange	Tr ² O ³ = 342	λ = about 400
Philippia	Yellow	Pp ² O ³ = 318	λ = about 449
Decipia	White (?)	Dp ² O ³ = 366	λ = about 416
Thoria	White	ThO ² = 263	None
Didymia	Brownish	Di ² O ³ = 338	λ = 372–377
Samaria	—	—	λ = 463.5 and 480
Y α	Faint orange-yellow	Y α 2O ³ = 361.5	No abs. spectrum
Y β	—	Y β 2O ³ = 346	(Abs. sp. like those of decipia and samaria)

J. L. Smith has obtained from the Samarskite of North Carolina an earth which he regards as peculiar, and designates as *Mosandria*. According to Marignac and Delafontaine, however, it is identical with terbia (*Compt. rend.* lxxxvii. 146, 281, 600; *Chem. Soc. J.* xxxvi. 12, 13, 117).

Ytterbium. *At. w.* 115 for YbO, 172.5 for Yb²O³. Marignac, in the course of his investigations on the gadolinite earths already noticed (p. 2155), obtained a small quantity of erbia, which subsequent experiments (*Compt. rend.* lxxxvii. 578) showed to be a mixture of two distinct oxides, viz. the true erbia and a new earth, which he calls *ytterbia*. This earth is colourless, and forms colourless salts; the nitrate is decomposed by heat without coloration.

Solutions of ytterbia give no absorption-bands, either in the ordinary spectrum or in the ultra-violet (Soret). The earth itself is less easily attacked by acids than the other earths of this family. It dissolves slowly in the cold, or at a gentle heat in slightly diluted acids; on boiling, it dissolves easily even in acetic and formic acids. *Ytterbium Sulphate* resembles, and is probably isomorphous with, the sulphates of yttrium and erbium; it dissolves easily and without residue in sulphate of potassium, no precipitate being formed even on boiling. A neutral and not too concentrated solution of *ytterbium chloride* is not precipitated by sodium thiosulphate; a very concentrated solution, containing erbium, gives a precipitate containing a larger proportion of erbium than is contained in the residual salts. *Ytterbia* precipitated by

potash, and submitted to a current of chlorine, dissolves completely in presence of excess of alkali.

The *formate* $C^0H^3YbO^0$ or $Yb^0O^3, 3C^0H^2O^3$ dissolves in less than its own weight of water, and crystallises in small crystalline nodules, resembling the formates of yttrium and erbium; it is decomposed with intumescence by heat, and loses its water of crystallisation at 100° .

The existence of this new earth in erbia throws doubts on the exactness of the equivalent of the latter, as determined by Bunsen and others, and would lead to the supposition that the molecular weight of erbia must be lower than that usually given.

Nilson (*Ber.* xii. 551) has also obtained ytterbia from gadolinite and from euxenite, and finds it to be a colourless, infusible earth of sp. gr. 9.175, insoluble in water, easily soluble in hot dilute acids, but attacked with difficulty, even by strong acids, in the cold. Its solutions have a sweet, astringent taste, are colourless, and give no absorption spectrum. The salts impart no colour to the Bunsen flame, but with the electric spark the chloride gives a brilliant spectrum. The *nitrate* forms large crystals, which melt in their water of crystallisation at 100° , and decompose when heated with evolution of nitric acid and nitrous fumes, and formation of insoluble basic nitrates. The *sulphate*, $Yb^2(SO^4)^3, 8H^2O$, forms large brilliant prisms which do not alter when exposed to the air, but lose their water at 100° . It dissolves slowly in boiling water, and is completely soluble in a saturated solution of potassium sulphate. The anhydrous sulphate may be heated to a high temperature without decomposition, but at a white heat it is completely converted into oxide. The *normal selenite* is obtained as a bulky amorphous precipitate by mixing solutions of sodium selenite and ytterbium sulphate. When treated with excess of selenious acid it yields an insoluble crystalline *acid selenite*, $Yb^2(SeO^3)^3, H^2SeO^3, 4H^2O$, which loses its water at 100° . The *oxalate*, $Yb^2(C^0O^4)^3, 10H^2O$, is formed as a bulky precipitate of small fine needles by the addition of oxalic acid to a solution of an ytterbium salt; this precipitate soon contracts, and assumes the form of short thick prisms. It loses $7H^2O$ at 100° , and is but slightly soluble in water and dilute acids.

That ytterbia is a sesquioxide is shown by the composition of the sulphate, analogous to and isomorphous with those of yttrium and didymium; by the composition of the acid selenite, and by that of the oxalate and formate, analogous respectively to the corresponding salts of didymium and yttrium; and, lastly, by the molecular heats and volumes of the oxide and the anhydrous sulphate.

Nilson finds the atomic weight of ytterbium to be somewhat higher than that given by Marignac, viz. 116 instead of 115, or 174 instead of 172.5.

Scandium. *At. w.* 44.03 (Nilson), 44.91 (Cleve), the metal being regarded as trivalent. This metal occurs only in gadolinite (0.002 to 0.003 per cent.) and yttritanite (0.005 per cent.) It was discovered by Nilson in 1879 (*Compt. rend.* lxxviii. 642; *Ber.* xii. 551), and further examined by Cleve (*Compt. rend.* lxxxix. 419) and by Nilson (*ibid.* xci. 118; *Ber.* xiii. 1439).

Scandia, Sc^2O^3 , may be separated from ytterbia by taking advantage of the fact that the nitrate decomposes more easily by heat than that of ytterbium, and that scandium sulphate produces in a saturated solution of potassium sulphate an insoluble double salt. This double salt nevertheless contains a little ytterbium sulphate, which may be finally removed by converting the two earths into nitrates, and submitting the latter to partial decomposition by heat; the ytterbium nitrate can then be washed out.

Scandia is a light, infusible, white powder resembling magnesia. It dissolves easily in boiling nitric and hydrochloric acids, but scarcely at all in the cold. It is not volatile, and gives no coloration to flame, although a very brilliant spectrum may be obtained from the chloride by the electric spark (Nilson).

The *hydrate* is a bulky white precipitate, drying up to semi-transparent fragments. It does not absorb carbonic acid from the air, is insoluble in ammonia and in potash, and does not decompose ammonium salts when heated with them (Cleve).

Scandium salts are colourless or white, and have an acid, astringent taste, very different from the sweet taste of the salts of the yttrium-metals. The *sulphate* does not form distinct crystals; the *nitrate*, *oxalate*, *acetate*, and *formate*, are crystallisable. The *chloride* exhibits the following reactions: It gives no spectrum when heated in a gas flame. Potash and ammonia produce bulky white precipitates, insoluble in excess; tartaric acid prevents the precipitation by ammonia in the cold, but on heating an abundant precipitate falls. Sodium carbonate gives a precipitate, soluble in excess. Sulphuretted hydrogen produces no change; ammonium sulphide precipitates the hydrate. Sodium orthophosphate gives a gelatinous precipitate. Oxalic acid gives a *curdy precipitate*, quickly becoming crystalline; this precipitate dissolves in strong acids, and cannot be completely reprecipitated. Although apparently more soluble

than the oxalates of the other yttrium metals, it is found in the first precipitates in the fractional precipitation of a mixture of scandium and ytterbium by oxalic acid. Acid potassium oxalate precipitates a crystalline double salt. Sodium thiosulphate precipitates a boiling solution easily, but incompletely. Sodium acetate behaves similarly. The sulphates of potassium and sodium precipitate crystalline double salts, soluble in a saturated solution of the precipitant (Cleve).

The *nitrate* crystallises from a strong solution in small prisms; when strongly ignited, it is converted into oxide, but on treating this with water, a very basic nitrate generally dissolves, forming an opaque milky solution, which never becomes clear: this reaction is very characteristic of scandium. The *sulphate*, $\text{Sc}^2(\text{SO}_4)^3 + 6\text{H}_2\text{O}$, may be prepared as before mentioned; it is unalterable in the air, but loses 4 mols. of water at 100° , and the anhydrous salt is produced on gentle ignition; when strongly heated, it loses sulphuric acid and forms scandia. The *double sulphate*, $\text{K}^2\text{SO}_4 \cdot \text{Sc}^2(\text{SO}_4)^3 + x\text{H}_2\text{O}$, forms characteristic groups of small prisms. It is very slightly soluble in water, and quite insoluble in a saturated solution of potassium sulphate. The *selenite* and *oxalate* may be prepared by precipitation with the corresponding sodium salts; both are insoluble. The spectrum of scandium, as obtained by passing a powerful induction spark between aluminium poles moistened with a solution of the chloride, is very complicated, and contains more than a hundred lines. All the lines, which are very characteristic, are fine, with the exception of some in the yellow and orange, and seven strong lines in the blue-violet. A line at 4374 is slightly more refrangible than a prominent yttrium line, with which it might be confounded. Some very faint bands, situated at 5900–5730, are probably due to the oxide, as are possibly also the broad lines in the blue-violet at 6193–6016 (Thalén, *Compt. rend.* xci. 45).

Scandium agrees very closely in its atomic weight, and in the properties of its oxide and salts, with the element whose existence was predicted by Mendelejeff (*Liebig's Annalen, Supplementband*, viii. 133) under the name of *Ekanbor*, e.g. in forming a white oxide, M_2O_3 , infusible, soluble with difficulty in acids after ignition, insoluble in alkalis; also in forming colourless salts, and a sulphate which unites with potassium sulphate, yielding a double salt analogous in composition to common alum.

Thulium and Holmium (?). Cleve (*Compt. rend.* lxxxix. 478), in attempting to prepare pure erbia, has been led to the discovery of two other earths which he designates as *thulia* and *holmia*. On fractionating the mixture, and subjecting the several fractions to spectroscopical examination, it was found that, in addition to bands common to all the fractions, one band, $\lambda = 6840$, was strong in the residues rich in ytterbia, and wanting in those containing yttria and erbia, whilst two others, $\lambda = 6400$ and 5360 , were strong in the yttria and ytterbia residues. The colour of the fraction treated for ytterbia was a violet-rose, whilst the yttria fraction had an orange tint.

The metal characterised by the first band, $\lambda = 6840$, Cleve proposes to name *thulium*; it would have an atomic weight of about 169.5 (the oxide being Tm_2O_3). Its oxide has a clear rose-colour. The other metal, *holmium*, is characterised by the bands $\lambda = 6400$ and 5360 ; it should have an atomic weight less than 162; its oxide seems to be yellow.

J. L. Soret (*Compt. rend.* lxxxix. 521) is of opinion that Cleve's holmium is identical with philippium, inasmuch as the bands $\lambda = 6400$ and 5360 , which are said to be characteristic of it, are likewise found in the spectrum of philippium. Soret also claims to have observed Cleve's thulium ($\lambda = 6840$) in the portions of the gadolinite earths rich in ytterbium.

Z

ZEOLITES (v. 1066). The zeolites occurring in the basalt of the Limperichkopf, near Asbach, have been described by E. Weiss (*Jahrb. f. Min.* 1873, 1819). Among those occurring together in a cavity, phillipsite (there of remarkable size) is the oldest, next follows natrolite, and lastly apophyllite.

Daubrée (*Compt. rend.* lxxx. 606) describes the recently formed zeolites from the spring of Bourbonne-les-Bains, Dep. Haute-Marne. Crystals of chabasite occur in small cavities in fragments of bricks, while those which are found imbedded in the mortar consist of lime-harmotome. C. Doelter (*Jahrb. f. Min.* 1875, 175) describes chabasite from the clefts in the monzonite of the Mal Inverno and of the Palle Rabbiosi, Monte Monzoni, and regards that of the latter locality as a secondary formation from anorthite.

See further GISMONDIN (p. 861): HEULANDITE (p. 1030); PHILLIPSITE (p. 1568).

ZEORA. The ethereal extracts of *Zeora sordida*, remaining after the usnic acid has crystallised out, contain two neutral crystallisable substances, zeorin and sordidin, which have been examined by Paternò (*Atti della Reale Accademia dei Lincei* [2], iii. [1876]; *Ber.* viii. 1359; x. 1382; *Gazz. chim. ital.* 1877, 281, 508). The separation and purification of these bodies is difficult, on account of the small proportion ($\frac{1}{4}$ per cent.) in which they occur in the lichen. The ethereal solution is evaporated down; the brown viscid residue is treated with cold alcohol, which removes a resinous substance; and the residue then left is boiled with a quantity of alcohol less than sufficient to dissolve the whole, so that nearly all the usnic acid present may remain undissolved. The alcoholic solution on cooling deposits the zeorin mixed with a small quantity of usnic acid, whilst the sordidin remains dissolved, and may be obtained by further concentration.

Zeorin, $C^{13}H^{22}O$, after purification by treatment with chloroform or boiling with potash-ley, which dissolves only the usnic acid, and crystallisation from ether-alcohol, forms very small but perfectly distinct pyramids with hexagonal base, colourless and transparent, and having a vitreous lustre. It melts at 230° – 231° , and volatilises without decomposition. It is but very slightly soluble in alcohol, ether, or chloroform, and quite insoluble in water. It is a neutral body, not attacked by alkalis. Nitric acid dissolves it, with emission of red fumes, and formation of a yellow substance insoluble in alcohol. It is but slightly attacked by dilute sulphuric acid. In composition and properties it is nearly allied to betulin.

Sordidin, $C^{13}H^{18}O^8$,* after repeated crystallisation from alcohol, forms colourless laminae or needles which melt at 210° , and volatilise without decomposition. It is insoluble in water, but dissolves readily in alcohol and benzene, sparingly in ether and in chloroform. By heating with aqueous potash, it is converted into a crystalline compound, which decomposes without fusion when heated above 250° . Zeorin is not decomposed by potash.

ZERECHTITE, see TSCHUKING (p. 2062).

ZINC. Atomic weight, 65. Occurrence in Plants and Animals.—Lechartier a. Bellamy (*Compt. rend.* lxxxiv. 687) have found zinc in the human liver, in calf's liver, in beef, poultry-eggs, wheat, barley, maize, beans, and vetches.

Metallurgy.—On the roasting of zinc-ores, and the causes of the loss of zinc in the process, see Hasenclever (*Dingl. pol. J.* cxcix. 284; ccxvi. 165; *Jahresb. f. Chem.* 1871, 980; 1875, 1014). A blast-furnace for the smelting of zinc-ores is described by F. L. Clerc (*Dingl. pol. J.* ccxxiv. 179; *Jahresb.* 1877, 1117).

Reactions.—Zinc immersed in an alcoholic solution of phosphorus, or in aqueous solutions of hydrogen phosphide, hydrogen sulphate, or iron salts, precipitates small quantities of phosphorus, sulphur, or iron on its surface, and retains them with great obstinacy. Zinc which has been kept in solutions containing phosphorus does not give up anything to water, alcohol, or ether, but carbon sulphide and chloroform dissolve phosphorus from it. It does not diminish in weight when heated at 140° in a stream of carbon dioxide, but it sustains some loss when agitated at ordinary temperatures with water and air. Zinc thus coated eliminates more hydrogen from dilute acids, &c. than unaltered zinc under conditions otherwise similar. Zinc may also be altered in like manner by solutions of hypophosphorous acid. The alteration appears to be due to surface attraction, not to chemical combination.

On the action of Zinc at high temperatures on mixtures of Hydrocarbons and Organic chlorides, see vii. 183, and p. 1063 of this volume.

Estimation.—C. Fahlberg (*Zeitschr. anal. Chem.* 1874, 379) describes a volumetric method of estimating zinc, depending upon the fact that this metal is completely precipitated from its solution in hydrochloric acid by potassium ferrocyanide, and that an excess of the normal solution is readily indicated by a solution of uranium. The accuracy of the method is not affected by the presence of manganese or aluminium, inasmuch as manganese ferrocyanide is soluble in potassium ferrocyanide, and aluminium solutions are not decomposed by that salt. The presence of nickel or cobalt is, however, injurious, since both these metals form insoluble ferrocyanides; but the quantity of them contained in zinc-ores is for the most part too small to have any sensible effect on the estimation. The ferrocyanide solution is made of such a strength that 1 c.c. of it will precipitate 0.01 g. zinc. It is titrated by means of pure zinc dissolved in hydrochloric acid, with addition of five times its weight of ammonium chloride. The zinc ferrocyanide readily falls out in thin flakes, and is free from alkaline ferrocyanide.

* Paternò originally assigned to sordidin the formula $C^{13}H^{18}O^7$; but subsequent experiments showed that the substance (m. p. 180°) whose analysis led to this formula was contaminated with zeorin.

The end of the reaction is determined by the brown colour produced on addition of a drop of uranium nitrate.

Ores containing galena or copper pyrites, besides blende, are treated with nitrohydrochloric acid, and the solution, after boiling with a little more hydrochloric acid, is saturated with sulphuretted hydrogen. The precipitated heavy metallic sulphides are filtered off; the iron in the solution is peroxidised with nitric acid; and the solution is allowed to cool before adding excess of ammonia. The iron is separated as ferric hydrate, and the solution now contains nearly the whole of the zinc. The precipitation is repeated till no more zinc is retained by the iron. The several ammoniacal solutions are neutralised with hydrochloric acid, 10 to 15 c.c. of acid of sp. gr. 1.12 being superadded, and the zinc is titrated with potassium ferrocyanide, regardless of the presence of manganese.

A similar method is described by F. W. Lyte (*Chem. News.* xxxi. 222; xxxvi. 89).

Zinc may also be estimated as *oxalate* in the same manner as manganese (Classen, p. 1264). The same reaction serves also to separate zinc from iron, which, in the state of ferric salt, is not precipitated by oxalic acid (p. 1104).

Compounds of Zinc.

On Alloys of Zinc and Copper, see COPPER (p. 566).

On the action of the 'Copper-zinc Couple' on various substances, see p. 1071.

Oxide, ZnO. Brühlmann (*Ann. Phys. Chem.* [2], lxxxvii. 1082) prepares this oxide in the crystalline state by heating zinc nitrate. It forms white or faintly yellowish, shining, hemimorphous pyramids belonging to the hexagonal system, and has a density of 5.782 at 215°. It is much less easily attacked by solvents than the amorphous oxide.

Zinc-dust.—The proportion of metallic zinc in the mixture of metal and oxide known by this name (vi. 1134) may be estimated by converting the hydrogen evolved by it into water by means of cupric oxide, and weighing the water (*Fresenius, Zeitschr. Anal. Chem.* 1878, 465).

A cask of zinc-dust partly wet, which was being conveyed in a steamer, became red-hot and gave rise to a conflagration (*Dingl. pol. J.* ccxxiv. 344).

Zinc Ferrite, ZnO, Fe²O³, is formed by precipitating a solution of ferrous chloride and zinc chloride with potash, and agitating the mixture with air till all the ferrous oxide is oxidised to ferric oxide; the precipitate dried and ignited exhibits magnetic properties.

Zinc Phosphates and Arsenates (Demel, *Ber.* xii. 1171, 1279). *Primary Zinc phosphate*, ZnH⁴(PO⁴)² + 2H²O, is obtained, by dissolving zinc oxide in phosphoric acid, and concentrating the solution, in large transparent triclinic crystals, which are not altered by alcohol or ether, but are decomposed by water, phosphoric acid passing into solution, and a white crystalline powder separating which has the composition 10ZnO, 4P²O⁵, 10H²O, and is probably a mixture of several phosphates.

A solution of zinc oxide in *arsenic acid* evaporated to a syrupy consistence, deposits after some time a crystalline crust composed of small plates, while the mother-liquor, on further concentration, yields an abundant crop of small white needles. Both these products, after washing with ether, consist of *secondary zinc arsenate*, ZnHAsO⁴ + H²O. This salt is decomposed by water, either hot or cold, giving up arsenic acid, and being converted into a crystalline salt having the composition 5ZnO, 2As²O⁵, 5H²O, previously obtained by H. Salkowski (vi. 226). On adding an alkali to a solution of either of these salts in hydrochloric acid, a white bulky precipitate is formed, consisting of *normal* or *tertiary zinc arsenate*, Zn³(AsO⁴)² + 3H²O, which Salkowski obtained by precipitating a solution of zinc sulphate with sodium arsenate.

Zinc-methyl, Zn(CH³)². This compound, treated with *tetraphylic silicate*, yields ethylic orthosilicoacetate together with zinc-methyl-ethoxyl or zinc methylethylate (p. 1793):

With *acetyl chloride* at low temperatures it forms acetone (Pawlow, *N. Petersb. Acad. Boll.* xxii. 497),

With *bromacetyl bromide* it yields methyl-isopropyl carbonol, see *PENTYL ALCOHOLS* (p. 1502).

Zinc-ethyl similarly treated appears to yield an octyl alcohol.

Zinc-ethyl treated with *sulphurous acid* yields ethylsulphurous or ethylsulphinic acid, $C^2H^4.SO^2H$ (Zuckschwerdt, *Ber.* vii. 292).

ZINNWALDITE. A variety of lithia mica from Zinnwald in Bohemia (see *Mica*, p. 1320).

ZIRCON. A. E. Törnebohm (*Jahrb. f. Min.* 1877, 97) finds that zircon occurs as a widely diffused accessory constituent of Swedish felsite-porphry, eurite, hella-finta, gneiss, and especially in Swedish granites, and has also been found in the granites of Switzerland, Saxony, Tyrol, and North America.

G. A. König (*ibid.* 203, 944) has analysed zircons: (1). Occurring, together with needles of columbite, in the amazon-stone of Pike's Peak, Colorado, in crystals 6 mm. long, exhibiting the combination $P.\infty P.\infty$. (2). Crystals of the combination $P.0P.\infty P$, imbedded in quartz or astrophyllite in El Paso county, Colorado:

SiO ² .	ZrO ²	Fe ² O ³	MgO	H ² O	Sp. gr.
1. 28.00	60.00	—	8.93	3.47 = 100.40	4.065
2. 29.70	60.98	9.20	0.30	— = 100.18	4.538 at 12°

The analysis of the latter leads to the formula $Fe^2Zr^{10}Si^{10}O^{43}$.

F. Zirkel (*Jahrbuch f. Min.* 1876, 201) has detected zircon as a microscopic constituent in the granulites and mica-slates of Saxony, the gneisses and crystalline slates of North America, and the eclogites of the Fichtelgebirge. In these latter Sandberger found macroscopic zircon.

ZIRCONIUM. *Atomic Weight*, 90. Several compounds of this metal have been prepared and examined by S. R. Paykull (*Ber.* vi. 1467; xii. 1719), viz., the *tetrachloride*, the *chloride of zirconium* and *sodium*, $ZrCl^4.2NaCl$, obtainable only in the dry way, *zircodiammonium chloride*, $ZrCl^4.4NH^3 = Cl^2Zr \begin{smallmatrix} NH^2(NH^4)Cl \\ NH^2(NH^4)Cl \end{smallmatrix}$, analogous to platino-diammonium chloride (vii. 998), the *hydrated oxychlorides*, $ZrOCl^2.8H^2O$, and $2ZrOCl^2.13H^2O$, the latter, which is amorphous, being formed on dropping a solution of the chloride into hydrochloric acid; the *hydroxide*, $ZrO(OH)^2$, which in the moist state appears to absorb carbonic acid from the air; the *normal sulphate*, $Zr(SO^4)^2.4H^2O$, and several crystallisable basic sulphates formed by combination of the normal salt with the hydroxide, e.g., $3ZrO^2.4SO^3 + 15H^2O$, and $6ZrO^2.7SO^3 + 19H^2O$, down to the formation of the *bisasic sulphate*, $ZrO^2.SO^3$, or $ZrO^2.Zr(SO^4)^2 + xH^2O$, which dries up to a gum. With potassium sulphate, several basic double salts have been obtained, e.g., $K^2SO^4.2[ZrO^2.Zr(SO^4)^2] + 14H^2O$. The precipitate formed on boiling a solution of the mixed salts is also, as found by Berzelius, a highly basic double salt. The *arsenate*, $2(2ZrO^2.As^2O^5) + 5H^2O$, and a *phosphate*, $5ZrO^2.4P^2O^5 + 12H^2O$, have also been obtained. The *normal oxalate* could not be prepared, but a *double oxalate*, $ZrC^2O^4.2K^2C^2O^4 + 3H^2O$ or $4H^2O$, has been obtained.

Soluble basic zirconium-compounds have also been prepared by Endemann (*J. pr. Chem.* [2], xi. 219). An alcoholic solution of zirconium *oxydichloride* prepared with the aid of heat yields, on addition of ether, an apparently crystalline precipitate, which,

after washing with anhydrous ether, has the composition $Zr^2O^3Cl^2$ or $\begin{array}{c} ClZr-O \\ || \\ ClZr-O \end{array} O$.

It dissolves readily in water, and remains on evaporation at a gentle heat in the form of an amorphous powder. It is soluble also in cold alcohol, but is decomposed by warm alcohol. On adding ether to a solution of this compound prepared in the cold, a gummy precipitate is obtained, having the appearance of aluminium hydrate dried at a low temperature, and likewise soluble in water. It contains only 7HCl to $8ZrO^2$. Endemann regards these compounds as analogous to the hydrochloride of metastannic oxide, $SnCl^4 + 3SnO^2 = 2(SnOCl)^2O$, and to the compound $8HCl.9SnO^2$. An aqueous solution of *normal zirconium sulphate*, gave on addition of alcohol, a precipitate which contained only $6SO^3$ to $7ZrO^2$, and was soluble in water. The *basic sulphate* dissolves in a small quantity of water, but is instantly decomposed, on addition of a larger quantity of cold water, into a more basic salt which separates out and an acid salt which remains in solution. The salt precipitated by alcohol always retains alcohol, perhaps in the place of water of crystallisation. *Zirconium oxydichloride*, when repeatedly dissolved in water, and evaporated at a low temperature, continually gives off hydrochloric acid and becomes uncrystallisable.

Alkaline tartrates give with zirconium salts a white precipitate of zirconium tartrate having the composition

The solubility of this salt in caustic alkalis and alkaline tartrates indicates the existence of easily soluble double zirconium tartrates; and such salts are in fact obtained in crystalline form by heating the acid tartrates of potassium and sodium with zirconia. Their composition has, however, not yet been determined, as they are very much disposed to split up into salts of various composition (R. Hornberger, *Liebig's Annalen*, clxxxi. 232).

Cyanogen-compounds.—A solution of zirconium sulphate mixed with barium thiocyanate forms at first a colourless solution of *normal zirconium thiocyanate*, $\text{Zr}(\text{CNS})^2$; but this solution quickly decomposes, depositing a yellow body (probably pseudothiocyanogen), while the compound $\text{Zr}(\text{CNS})^2$ remains in solution.

Potassium ferrocyanide produces in zirconium solutions a yellowish-white precipitate, which soon turns greenish-blue, and forms when dry a powder having a fine blue colour with a greenish tinge, insoluble in water and decomposed by acids with evolution of hydrogen cyanide. Its composition is represented by the formula $(\text{Fe}^2)^{+1}(\text{CN})^{12}(\text{Zr}'')^3$, analogous to that of Turnbull's blue, $(\text{Fe}^2)^{+1}(\text{CN})^{12}(\text{Fe}')^3$ (Hornberger).

ZÖBLITZITE. A hydrated magnesium silicate occurring at Zöblitz, at Kändler near Limbach (A), and as a coating on chrome iron ore in the serpentine of Hrubschitz, Moravia (B), also at Lettowich in Moravia:

SiO^2	Al^2O^3	FeO	MgO	H^2O	Sp. gr.
42.44	4.67	0.91	38.49	13.48 = 99.99	2.49 at 20°
42.57	9.12	1.82	32.90	13.19 = 99.60	—

Regarding the alumina as replacing part of the silica, these analyses lead to the proportions:

	SiO^2	Mg	H^2O
A	= 1	: 1.3	: 1
B	= 1	: 1.15	: 1

(A. Frenzel, *Jahrb. f. Min.* 1875, 680).

ZOISITE. This mineral, originally found on the Sau Alp and at Sterzing in Tyrol, at Fusch in Salzburg, and at Baireuth and Conradsreuth in Bavaria (v. 1085), occurs also in the island of Syra, in the corundum region of North Carolina, and in Delaware County, Pennsylvania.

Analyses. 1. From the glaucophane-bearing rocks of Syra (Lüdecke, *Zeitschr. Geol. Ges.* xxviii. 258, 262). 2. Dark rose-red to faintly reddish zoisite, occurring, together with green zeolites and green and yellow grossular, in friable grey quartz which forms a vein in the mica-slate gneiss of Leiperville, on the Crum Creek, Delaware County, Pennsylvania. Sp. gr. = 3.642 (G. A. König, *Zeitschr. Kryst.* ii. 302). 3. From the Cullakenee Mine, Clay County, North Carolina; greenish-white, formed from rose-red corundum. Sp. gr. 3.286 (König). 4. Greyish-white, formed from blue-grey corundum, which is still present in the nucleus; identical with the *unionite* of Smith a. Brush. Sp. gr. 3.224.

	SiO^2	Al^2O^3	Fe^2O^3	FeO	MnO	CaO	MgO	K^2O	Na^2O	H^2O	
1.	42.85	32.60	trace	—	—	21.37	0.21	—	—	2.55 =	99.58
2.	40.70	33.30	2.40	0.70	0.43	19.70	0.15	—	—	2.40 =	99.78
3.	40.70	33.86	0.81	—	—	24.05	0.22	not det.		0.63 =	100.27
4.	39.86	33.84	1.62	—	—	23.82	0.18	0.09	0.22	0.78 =	100.41

J. L. Smith (*Compt. rend.* lxxvii. 440) has published under the name of 'zoisite,' the analyses of two varieties, (A) light-green, (B) black, of a mineral which accompanies the corundum of North Carolina.

SiO^2	Al^2O^3	Fe^2O^3	Cr^2O^3	CaO	MgO	Na^2O	H^2O
45.70	24.01	4.56	0.52	13.44	8.03	2.91	0.60
45.90	13.34	11.46	—	12.20	12.53	3.39	0.66

The proportion of silica is, however, rather large for an epidote or zoisite. The light-coloured variety has been described by Gemh (*Jahresh. f. Chem.* 1873, 1152) as smaragdite.

ADDENDA.

ANTHRARUFIN, $C^{14}H^8O^4 = C^6H^2(OH).C^2O^2.C^6H^2(OH)$. (Schunck a. Roemer *Ber.* xi. 1176; Liebermann a. Böck, *ibid.* 1613). A dihydroxyanthraquinone formed in small quantity (2 p. c.) by the action of strong sulphuric acid on metahydroxybenzoic acid. It may be separated from anthraflavic acid and metabenzdihydroxyanthraquinone formed at the same time, by means of baryta-water, which dissolves those compounds, and purified by recrystallisation from glacial acetic acid.

Anthrurufin sublimes readily at 120° – 130° , and melts at 280° . It is nearly insoluble in water, and dissolves but sparingly in alcohol, forming a yellow solution from which it crystallises in yellow quadratic tables, exhibiting considerable iridescence. It dissolves sparingly also in glacial acetic acid, and crystallises therefrom in regular yellow saw-shaped crystals. The solution exhibits a faint green fluorescence. Anthrarufin dissolves to a considerable amount in benzene, less freely in ether and carbon sulphide. From chloroform it crystallises in prisms. These solutions produce no absorption-bands, but only a darkening of the spectrum.

A concentrated solution of anthrarufin in strong sulphuric acid exhibits a cherry-red colour by transmitted light and a strong scarlet fluorescence by reflected light. These colour reactions are extremely delicate. One part of anthrarufin in 1,000,000 pts. sulphuric acid, shows an evident carmine-red colour in strata 1 inch thick, while absorption-bands may be observed in solutions that appear colourless. Small quantities of nitric or nitrous acid change the carmine-red into a deep yellow which no longer exhibits any absorption-bands.

Anthrurufin dissolves in potash-solution with greenish-yellow colour; the addition of hydrochloric acid produces an orange-coloured precipitate, which when boiled with zinc-dust changes to a green fluorescent liquid. It is almost insoluble in sodium carbonate and in ammonia. Alcoholic lead acetate gives no precipitate in solutions of anthrarufin, but alcoholic copper acetate gives a brownish-red precipitate. Anthrarufin is not attacked by bleaching-powder, and does not produce lakes with alumina or oxide of iron. It yields a nitro-derivative.

Anthrurufin boiled with potash-solution gives, at a certain degree of concentration of the liquid, a brownish potassium-salt crystallising in needles; and on further evaporation an indigo-blue salt is obtained, which on addition of water is reconverted into the brown-red modification. Finally, if the mass be heated to fusion, a dark-blue lustrous mass is produced, which dissolves in water with a violet-blue colour; and on removing the unattacked anthrarufin and adding hydrochloric acid, a yellowish-brown substance is obtained which on sublimation yields small brown-red needles consisting of a trihydroxyanthraquinone or purpurin, $C^{14}H^8O^3$, which appears to differ from all the purpurins hitherto known; it dissolves with indigo-blue colour in potash, with violet colour in sulphuric acid.

Diacetyl-anthrurufin, $C^{14}H^6(C^2H^3O)^2O^4$, obtained by heating anthrarufin at 200° with glacial acetic acid, crystallises in yellow needles melting with decomposition at 245° (Schunck a. Roemer), at 244° (Liebermann a. Böck). It is quite insoluble in potash-ley, very slightly soluble in alcohol, more freely in glacial acetic acid; behaves with strong sulphuric acid like anthrarufin, and is reconverted into anthrarufin by boiling with potash.

HYDROKETHYLANILINE, $C^6H^{11}NO = C^6H^5.NH(C^2H^4OH)$. *Oxethylenc-aniline* (E. Demole, *Ber.* vi. 1024).—This compound is formed by adding aniline in molecular proportion to ethylene oxide in a well-cooled tube, then sealing the tube, exposing it for a few hours to a temperature of 50° , and fractioning the product till a portion is obtained boiling between 279° and 282° . It is a liquid colourless when recently prepared, very slightly soluble in water, alcohol, and ether, easily in chloroform. Its aqueous solution is coloured green by chloride of lime. When pure it boils at 280° .

HYDROXYETHYL TOLUIDINE, $C^8H^{12}NO = C^7H^7.NH(C^2H^4OH)$. *Oxethylene-toluidine* (Demole, *Ber.* vii. 635; *Liebig's Annalen*, clxxviii. 123).—This base is prepared by heating molecular proportions of ethylene oxide and paratoluidine at 100° in a sealed flask. The product, subjected to fractional distillation, yields a liquid which boils at 286° – 288° , and solidifies in dense tufts of white silky crystals melting at 37° , turning yellow on exposure to light, very soluble in alcohol, ether, chloroform, and benzene, soluble also in water. It is a strong base, yielding a deliquescent hydrochloride, and a platinumchloride which forms brown not very regular crystals, and is not decomposed by boiling with water or alcohol—a character by which it is distinguished from the corresponding salt of hydroxyethylamine. The *oxalate* forms small prismatic crystals or white tufts; the *acid sulphate* crystallises in colourless prisms.

Methylhydroxyethyltoluidine, obtained by heating molecular proportions of hydroxyethyltoluidine and methyl iodide in a sealed tube at 50° , is a fragrant uncrystallisable liquid; its platinumchloride separates in tufts of red-brown very brittle crystals. By heating the monomethylated base with excess of methyl iodide at 100° , a liquid uncrystallisable iodide is obtained, which dissolves very readily in water and in alcohol, but is insoluble in ether. When treated with silver oxide it gives up its iodine, and is converted into a strong base, the platinum salt of which forms hard, ruby-coloured, highly lustrous crystals, having the composition of *dimethyl-tolyl-hydroxyethylammonium platinumchloride*, $C^{12}H^{20}N^2O \cdot PtCl^6 = [(CH^3)^2(C^7H^7)(C^2H^4OH)NCl]^2PtCl^4$. With gold chloride very delicate tufts are obtained, having a splendid yellow colour.

Dihydroxyethyltoluidine, $C^{11}H^{12}NO^2 = C^7H^7.N(C^2H^4OH)^2$, is formed as a bye-product in the preparation of hydroxyethyltoluidine. It is a colourless, viscid, uncrystallisable liquid, boiling without decomposition at 338° – 340° ; turns brown somewhat quickly in contact with the air; is less soluble in alcohol than the monohydroxyethyl base. Its *platinum salt* is much more soluble in alcohol than that of the latter, and crystallises in shining ochre-yellow spangles.

INULIN, $C^{12}H^{20}O^{10}$. Lescœur a. Morelle (*Compt. rend.* lxxxvii. 216) have prepared inulin from elecampane, dahlia, and chicory, and find, contrary to the statement of Ferrouillat and Savigny (*ibid.* lxxviii. 1571), that, from whatever source this substance is obtained, it is identical in chemical and physical properties.

Inulin prepared in the same manner from elecampane, dahlia, and chicory, gave with Laurent's polarimeter a rotatory power, $[\alpha]_D = -36.56$, -36.57 , -36.18 respectively. Sodium inulate has a rotatory power = -33° . Its acetic acid derivatives, obtained by the action of acetic anhydride, also correspond in character and composition; compounds have been obtained of the formulæ—

Inulin also plays the part of a weak acid, forming with alkalis compounds which are soluble in water, but are precipitated therefrom by alcohol. These compounds are amorphous, viscid, and translucent; they are unstable, as from their solution in water inulin is again precipitated on adding more water, or on passing carbon dioxide through the solution.

LACTIC ACIDS, ISOMERIC. Wislicenus, from experiments on the lactic acid obtained from flesh (sarcolactic acid), was led to regard it as a mixture of two acids, viz. *paralactic acid*, a dextrogyrate acid forming well-crystallised salts, and *ethylene-lactic acid*, the salts of which show but little tendency to crystallise. Erlenmeyer, on the other hand, failed to obtain an ethylene-lactic acid from sarcolactic acid, finding indeed in the mother-liquors of zinc paralactate nothing but a small quantity of the zinc salt of ordinary lactic acid, together with a nitrogenous body. In another preparation of zinc sarcolactate made according to Liebig's directions (iii. 457) he found that the solution of that salt crystallised to the last drop. Erlenmeyer also finds that ethylene-lactic acid, $CH^2OH.CH^2.COOH$, prepared by the action of hydrochloric acid or of caustic soda-ley on ethylene-cyanhydrin, $CH^2OH.CH^2.CN$, is absolutely identical with the so-called *hydracrylic acid* (vii. 717) obtained by the action of silver oxide on β -iodopropionic acid, $CH^2I.CH^2.COOH$. Wislicenus regarded the acids obtained by these two processes as isomeric, because he did not succeed in converting ethylene-lactic acid by the action of hydriodic acid into β -iodopropionic acid; but Erlenmeyer finds that the ethylene-lactic acid prepared from ethylene cyanhydrin is easily converted by this reaction into β -iodopropionic acid. It also yields the sparingly soluble zinc-calcium salt which is especially characteristic of hydracrylic acid.

It appears, then, that there are but two metameric modifications of *lactic* or hydroxypropionic acid, viz.:

The first of these is however susceptible of two isomeric modifications; one, the ordinary lactic acid of fermentation, being optically inactive, while the other (sarcolactic or paralactic acid), obtained from flesh, is dextrogyrate.

NORWEGIUM. A metal occurring, according to Töllef Dahl (*Ber.* 1879, xii. 1731), in a nickel-glance from the small island of Oterö. It is found as a black sulphide, together with copper, in the precipitate formed by hydrogen sulphide, and may be easily separated from copper by dissolving the precipitate in hydrochloric acid and mixing the slightly acid solution with a large quantity of water, whereupon the norwegium is precipitated as oxychloride. This metal is very similar to bismuth. Its specific gravity is 9.441, and atomic weight 145.95 for RO, or 218.93 for R²O³; melting point, 254°. Norwegium oxide, like bismuth oxide, is fusible and yields a metallic deposit before the blowpipe. The reactions of norwegium with potassium iodide, &c. are very much like those of bismuth. It is only in the reactions with alkalis and alkaline carbonates that any considerable difference between the two is to be observed, norwegium hydroxide being soluble in caustic potash and in a large excess of the carbonate of ammonium or sodium, whereas bismuth oxide is sparingly soluble or insoluble therein.

OZONE. *Liquefaction and Colour in the Gaseous State.*—When a gaseous mixture very rich in ozone, obtained by the action of electricity on oxygen at a very low temperature, was submitted to strong pressure at a temperature of -23°, an azure-blue colour appeared in the tube, and as the pressure increased, the colour deepened, until, when the gas was under a pressure of several atmospheres, the colour had become indigo-blue. On suddenly removing the pressure, a momentary white mist was observed in the tube, indicating a condensation to the liquid, or perhaps to the solid state. The blue colour is an essential character of ozone, and may be seen whenever a sufficient thickness of a mixture containing it is viewed. Thus the oxygen issuing from Berthelot's silent discharge apparatus exhibits a sky-blue colour when viewed through a column 1 meter long (Hautefeuille a. Chappuis, *Compt. rend.* xci. 522).

On the effect of Ozone on the Colour of the Atmosphere, see Hartley (*Chem. Soc. J.* 1880, xxxix. 113).

PHENOL-DIAZINS, or *Azophenols* (Weselsky a. Benedikt, *Wien. Akad. Ber.* [2 Abth.], lxxvii. 773; *Ber.* xi. 398).

Diphenol-diazins, C⁶H⁴(OH).N=N.C⁶H⁴(OH). The *ortho*- and *para*-compounds are formed by the action of melting potassium hydroxide on the corresponding nitrophenols. Metanitrophenol does not yield a diazin-compound. To prepare *o*-diphenol-diazin, 5 g. orthonitrophenol are added to a four- or five-fold amount of potassium hydroxide melted with a small quantity of water, and the mixture, which has at first a red colour, due to the presence of potassium-*o*-nitrophenol, becomes dark green with metallic lustre, and begins to froth up strongly and give off ammonia. The froth sinks rapidly, leaving a dark red melt, which is to be dissolved in water and supersaturated with dilute sulphuric acid; and the yellow-brown flocks thereby separated are freed from undecomposed nitrophenol by washing with water, then pulverised and exhausted with boiling ether. On leaving the ether to evaporate, the diphenol-diazin remains, and may be purified by crystallisation from alcohol.

Orthodiphenol-diazin is insoluble in water, dissolves in about 300 pts. cold alcohol, more freely in boiling alcohol, abundantly in ether, and crystallises from alcohol in anhydrous laminæ having a golden lustre; it melts at 171°, and volatilises without decomposition, subliming in reddish-yellow needles. It dissolves in alkalis, forming reddish-yellow solutions from which it is precipitated unaltered by acids. Its *lead salt*, C¹²H⁸N²O²Pb, separates as a red anhydrous precipitate on mixing the alcoholic solution of lead acetate and *o*-diphenol-diazin. The *barium salt*, prepared by adding titrated solutions of caustic baryta to alcoholic solutions of the diphenol-diazin, crystallises after some time in wavelitic groups of needles having a splendid red colour. At 100° it gives off its water of crystallisation, and acquires a fine brown colour. *Tetrabrom-o-diphenol-diazin*, prepared like the corresponding *para*-compound (*infra*) by treating *o*-diphenol-diazin in ethereal solution with excess of bromine, crystallises in needles having a dark yellow colour and metallic lustre. When fused with potash it turns reddish-violet.

Para-diphenol-diazin is formed: 1. When *p*-nitrophenol in portions of 5 to 10 grams is added to a five-fold quantity of potassium hydroxide fused with a little water, and the mixture is heated till it ceases to froth, and assumes a brown-violet colour. On saturating it with dilute sulphuric acid, crude *p*-diphenol-diazin separates

in the form of a yellow scum, which is to be collected, dried, dissolved in ether, then freed by filtration from considerable quantities of gummy and carbonaceous substances, and the ether finally evaporated off. By repeated crystallisation from dilute alcohol, the *p*-diphenol-diazin is obtained in bent needles or compact grains having a red-brown colour and mostly a steel-blue reflex. The product amounts to 30 per cent. of the calculated quantity. For purification it is dissolved in dilute potash-ley, precipitated by carbonic acid, and recrystallised from dilute alcohol. 2. By the action of potassium-phenol on the nitrate of *p*-diazophenol:

To prepare it, the solutions of 10 g. diazophenol nitrate in 200 c.c. water and 7.22 g. potassium-phenol are mixed together, whereupon the liquid quickly turns dark red and begins to deposit a resin. On filtering the liquid after twenty-four hours, and adding dilute sulphuric acid, a copious dark red crystalline precipitate is formed which may be partly purified by washing with cold water and agitation with dilute solution of sodium carbonate. The paradiphenol-diazin then remains undissolved, and may be further purified by agitation with ether, which dissolves it, evaporating off the ether, and recrystallising the residue from alcohol with the aid of animal charcoal.

Paradiphenol-diazin is nearly insoluble in water, but dissolves readily in alcohol, ether, and benzene, and crystallises in light brown shining triclinic crystals, without metallic reflex. It melts at about 204° , and at the same temperature begins to decompose with strong intumescence. Its compounds with alkalis dissolve in water and in alcohol with splendid orange colour; it has not yet been separated from these solutions. The *barium salt*, $\text{C}^{12}\text{H}^8\text{N}^2\text{O}^2\text{Ba} + 4\text{H}^2\text{O}$, obtained by mixing an alcoholic solution of the diazin with the equivalent quantity of caustic baryta in aqueous solution, forms yellow crystalline granules which at 100° give off their water and turn brown-red. The *lead salt* may be prepared in a similar manner.

Tetrabromo-p-diphenol-diazin, $\text{C}^{12}\text{H}^8\text{Br}^4\text{N}^2\text{O}^2$, is obtained by treating the diphenol-diazin dissolved in 60 pts. of ether with an excess of bromine, as a granular substance which dissolves in benzene and crystallises therefrom in golden-yellow needles. It does not dissolve without decomposition in potash-ley, and when fused with excess of potassium hydroxide and a few drops of water, it yields a blue melt, which on exposure to the air becomes first violet and then red.

SILICON-ETHYL SERIES. Compounds containing a double atom of silicon, $\equiv\text{Si}-\text{Si}\equiv$, and therefore analogous to ethane and its derivatives, have been prepared by Friedel and Ladenburg (*Ann. Chim. Phys.* [5], xix. 390). The starting-point for the preparation of these compounds is *silicon tri-iodide*, Si^2I^6 , which is prepared by heating silicon tetr iodide with finely divided silver (reduced by zinc from moist silver chloride), in sealed tubes at 290° – 300° for several hours. The contents of the tube are freed from unaltered tetr iodide by repeated washing with small portions of dry carbon bisulphide; a larger quantity of hot carbon bisulphide is then added, and the mixture filtered as rapidly as possible out of contact with the moisture of the air. On cooling, the solution deposits small colourless hexagonal prisms of Si^2I^6 , which fume in moist air, and dissolve in potash with evolution of hydrogen. Silicon tri-iodide may be fused in a vacuum, but decomposes partially at 250° . It cannot be distilled at atmospheric pressure or in a vacuum, but on heating it, a portion sublimes, and the remainder decomposes into the tetr iodide and an orange-coloured substance which appears to be SiI^2 .

Silicon tribromide, Si^2Br^6 , is obtained by adding an equivalent of bromine to a solution of the hex iodide in carbon bisulphide. It crystallises in rhombic plates, presenting the optical phenomena of biaxial crystals, and is therefore not isomorphous with the corresponding iodide.

Silicon trichloride, Si^2Cl^6 , is obtained by gently heating a mixture of silicon tri-iodide and mercuric chloride. The product is distilled off, rectified over mercuric chloride, and purified by fractional distillation. It is a colourless liquid, distilling between 144° and 148° , and crystallising at about -1° ; it fumes in the air, and is decomposed by water, with formation of a product which in great part dissolves in the acid liquid. All attempts to prepare this substance in the dry way by the action of silicon, silver, zinc, sodium, and hydrogen on silicon tetrachloride at a high temperature were unsuccessful. Troost and Hautefeuille, however, have recently prepared Si^2Cl^6 by the action of silicon tetrachloride on fused silicon, at a temperature at which porcelain begins to soften.

Silico-oxalic hydroxide, $\text{H}^2\text{Si}^2\text{O}^4$.—When crystals of silicon tribromide are introduced into ice-water, hydrogen is evolved, and a white substance deposited which, after drying in a vacuum and then at 100° , has a composition expressed by the

formula $\text{H}^2\text{Si}^2\text{O}^4$. Treated with potash, it gives off hydrogen in theoretical proportion, and when burnt with oxygen or heated in the air, it decomposes with incandescence, leaving a residue of silica in the proportion required by the equation: $\text{H}^2\text{Si}^2\text{O}^4 + \text{O} = \text{H}^2\text{O} + 2\text{SiO}^2$. The air-dried substance contains 10.4 per cent. water, th^y formula $\text{H}^2\text{Si}^2\text{O}^4 + 2\text{H}^2\text{O}$ requiring 12.8 per cent. The formation of silico-oxalic hydroxide may be explained by supposing that $\text{Si}^2(\text{HO})^6$ is first produced, and then converted into $\text{Si}^2\text{O}^2(\text{HO})^2$ by the loss of $2\text{H}^2\text{O}$. Although this substance is the chemical analogue of oxalic acid, it has no acid functions; bases, even the most dilute, decompose it with evolution of hydrogen, just as oxalic acid under certain conditions is decomposed by potash. Silico oxalic hydroxide may also be prepared by the action of silicon triiodide on absolute alcohol, the ethyl iodide, which is formed at the same time, being removed by distillation.

Silicon triethide, $\text{Si}^2(\text{C}^2\text{H}^3)^6$.—Silicon tri-iodide is added in small quantities to zinc-ethyl in the proportion of Si^2I^6 to $3\text{Zn}(\text{C}^2\text{H}^5)^2$. A brisk reaction ensues, and a white substance is deposited. The product is distilled, the distillate washed with water to remove zinc-ethyl, agitated with concentrated sulphuric acid (to remove a substance which appears to be the oxide of silicon-triethide, vii. 1083), again washed with water, dried, and submitted to fractional distillation. The distillate boiling at 150° – 154° is silicon tetrethide, that coming over between 250° and 253° is silicon triethide, $\text{Si}^2(\text{C}^2\text{H}^3)^6$. Silicon triethide is a limpid, slightly oily liquid, with a faint odour resembling that of silicon tetrethide. It burns with a bright flame, producing clouds of silica. Two vapour-density determinations, made at about 300° , gave the numbers 8.53 and 8.63, theory requiring 7.96. The excess was probably due to the presence of the above-mentioned oxide of silicon-triethide. The density of the liquid silicon triethide is 0.8510 at 0° , 0.8403 at 20° , compared with water at 0° and 20° respectively.

SUCCINIMIDE, $\text{C}^4\text{H}^3\text{NO}^2 = \begin{array}{c} \text{CH}^2.\text{CO} \\ | \\ \text{CH}^2.\text{CO} \end{array} \text{NH}$. This compound, treated with bromine, yields dibromosuccinimide, which crystallises in rhombic prisms melting at 225° , together with bromofumarimide, $\begin{array}{c} \text{CBr}.\text{CO} \\ || \\ \text{CH}.\text{CO} \end{array} \text{NH}$, melting at 150° – 152° , and another body, perhaps monobromosuccinimide, which melts at 105° – 120° (Kisielinski, *Wien. Acad. Ber.* [2 Abth.], lxxiv. 561).

SUCCINURAMIDE, $\text{C}^8\text{H}^9\text{N}^3\text{O}^4$, is obtained by evaporating the mixed solutions of potassium cyanate and asparagine:

It forms colourless prismatic crystals, sparingly soluble in water, nearly insoluble in ether and in alcohol. It melts at 137° – 138° , decomposing at the same time, with formation of amidomalylureide, which when evaporated down with hydrochloric acid of sp. gr. 1.12, yields malyllureidic acid:

SUCCINYL-SUCCINIC ACID, $\text{C}^8\text{H}^6\text{O}^6$. The diethylic ether of this acid,

which Fehling obtained by the action of potassium on diethylic succinate, regarding it however as $\text{C}^8\text{H}^6\text{O}^5$ (v. 463), has been further examined by F. Herrmann (*Ber.* vii. 1039). It is neutral, insoluble in water, but dissolves in alcohol, ether and benzene, forming solutions which exhibit a splendid light blue fluorescence, and separates in large light-yellowish triclinic crystals melting at 126° – 127° . On the crystalline form see Arzruni (*Zeitschr. Kryst.* i. 449).

Alcoholic potash added to its alcoholic solution throws down the *monopotassium compound*, $\text{C}^{12}\text{H}^{14}\text{KO}^6$, which, when treated with excess of potash, is converted into the *dipotassium-compound*, $\text{C}^{12}\text{H}^{14}\text{K}^2\text{O}^6$, which has a splendid orange colour, and forms a yellow solution in water. This solution is very unstable, but when recently prepared gives with magnesium salts a purple precipitate of the magnesium-compound

which gives off water and turns yellow at 80°, but recovers its original colour when drenched with water.

Ira Remsen (*Ber.* viii. 1408) has also obtained this magnesium compound, but not in the pure state, by boiling the ether, $C^{12}H^{16}O^6$, with magnesia. He describes this ether as crystallising in flat needles with a tinge of yellow, and melting at 128°. By adding an alcoholic solution of soda to a solution of the ether in alcohol, or by the action of sodium-amalgam on the latter, he obtained immediately a fine red bulky precipitate made up of microscopic needles, which, after washing and drying (whereupon it turned yellow), had the composition of the sodium-salt, $C^{12}H^{14}Na^2O^6 + 4H^2O$. This sodium-compound is very soluble in water, and hydrochloric acid added to the solution throws down the original ether. The *barium compound*, $C^{12}H^{14}BaO^6 + H^2O$, is obtained in like manner as a precipitate, having a fine rose-red colour, and turning yellow on drying. It is not decomposed by boiling with water or alcohol. With lime-water, the lemon-yellow *calcium-compound*, $C^{12}H^{14}CaO^6 + H^2O$, is obtained. The ether, $C^{12}H^{14}(C^2H^5)^2O^6$, is not attacked by acetyl chloride, ammonia, or nascent hydrogen; it is very slowly oxidised by potassium permanganate and by nitric acid; decomposed by water at 150°. Remsen does not consider that the constitutional formula proposed by Wislicenus for the acid, $C^{12}H^{16}O^6$, is satisfactorily established.

Action of Alkalis on Diethylic Succinylsuccinate (Hermann, *Ber.* x. 107). The mode of action of alkalis on this ether varies accordingly as it takes place in presence or absence of air.

I. *In absence of air*.—1. When the yellow alkaline solution is left for two hours, the undecomposed ether then precipitated by carbon dioxide, and the filtered liquid acidified with acetic acid, there is thrown down a crystalline greenish-white powder, which is sparingly soluble in cold alcohol, ether, and cold water. Neutral solutions of this body are coloured deep violet by ferric chloride. It melts at 98°, evolving carbon dioxide, to a pale yellow liquid, which does not solidify, and is readily decomposed by boiling water, with copious evolution of carbon dioxide. According to analysis the substance is *monethylic succinylsuccinate*, having the formula—

This formula is supported by the facts that the substance yields alcohol when heated with potash, and that it gives off at 100° a quantity of carbon dioxide agreeing with the following equation, thus yielding *ethylic succinylpropionate* :—

The last product is an oily liquid of intensely bitter taste and faint odour, dissolving easily in alcohol and ether, and sparingly in cold water. Its solutions are coloured a pure violet by ferric chloride.

2. In the liquid filtered from monethylic succinylsuccinate, dilute sulphuric acid produces a yellowish-white, crystalline precipitate having an acid reaction, sparingly soluble in cold water, more freely in alcohol and ether. The solutions are coloured violet by ferric chloride. This substance is readily decomposed by boiling water, evolving carbon dioxide. It is regarded by Hermann as *succinylsuccinic acid*.

3. The liquid from which the preceding substances have been separated contains yet another decomposition-product, which has not been isolated.

II. *In presence of air* the decomposition described above is accompanied by absorption of oxygen, in consequence of which there is formed, besides the foregoing decomposition-products, an acid which crystallises from boiling water in pale yellow, hair-like needles. This body dissolves very easily in alcohol, ether, and boiling water, the solutions exhibiting a greenish fluorescence, and giving a deep blue colour with ferric chloride. When cautiously fused with potash and afterwards acidified with sulphuric acid, it evolves carbon dioxide, and yields quinol. From these reactions, and the numbers obtained by analysis, it is inferred that the substance is *quinol-dicarboxylic acid*, $C^6O^2H^4(COOH)^2$.

VINYL-TOLUIDINE, $C^8H^{11}N$, which Wurtz obtained by heating toluidine with ethylene chlorhydrin (vi. 1105), is also produced in small quantity by heating hydroxethylene-toluidine (p. 2165) for two or three hours at 280° in contact with the air: $C^8H^{11}NO = C^8H^{11}N + H^2O$. It is very slightly soluble in alcohol; crystallises from benzene in somewhat irregular nacreous crystals; melts at 189°-190°. The same compound is formed by the distillation of hydroxethylene-toluidine oxalate, and as a secondary product (passing over at about 360°) in the preparation of hydroxethylene-

toluidine. In this last case the product also contains a substance melting at 155°-160°, the chemical nature of which has not yet been made out; it exhibits strong basic properties, and forms a hydrochloride which crystallises in needles.

Vinyl-toluidine, heated at 100° with *methyl iodide*, yields the compound $\begin{smallmatrix} (\text{C}^7\text{H}^7)^2 \\ (\text{C}^2\text{H}^4)^2 \end{smallmatrix} \text{N}^2, \text{CH}^3\text{I}$, which separates from alcoholic solution in splendid dark-red crystals, yielding a nearly colourless powder. It is not attacked by caustic potash, but moist silver oxide decomposes it, with separation of silver iodide, and formation of a very strong base. From the reaction of vinyl-toluidine with methyl iodide, Demole infers that it has the constitution of a tertiary base,

Errata in Vols. VI., VII., and VIII.

The Errata here given for Vols. VI. and VII. (First and Second Supplements) apply to the first Editions of these volumes; most of them have been corrected in reprints. The asterisk in the second column denotes that the line is to be counted from the bottom.

VOL. VIII., PT. II.

On p. 1507, at foot, for paragraph on Perthiocyanic Acid, read as under :—

PERTHIOCYANOGEN or **PSEUDOTHIOCYANOGEN**, $C^2H^2N^2S^2$. This, and not *perthiocyanic acid*, is the substance on which the experiments of Ponomareff (p. 608) were made. The formula of perthiocyanic acid is $C^2H^2N^2S^2$ (Atkinson). Ponomareff finds by further experiments (*Compt. rend.* lxxx. 1898) that perthiocyanic acid, heated with ammonia to a temperature not exceeding 100° (in his former experiments the heat was raised to 150° – 160°), yields a compound, $C^2H^2N^2S^2$, which he designates as thiamelline, together with thiomelanurenic acid, $C^2H^2N^2S^2$. Thiamelline is a white sandy powder which dissolves in 145 pts. of boiling water, and when heated with potash gives off ammonia and yields cyanate and thiocyanate of potassium. Hot strong hydrochloric acid resolves it into hydrogen sulphide, sal-ammoniac, and cyanuric acid. Nitric acid oxidises it to ammeline nitrate. Heated with ammonia, it yields a body having the properties of melamine. Thiamelline dissolves in acids and alkalis, and forms precipitates with the salts of the heavy metals. On the composition of pseudothiocyanozen see further page 1697.

END OF THE EIGHTH VOLUME.

'The appearance of a seventh volume, being the first part of a third supplement to Mr. HENRY WATTS's valuable *Dictionary of Chemistry*, will serve to remind the studious of the marvellously rapid progress of chemical science in recent years. This first instalment of the supplement is a solid volume of upwards of 800 pages, entirely devoted, as were the previous two supplements, to recent discoveries, which are explained concisely under the old alphabetical arrangement. Thus the record of chemical discovery is brought—or rather will be brought when the second volume is published—down to the year 1877, including, however, some of the more important discoveries which have appeared in 1878. The labours of the Editor and his contributors of course lie chiefly in methodising, arranging, and reducing to the most concise form the results of experiment and investigation, English and foreign; but many of the articles embody the fruits of original research. Among the most curious as well as practically valuable articles in the present volume is that on *Flame*, contributed by Professor E. T. THORPE.'

DAILY NEWS.

'WATTS's Dictionary is well known to all who take any interest in chemical science. The second supplement was published in 1875, and the contributions to chemical literature have been so great since that time that it is found necessary to issue the third supplement in two parts instead of one, as has been the case usually. In chemical philosophy one of the most important articles is by Dr. MILLS on *cumulative resolution*, a term proposed by the author as referring to the combination of a substance with itself after a certain portion has been withdrawn. Thus the compound known as magistery of bismuth is obtained by adding water to the nitrate of bismuth, when a precipitate is formed containing a portion of the metal. If more water be added, a further precipitate is obtained containing a larger portion of the metal. The ordinary law of multiple proportion is inadequate to explain the series of changes; but cumulative resolution gives the mathematical law governing the change. An article on *Flame*, by Professor THORPE, is an important one, giving as it does the most recent views of chemists and physicists as to the source of luminosity in flames. Of articles relating to agriculture, there is one by Mr. R. WARINGTON, on barley, in which various analyses of the plant are given. Particular reference is made to experiments by LAWES and GILBERT, and, after giving some tabular statements, the following passage occurs:—"The results quoted above teach us that with barley, as with other cereals, the ordinary supply of combined nitrogen from the atmosphere is quite insufficient for vigorous growth, and that to maintain crops of average luxuriance, nitrogenous manures are indispensable. The atmospheric supply of carbon is, on the other hand, quite sufficient for the crop." The article on *Forest Trees*, by the same contributor, contains very elaborate tables, showing the composition of different trees, the quantity of materials removed from an acre of soil by forest trees, &c. Other important articles, of which we have only room to give the titles, are Analine Colours, Arsenic, Benzenes, Butter, Chemical Action, Chlorophyll, Coal Gas, Dye Stuffs, Electricity, Ferments. In concluding this notice we must refer to the great value of the work to chemists, and may be allowed, perhaps, to express a hope that other branches of science will some day have their dictionaries modelled on the plan of Mr. WATTS's encyclopædic and invaluable work.'

MORNING ADVERTISER.

NOVEMBER, 1881.

WORKS ON MEDICINE, SURGERY, AND GENERAL SCIENCE,

PUBLISHED BY

MESSRS. LONGMANS AND CO.,

PATERNOSTER ROW, LONDON.

Anatomy, Surgery and Physiology.

THE SCIENCE AND ART OF SURGERY ;

Being a Treatise on Surgical Injuries, Diseases, and Operations. By JOHN ERIC ERICHSEN, F.R.C.S., Surgeon-Extraordinary to H.M. Queen Victoria ; Member of Council and of the Court of Examiners of the Royal College of Surgeons ; Emeritus Professor of Surgery and of Clinical Surgery in University College ; Consulting-Surgeon to University College Hospital, and to various Medical Charities. The Seventh Edition, enlarged and carefully revised ; pp. 2,072, illustrated by 862 Engravings on Wood. 2 vols. 8vo, price 36s.

A SYSTEM OF SURGERY,

Theoretical and Practical, in Treatises by various Authors. Edited by TIMOTHY HOLMES, M.A., Surgeon and Lecturer on Surgery, St. George's Hospital. Second Edition, thoroughly revised, with numerous Woodcuts, Lithographs, and Chromolithographs ; in all 472 Illustrations. In Five Volumes, 8vo, price One Guinea each.

* * Each Volume may be had separately, as follows :—

VOL. I., price 21s., comprises all the articles on GENERAL PATHOLOGY contained in the First Volume of the previous Edition down to the end of "Collapse," with the addition of Mr. CROFT'S essay on Hectic and Traumatic Fever and the After-Treatment of Operations, which formed part of the Appendix to the previous Edition.

VOL. II., price 21s., comprises all the Treatises in the previous Edition relating to General and Special Injuries.

VOL. III., price 21s.—Diseases of the Eye and Ear, of the Organs of Circulation, Muscles, and Bones.

VOL. IV., price 21s.—Diseases of the Organs of Locomotion, of Innervation, of Digestion, of Respiration, and of the Urinary Organs.

VOL. V., price 21s.—Diseases of the Genital Organs, of the Breast, Thyroid Gland, and Skin ; Operative Surgery ; APPENDIX of Miscellaneous Subjects ; with a General Alphabetical INDEX to the whole Work, and a List of the Authors.

QUAIN'S ELEMENTS OF ANATOMY.

The Eighth Edition. Re-edited by WILLIAM SHARPEY, M.D., LL.D., F.R.S., L. & E. Emeritus Professor of Anatomy and Physiology in University College, London; ALLEN THOMSON, M.D., LL.D., F.R.S., L. & E., Professor of Anatomy in the University of Glasgow; and EDWARD ALBERT SCHÄFER, Assistant Professor of Physiology in University College, London. With 1,000 Woodcut Illustrations. 2 vols. 8vo, price 32s.

ANATOMY, DESCRIPTIVE AND SURGICAL.

By HENRY GRAY, F.R.S., late Lecturer on Anatomy at St. George's Hospital. With 438 large Woodcut Illustrations; those in the First Edition after Original Drawings by Dr. CARTER, from Dissections made by the Author and DR. CARTER; the additional Drawings in the Second and subsequent Editions by DR. WESTMACOTT. Ninth Edition, by T. HOLMES, M.A., Surgeon to St. George's Hospital; with an Introduction on General Anatomy and Development by the EDITOR. Royal 8vo, 30s.

A MANUAL OF OPERATIVE SURGERY ON THE DEAD BODY.

By THOMAS SMITH, Surgeon to, and Lecturer on Anatomy at, St. Bartholomew's Hospital. A New Edition, re-edited by W. J. WALSHAM, Demonstrator of Anatomy and Operative Surgery to St. Bartholomew's Hospital Medical School. With 46 Illustrations. 8vo, price 12s.

ANATOMICAL OUTLINES FOR THE USE OF STUDENTS IN THE DISSECTING ROOM.

By ARTHUR HENSMAN, Senior Demonstrator of Anatomy at the Middlesex Hospital. Comprising 117 Plates from original Drawings by ARTHUR E. FISHER, with Explanatory Tables by Mr. HENSMAN. Complete in super-royal 8vo, in Four Parts, each to be had separately. PART I. *The Upper Limb*, 3s. 6d.; PART II. *The Lower Limb*, 3s. 6d.; PART III. *The Thorax and Abdomen*, 3s. 6d.; PART IV. *The Head and Neck*, 3s. 6d.

NOTES ON PHYSIOLOGY FOR THE USE OF STUDENTS PREPARING FOR EXAMINATION.

By HENRY ASHBY, M.D. Lond., Physician to the General Hospital for Sick Children, Manchester; formerly Demonstrator of Physiology, Liverpool School of Medicine. Third Edition, thoroughly revised, with new matter added in several of the Sections. 18mo, price 5s.

TABLETS OF ANATOMY AND PHYSIOLOGY.

By THOMAS COOKE, F.R.C.S., Senior Assistant-Surgeon to the Westminster Hospital, and Lecturer at the School of Anatomy, Physiology and Operative Surgery. Being a Synopsis of Demonstrations given in the Westminster Hospital Medical School, A.D. 1871-1875. With an Appendix containing most of the New Discoveries of Importance. Anatomy, complete, Second Edition. 4to, price 15s. Physiology, complete, Second Edition. 4to, price 10s.

* * * These TABLETS may still be had in separate Fasciculi as originally published.

COMPARATIVE ANATOMY AND PHYSIOLOGY OF THE VERTEBRATE ANIMALS.

By RICHARD OWEN, F.R.S., Superintendent of the Nat. Hist. Departments, British Museum. 3 vols. 8vo, with 1,472 Woodcuts, 73s. 6d.

VOL. I. *Fishes and Reptiles*, with 452 Woodcuts, 21s.

VOL. II. *Warm-blooded Vertebrates*, with 406 Woodcuts, 21s.

VOL. III. *Mammalia, including Man*, with 614 Woodcuts, 31s. 6d.

OUTLINES OF PHYSIOLOGY, HUMAN AND COMPARATIVE.

By JOHN MARSHALL, F.R.S., Professor of Surgery in University College, London; Surgeon to the University College Hospital. With 122 Woodcut Illustrations. 2 vols. crown 8vo, 32s.

HISTOLOGICAL DEMONSTRATIONS.

A Guide to the Microscopical Examination of the Animal Tissues in Health and in Disease; being the Substance of Lectures delivered by G. HARLEY, M.D., F.R.S., formerly Physician to Univ. Coll. Hospital, and Prof. in Univ. Coll. London. Edited by G. T. BROWN, M.R.C.V.S. Second Edition, revised; with Coloured Plate and 220 Woodcuts. Crown 8vo, price 12s.

HEALTH IN THE HOUSE.

Twenty-five Lectures on Elementary Physiology in its application to the Daily wants of Man and Animals. By MRS. C. M. BUCKTON, Member of the Leeds School Board. New and cheaper Edition, thoroughly revised; with 41 Woodcuts and Diagrams. Small 8vo, price 2s.

THE LAWS OF HEALTH.

By W. H. CORFIELD, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), Professor of Hygiene and Public Health, Univ. Coll., London; Medical Officer of Health for St. George's, Hanover Square. With 22 Diagrams engraved on Wood. Fcp. 8vo, 1s. 6d.

Medical and Psychological Literature.

LECTURES ON THE PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London, by SIR THOMAS WATSON, Bart., M.D., F.R.S., Hon. LL.B. Cantab., Hon. D.C.L. Oxon., &c., Physician-in-Ordinary to the Queen. Fifth Edition, revised and enlarged, with two Plates. 2 vols. 8vo, price 36s.

CLINICAL LECTURES AND ESSAYS,

By SIR JAMES PAGET, Bart., F.R.S., D.C.L. Oxon., LL.D. Cantab., &c., Serjeant-Surgeon to the Queen, Surgeon to the Prince of Wales, Consulting-Surgeon to St. Bartholomew's Hospital. Edited by F. HOWARD MARSH, Assistant-Surgeon to St. Bartholomew's Hospital. Second Edition, revised. 8vo, 15s.

EXAMINATION QUESTIONS IN ANATOMY, PHYSIOLOGY, BOTANY, MATERIA MEDICA, SURGERY, MEDICINE, MIDWIFERY, AND STATE-MEDICINE.
 Arranged by H. A. HUSBAND, M.B., M.C., M.R.C.S., L.S.A., &c.
 Second Edition, revised and augmented. 32mo, price 4s. 6d.

A DICTIONARY OF MEDICINE.

Edited by RICHARD QUAIN, M.D., F.R.S., Fellow of the Royal College of Physicians, and Physician to the Hospital for Diseases of the Chest at Brompton; assisted by numerous Eminent Writers. In One Volume, 8vo. *[In the Press.]*

THE SENSES AND THE INTELLECT.

By ALEXANDER BAIN, LL.D., Professor of Logic in the University of Aberdeen. Third Edition, with numerous Emendations, and a Review of Darwin on Expression as a Postscript. 8vo, 15s.

THE EMOTIONS AND THE WILL.

By the same Author. Third Edition, thoroughly revised, and in great part re-written. 8vo, price 15s.

MENTAL AND MORAL SCIENCE:

A Compendium of Psychology and Ethics. By the same Author. Fourth Edition. Crown 8vo, 10s. 6d.

LOGIC, DEDUCTIVE AND INDUCTIVE.

By the same Author. In Two Parts, crown 8vo, price 10s. 6d. Each Part may be had separately:—

PART I., *Deduction*, price 4s.; PART II., *Induction*, price 6s. 6d.

THE HISTORY OF PHILOSOPHY FROM THALES TO COMTE.

By GEORGE HENRY LEWES. Fourth Edition, re-written and greatly enlarged. 2 vols. 8vo, price 32s.

A SYSTEM OF LOGIC, RATIOCINATIVE AND INDUCTIVE;

Being a Connected View of the Principles of Evidence and the Methods of Scientific Investigation. By JOHN STUART MILL. The Tenth Edition. 2 vols. 8vo, price 25s.

ANALYSIS OF J. S. MILL'S SYSTEM OF LOGIC.

By W. STEBBING, M.A. Latest Revised Edition. 12mo, 3s. 6d.

HANDBOOK OF J. S. MILL'S SYSTEM OF LOGIC.

By the Rev. A. H. KILLICK, M.A. Third Edition [1877], revised. Crown 8vo, 3s. 6d.

Pathology and the Treatment of Disease.

LECTURES ON SURGICAL PATHOLOGY,

Delivered at the Royal College of Surgeons of England. By Sir JAMES PAGET, Bart., F.R.S., D.C.L. Oxon., LL.D. Cantab., &c., Serjeant-Surgeon to the Queen, Surgeon to the Prince of Wales, Consulting-Surgeon to St. Bartholomew's Hospital. Third Edition, re-edited by the AUTHOR and W. TURNER, M.B. 8vo, with 131 Woodcuts, 21s.

A TREATISE ON MEDICAL ELECTRICITY, THEORETICAL AND PRACTICAL;
